Preface to the Third Edition

Encouraged by the overwhelming response to the first two editions, I am delighted to present third edition of this widely acclaimed *Textbook of Pediatrics*. Present edition has been extensively revised and updated to provide state of the art information on the subject in a concise and simplified format, according to the Competency Based Medical Education Curriculum, prescribed by National Medical Commission.

Apart from being a primary resource to undergraduate students, it is also expected to benefit postgraduates and practicing pediatricians as primer for further study.

This edition includes latest guidelines (till 2023) from various national and international academic and regulatory bodies including World Health Organization, Government of India and Indian Academy of Pediatrics (IAP), including recent Standard treatment guidelines (2022) and Guidelines for parents (2022). It also covers updated information on major national health programmes from pediatric perspectives, either in corresponding chapters or in the chapter on *Social pediatrics*. Revised IMNCI Guidelines 2021 have been presented in a new and independent Chapter 29.

While India has made major strides in the field of public health during last decade, expectations have been fuelled further with setting up of many ambitious targets under national health mission to improve healthcare for children as well as control or eliminate many infectious illnesses. This edition includes authentic demographic data from latest sources, e.g. National Family Health Survey –5 (2021) and Sample Registration Survey (2022), as well as current targets set-up under national health mission/policy.

Among other noteworthy features of this edition are exclusive chapters on *History taking*, *General examination and Procedures and Equipments* to enhance clinical skills and *Pediatric Pharmacology* for ready reference. Most of the chapters on systemic pediatrics have dedicated Sections on Basic considerations, Clinical evaluation and Laboratory investigations to enhance fundamental understanding of the subject and strengthen clinical skills. Over 200 clinical images and illustrations have been updated or added to enhance the visual appeal or many new diagnostic algorithms or step-by-step approaches have been included to simplify the process of decision making.

I am extremely grateful to renowned chapter contributors for their scholarly inputs and valuable suggestions, while updating the chapters. Special thanks are also due to Dr Niranjan Shindurnikar, my close friend and mentor in the field of publication matters, as well as colleagues and residents, who provided useful inputs and some excellent images with permission to use them.

My family has always been a constant source of inner strength including my wife Reena and Daughter Paankhi, with heavenly support of my parents and son Ayush. Further, my grandson Rahil has been kind enough to permit me work undisturbed, sometimes.

Finally, I wish to place on record my special thanks to Mr Satish Kumar Jain (Chairman) for his commitment to publish this edition at earliest, along with Mr YN Arjuna, (Senior Vice-President – Publishing, Editorial and Publicity) and his team at CBS Publishers for the commendable job, specially the illustrations.

I am sure that this edition will also be widely accepted by the students and practitioners of pediatrics as a primary resource to acquire, enhance and update their knowledge. Corrections, suggestions, feedback and reviews are welcome from readers to improve further editions, which may be sent at dr_mukesh_agrawal@yahoo.co.in

Preface to the First Edition

Over forty percent of the Indian population falls below fourteen years of age with its unique health problems, assessment approaches and interventional needs. Add another ten percent of adolescent population and the quantitative burden of pediatric health services become obvious. Further, young children need special attention not only when sick but also when healthy, for the purpose of growth monitoring, immunization, dietary advice, etc.

Care of a child is as much an art as it is the science. While Pediatrics is an established specialty at post-graduate level, the need to strengthen pediatric training in India for undergraduates has been recognized recently with inclusion of pediatrics as a separate subject in MCI curriculum.

Although many excellent textbooks on pediatrics have been published during last decade, most of them concentrate on the training at postgraduate level and often considered as too advanced for undergraduates. Present book has been written with primary objective of undergraduate training, to provide them state-of-the-art information but in a concise and simplified format. However, postgraduates, especially Diploma students, are also expected to benefit by using this source to refresh their knowledge before further reading.

I am extremely grateful to all contributors, who promptly acceded to my request and wrote their chapters with diligence, excellence and relevance within the format and space constraints of the book.

I am indeed honored that Dr YK Amdekar, the renowned pediatrician and academician, as well as Dr SN Oak, beloved Dean and Professor & Head of Pediatric surgery at my institute, readily agreed to review the book and write Forewords to this edition.

I have no words to thank Dr Niranjan Shindurnikar, my close friend and the guiding force behind this book, who introduced me to the nitty-gritty of publication matters. My sincere thanks are also due to my colleagues and well-wishers for their ideas and cooperation. A special mention is needed for Dr Milind Tullu for proofreading and Dr Nilesh Jaiswal for illustrations. Dr CT Deshmukh, Dr Uday Khopkar, Dr Sudhir Shrivastava, Dr Kumar Doosa, Dr Radha Ghildiyal, Dr Sushma Malik and some of my residents provided me some excellent clinical photographs and X-rays, with permission to use them.

My parents have been the constant source of inner strength, so also my wife Reena and kids Paankhi & Ayush, who always encouraged me to take up this challenge and bring it to logical conclusion.

Finally, I wish to place on record my appreciation for Mr Rajesh Bhalani and their staff, for prompt and skilled publications work, as well Ms Sunita Tikare for her excellent print-setting work.

14. Gastrointestinal Disorders 372

Prachi S Karnik, Aditi Dharap, Mukesh Agrawal

14.1 Basic Considerations *372*
14.2 Clinical Evaluation of GIT Disease *373*
14.3 Laboratory Evaluation of GIT Disease *374*
14.4 Common Presentations in GIT Disease *375*
14.4.1 Dysphagia *376*
14.4.2 Vomiting *376*
14.4.3 Abdominal Pain *378*
14.4.4 Constipation *380*
14.4.5 GIT Bleeding *381*
14.4.6 Abdominal Distension *382*
14.4.7 Abdominal Mass/Lump *382*
14.5 Disorders of Oral Cavity *382*
14.5.1 Cleft Lip and Cleft Palate *382*
14.5.2 Dental Caries *383*
14.5.3 Oral Cavity Inflammations *384*
14.5.4 Tongue Disorders *385*
14.5.5 Salivary Gland Disorders *385*
14.6 Esophageal Disorders *385*
14.6.1 Tracheoesophageal Fistula *385*
14.6.2 Gastroesophageal Reflux Disease *386*
14.7 Diaphragmatic Disorders *387*
14.7.1 Congenital Diaphragmatic Hernia *387*
14.8 Gastric Disorders *389*
14.8.1 Infantile Hypertrophic Pyloric Stenosis *389*
14.9 Intestinal Malformations *391*
14.9.1 Small Bowel Malformations *391*
14.9.2 Hirschsprung's Disease *392*
14.9.3 Anorectal Malformations *394*
14.9.4 Abdominal Wall Defects *395*
14.10 Acute Diarrhea *396*
14.11 Persistent Diarrhea *401*
14.12 Malabsorption Syndromes (Chronic Diarrhea) *404*
14.13 Acute Intestinal Obstruction *409*
14.14 Acute Appendicitis *410*
14.15 Perianal Disorders *411*
14.16 Pancreatic Disorders *412*
14.17 Disorders of Gallbladder *413*
14.18 Disorders of Peritoneum *413*

15. Disorders of Hepatobiliary System 416

Aditi Dharap, Prachi S Karnik, Mukesh Agrawal

15.1 Basic Considerations *416*

15.2 Hepatomegaly *417*
15.3 Jaundice *418*
15.4 Viral Hepatitis *419*
15.5 Acute Hepatic Failure *422*
15.6 Liver Abscess *423*
15.7 Chronic Liver Disease *424*
15.8 Portal Hypertension *428*

16. Respiratory Disorders 430

Chandrahas T Deshmukh, Mukesh Agrawal

16.1 Basic Considerations *430*
16.2 Clinical Evaluation of Respiratory Disease *433*
16.3 Laboratory Investigations in Lung Disease *436*
16.4 Common Clinical Presentations *438*
16.4.1 Recurrent/Persistent Cough *438*
16.4.2 Respiratory Distress *440*
16.4.3 Stridor *440*
16.4.4 Wheezing *441*
16.5 Ear, Nose and Throat Disorders *442*
16.5.1 Nasal Disorders *443*
16.5.2 Sinusitis *445*
16.5.3 Throat Disorders *445*
16.5.4 Ear Disorders *447*
16.6 Acute Croup *449*
16.7 Acute Bronchiolitis *451*
16.8 Bronchial Asthma *452*
16.9 Pneumonia *460*
16.9.1 Infective Pneumonia *460*
16.9.2 Non-infective Pneumonia *464*
16.10 Chronic Lung Diseases *466*
16.10.1 Bronchiectasis *466*
16.10.2 Lung Abscess *467*
16.10.3 Cystic Fibrosis *468*
16.10.4 Interstitial Lung Diseases *469*
16.10.5 Congenital Lung Malformations *470*
16.11 Miscellaneous Lung Disorders *471*
16.12 Pleural Disorders *473*
16.12.1 Empyema Thoracis *473*
16.12.2 Pneumothorax *475*

17. Disorders of Cardiovascular System 477

Radha Ghildiyal, Mukesh Agrawal

17.1 Developmental Cardiology *477*
17.1.1 Development of Heart *477*
17.1.2 Fetal Circulation *478*
17.1.3 Fetal to Neonatal Transition *478*
17.1.4 Postnatal Circulation *479*
17.2 Clinical Evaluation for Cardiac Disease *480*
17.3 Investigations in Cardiac Disease *486*
17.4 Congestive Cardiac Failure *490*
17.5 Congenital Heart Disease *494*
17.5.1 General Considerations *494*
17.5.2 Acyanotic CHDS *495*
17.5.3 Cyanotic CHDS *503*
17.5.4 Diagnostic Approach in CHD *506*
17.6 Rheumatic Fever *507*
17.7 Rheumatic Heart Disease *511*
17.8 Infective Endocarditis *515*
17.9 Myocardial Disorders *516*
17.9.1 Myocarditis *516*
17.9.2 Cardiomyopathies *517*
17.10 Arrhythmia *519*
17.11 Pericarditis *522*
17.12 Childhood Hypertension *523*

18. Disorders of Central Nervous System 528

P Keerthi Kundana, Mona Gajre, Alpana Kondekar Mukesh Agrawal

18.1 Clinical Evaluation in Neurological Disease *528*
18.2 Laboratory Evaluation in CNS Disease *532*
18.3 Comatose Child *534*
18.4 Raised Intracranial Pressure *537*
18.5 Headache *539*
18.6 Seizure Disorders *540*
18.6.1 General Considerations *540*
18.6.2 Status Epilepticus *545*
18.6.3 Febrile Seizures *545*
18.6.4 Epilepsy in Childhood *547*
18.6.5 Seizure-Like Disorders (Seizure Mimics) *550*
18.7 Cerebrovascular Strokes *551*
18.8 Hemiplegia *553*
18.9 Movement Disorders *554*
18.10 Congenital CNS Malformations *557*
18.10.1 Neural Tube Defects *557*
18.10.2 Hydrocephalus *560*
18.11 Cerebral Palsy *563*
18.12 Intracranial Infections *565*
18.12.1 Bacterial Meningitis *565*

18.12.2 Tubercular Meningitis *567*
18.12.3 Viral Encephalitis *569*
18.12.4 Autoimmune Encephalitis *571*
18.12.5 Reye Syndrome *572*
18.12.6 Cerebral Malaria *572*
18.12.7 Brain Abscess *573*
18.12.8 Tuberculoma *574*
18.12.9 Neurocysticercosis *574*
18.13 Brain Tumors *575*
18.14 Neurocutaneous Syndromes *577*
18.15 Neurodegenerative Disorders *580*
18.16 Spinal Cord Disorders *583*
18.16.1 Acute Transverse Myelitis *583*
18.16.2 Spinal Cord Injuries *583*
18.16.3 Spinal Cord Malformations *584*
18.16.4 Spinal Cord Tumors *584*
18.17 Paraplegia *584*
18.18 Neuromuscular Disorders *586*
18.18.1 Anterior Horn Cell Disorders *587*
18.18.2 Peripheral Neuropathies *588*
18.18.3 Neuromuscular Junction Disorders *590*
18.18.4 Myopathies *591*
18.19 Floppy Infant *594*
18.20 Disorders of Autonomic System *595*

19. Hematological Disorders 597

Sujata Sharma, Priyashree Mukherjee, Purvi Kadakia Kutty
Mukesh Agrawal

19.1 Basic Considerations *597*
19.2 Anemia-General Concepts *599*
19.3 Physiological Anemia of Infancy *602*
19.4 Nutritional Anemia *602*
19.4.1 Iron Deficiency Anemia *602*
19.4.2 Megaloblastic Anemia *605*
19.5 Hemolytic Anemia *606*
19.5.1 Hereditary Spherocytosis *607*
19.5.2 G6PD Deficiency Anemia *608*
19.5.3 Thalassemia *609*
19.5.4 Sickle Cell Disease *612*
19.5.5 Autoimmune Hemolytic Anemia *614*
19.6 Aplastic Anemia *614*
19.7 Polycythemia *616*
19.8 Leukocyte Disorders *616*
19.9 Physiology of Hemostasis *619*
19.10 Hemorrhagic Disorders *620*
19.11 Platelet Disorders *622*
19.11.1 Immune Thrombocytopenic Purpura *622*
19.12 Coagulation Disorders *625*
19.12.1 Hemophilia *625*
19.13 Disseminated Intravascular Coagulation *627*
19.14 Hypercoagulable States *628*
19.15 Specific Therapeutic Modalities in Hematology *629*
19.15.1 Blood-product Transfusions *629*
19.15.2 Hematopoietic Stem-cell Transplantation *631*
19.15.3 Hematopoietic Growth Factors *632*
19.16 Disorders of Spleen *632*
19.16.1 Splenomegaly *632*
19.16.2 Hyposplenic States *634*
19.17 Disorders of Lymphatic System *634*

20. Oncological Disorders 637

Purvi Kadakia Kutty, Sujata Sharma, Mukesh Agrawal

20.1 Basic Considerations *637*
20.2 Leukemia *639*
20.2.1 Acute Lymphoblastic Leukemia *639*
20.2.2 Acute Myelogenous Leukemia *642*
20.2.3 Chronic Myelogenous Leukemia *643*
20.3 Lymphoma *643*
20.3.1 Hodgkin Lymphoma *643*
20.3.2 Non-Hodgkin's Lymphoma *644*
20.4 Neuroblastoma *646*
20.5 Wilms Tumor *647*
20.6 Retinoblastoma *648*
20.7 Skeletal Malignancies *648*
20.8 Soft Tissue Sarcoma *649*
20.9 Hepatic Tumors *650*
20.10 Histiocytosis *650*

21. Renal Disorders 653

Varsha D Phadke, Apurva Shah, Neha Pandey
Mukesh Agrawal

21.1 Basic Considerations *653*
21.2 Evaluation in Renal Disease *655*
21.3 Congenital Renal Malformations *658*
21.4 Hereditary Nephropathies *660*
21.5 Hematuria *660*

21.6 Glomerulonephritis *661*
21.6.1 Acute Glomerulonephritis *662*
21.6.2 Rapidly Progressive Glomerulonephritis *663*
21.6.3 Chronic Glomerulonephritis *663*
21.6.4 Hemolytic Uremic Syndrome *664*
21.6.5 Renal Vein Thrombosis *665*
21.7 Proteinuria *666*
21.8 Nephrotic Syndrome *666*
21.9 Acute Kidney Injury *671*
21.10 Chronic Kidney Disease *675*
21.11 Tubular Disorders *677*
21.11.1 Renal Tubular Acidosis *677*
21.11.2 Hereditary Tubular Disorders *679*
21.11.3 Acute Tubular Necrosis *680*
21.12 Acute Interstitial Nephritis *680*
21.13 Urinary Tract Malformations *680*
21.14 Obstructive Uropathy *683*
21.15 Urinary Tract Infections *685*
21.16 Penoscrotal Disorders *688*

22. Disorders of Endocrine System 691

Shruti A Mondkar, Mukesh Agrawal

22.1 Basic Considerations *691*
22.2 Pituitary Disorders *691*
22.2.1 Hypopituitarism *692*
22.2.2 Growth Hormone Deficiency *692*
22.2.3 Hyperpituitarism *693*
22.2.4 Diabetes Insipidus *694*
22.2.5 Syndrome of Inappropriate ADH Secretion *694*
22.3 Thyroid Disorders *695*
22.3.1 Hypothyroidism *695*
22.3.2 Goiter *697*
22.3.3 Iodine Deficiency Disorders *698*
22.3.4 Hyperthyroidism *699*
22.4 Parathyroid Disorders *699*
22.5 Adrenal Disorders *700*
22.5.1 Adrenocortical Insufficiency *701*
22.5.2 Congenital Adrenal Hyperplasia *702*
22.5.3 Addison Disease *703*
22.5.4 Cushing Syndrome *703*
22.5.5 Hyperaldosteronism *704*
22.5.6 Adrenal Sex-steroid Producing Tumours (Adrenogenital Syndrome) *705*
22.5.7 Pheochromocytoma *705*
22.6 Disorders of Sex-steroids *705*
22.6.1 Disorders of Sex Development (Ambiguous Genitalia) *706*
22.6.2 Disorders of Puberty *708*
22.7 Diabetes Mellitus *710*
22.7.1 Type I Diabetes Mellitus (T1DM) *711*
22.8 Hypoglycemia *716*

23. Disorders of Bones and Joints 719

Mukesh Agrawal

23.1 Basic Considerations *719*
23.2 Developmental Bone Disorders *719*
23.2.1 Craniofacial Malformations *720*
23.2.2 Developmental Limb Disorders *721*
23.2.3 Spinothoracic Disorders *726*
23.3 Limping Child *728*
23.4 Skeletal Dysplasia *728*
23.5 Bone and Joint Infections *731*
23.5.1 Acute Osteomyelitis *731*
23.5.2 Septic Arthritis *732*
23.5.3 Osteoarticular Tuberculosis *733*
23.6 Osteochondroses *734*
23.7 Bone Masses and Tumors *735*
23.8 Fractures in Childhood *736*

24. Rheumatic Disorders 738

Divya Ramadoss, Mukesh Agrawal

24.1 Basic Considerations *738*
24.2 Juvenile Idiopathic Arthritis *739*
24.3 Systemic Connective Tissue Disorders *743*
24.3.1 Systemic Lupus Erythematosus *743*
24.3.2 Juvenile Dermatomyositis *745*
24.3.3 Scleroderma *746*
24.4 Vasculitis Syndromes *747*
24.4.1 Henoch-Schönlein Purpura (IGA Vasculitis) *747*
24.4.2 Wegener Granulomatosis *748*
24.4.3 Kawasaki Disease *748*
24.4.4 Polyarteritis Nodosa *749*
24.4.5 Takayasu Disease *750*

25. Skin Disorders 751

Mukesh Agrawal

25.1 Basic Considerations *751*
25.2 Developmental Skin Disorders *753*
25.3 Common Skin Infections *756*

25.3.1 Bacterial Infections *756*
25.3.2 Fungal Infections *758*
25.3.3 Viral Infections *759*
25.3.4 Parasitic Infestations *759*
25.4 Pigmentary Skin Disorders *760*
25.4.1 Hyperpigmented Lesions *760*
25.4.2 Hypopigmented Lesions *761*
25.5 Maculopapular Disorders *762*
25.6 Vesiculobullous Disorders *765*
25.7 Papulosquamous Disorders *768*
25.8 Eczematous Skin Disorders *770*
25.9 Disorders of Dermis *772*
25.10 Disorders of Subcutaneous Fat *772*
25.11 Disorders of Skin Appendages *773*
25.11.1 Hair Disorders *773*
25.11.2 Sebaceous Gland Disorders *773*
25.11.3 Sweat Gland Disorders *774*
25.11.4 Nail Disorders *775*

26. Ophthalmic Disorders 776

Mukesh Agrawal

26.1 General Considerations *776*
26.2 Ocular Disorders *776*
26.2.1 Disorders of Orbit *776*
26.2.2 Disorders of Eyelids *777*
26.2.3 Disorders of Lacrimal System *778*
26.2.4 Conjunctival Disorders *778*
26.2.5 Scleral Disorders *780*
26.2.6 Corneal Disorders *780*
26.2.7 Uveal Tract Disorders *781*
26.2.8 Pupillary Disorders *782*
26.2.9 Glaucoma *782*
26.2.10 Lens Disorders *783*
26.2.11 Retinal Disorders *783*
26.2.12 Optic Nerve Disorders *785*
26.2.13 Ocular Injuries *785*
26.3 Vision Disorders *786*
26.3.1 Amaurosis (Blindness) *786*
26.3.2 Amblyopia *787*
26.3.3 Refractive Errors *787*
26.3.4 Strabismus (SQUINT) *788*
26.3.5 Nystagmus *789*

27. Critical Care 790

Sushma Save, Pritha Das, Mukesh Agrawal

27.1 Cardiopulmonary Resuscitation *790*
27.1.1 Pediatric Basic Life Support *790*
27.1.2 Transport of Sick Child *794*
27.1.3 Pediatric Advanced Life Support *795*
27.2 Acute Respiratory Failure *798*
27.3 Shock *802*
27.4 Pediatric Intensive Care *806*
27.4.1 Consensus Guidelines for PICU *806*
27.4.2 Admission Criteria for PICU *806*
27.4.3 Vascular Access in Sick Children *806*
27.4.4 Monitoring of Critically Sick Child *807*
27.4.5 Nutrition In Critically Sick Child *808*
27.4.6 Sedation and Analgesia in Intensive Care *808*
27.4.7 Prediction of Outcome (Prism Score) *809*
27.4.8 Counseling Parents of Serious/ Terminally Ill Child *809*
27.4.9 Death Criteria and Brain Death *809*
27.5 Accidents in Childhood *810*
27.5.1 Childhood Trauma *810*
27.5.2 Burns and Scalds *814*
27.5.3 Drowning and Near Drowning *815*
27.5.4 Foreign Body Accidents *816*
27.5.5 Snake Bite *817*
27.5.6 Scorpion Sting *818*
27.5.7 Heat Injuries *819*
27.6 Poisoning in Children *820*
27.6.1 General Principles of Management *820*
27.6.2 Common Specific Poisonings *823*
27.7 Sudden Infant Death Syndrome *827*

28. Social Pediatrics 829

Mukesh Agrawal

28.1 National Health Objectives *829*
28.2 Child Health Indicators in India *829*
28.3 National Health Programmes *832*
28.3.1 National Health Mission *832*
28.3.2 Reproductive, Maternal, Newborn, Child and Adolescent Health (RMNCH+A) Approach *833*
28.3.3 Integrated Child Development Services *833*
28.3.4 Rashtriya Bal Swasthya Karyakram *834*
28.3.5 Navjaat Shishu Suraksha Karyakram *835*
28.3.6 India Newborn Action Plan *835*

28.3.7 Janani Shishu Suraksha Karyakaram *835*
28.3.8 Home-based Newborn Care *836*
28.3.9 Rashtriya Kishor Swasthya Karyakram *836*
28.3.10 National Vector Borne Disease Control Programme *836*
28.3.11 Under-Fives' Clinics *837*
28.3.12 School Health Service *837*
28.4 Socially At-Risk Children *837*
28.4.1 Child Abuse and Neglect (Child Maltreatment) *838*
28.4.2 Child Labour *839*
28.4.3 Street Children *839*
28.4.4 Girl Child *839*
28.4.5 Handicapped Child *840*
28.4.6 Juvenile Delinquency *840*

29. Integrated Management of Neonatal and Childhood Illnesses 842

Mukesh Agrawal

29.1 Outpatient Management of Children from 2 Months up to 5 Years *844*
29.2 Outpatient Management of Children below 2 Months (Sick Young Infants) *847*

30. History Taking in Pediatrics 850

Mukesh Agrawal

31. General Physical Examination 856

Mukesh Agrawal

32. Procedures and Equipments 867

Mukesh Agrawal

32.1 General Principles *867*
32.2 Injection Devices and Routes *867*
32.3 Vascular Access Procedures *868*
32.4 Resuscitation Procedures and Devices *873*
32.5 Aerosol Devices and Techniques *876*
32.6 Aspiration and Biopsy Procedures *879*
32.7 Feeding Support Procedures and Devices *884*
32.8 Urinary Catheters and Drainage Devices *884*
32.9 General Monitoring Equipment *886*

33. Drugs and Medications 888

Mukesh Agrawal, Snehal Keni, Aparanta Chandra

33.1 Anti-bacterial Therapy *888*
33.2 Anti-tubercular Agents *893*
33.3 Anti-viral Agents *894*
33.4 Anti-fungal Agents *896*
33.5 Anti-malarial Agents *896*
33.6 Anti-protozoal and Anti-parasitic Agents *897*
33.7 General Medications *899*

Index *923*

Index of Competencies

As per the latest NMC Guidelines | Competency Based Medical Education (CBME) Curriculum under Graduate Medical Education Regulation

TOPIC: Normal Growth and Development		CHAPTER
PE1.1:	Define the terminologies growth and development and discuss the factors affecting normal growth and development	2.1
PE1.2:	Discuss and describe the patterns of growth in infants, children and adolescents	2.2
PE1.3:	Discuss and describe the methods of assessment of growth including use of WHO and Indian national standards. Enumerate the parameters used for assessment of physical growth in infants, children and adolescents	2.3, 2.4
PE1.4:	Perform Anthropometric measurements, document in growth charts and interpret	2.5
PE1.5:	Define development and discuss the normal developmental milestones with respect to motor, behavior, social, adaptive and language	2.6
PE1.6:	Discuss the methods of assessment of development	2.7
PE1.7:	Perform developmental assessment and interpret	2.7
TOPIC: Common Problems Related to Growth		
PE2.1:	Discuss the etiopathogenesis, clinical features and management of a child who fails to thrive	3.1
PE2.2:	Assessment of a child with failing to thrive including eliciting an appropriate history and examination	3.1
PE2.3:	Counseling a parent with failing to thrive child	3.1
PE2.4:	Discuss the etiopathogenesis, clinical features and management of a child with short stature	3.3
PE2.5:	Assessment of a child with short stature: Elicit history, perform examination, document and present	3.3
PE2.6:	Enumerate the referral criteria for growth related problems	3.3
TOPIC: Common Problems Related to Development–1 (Developmental Delay, Cerebral Palsy)		
PE3.1:	Define, enumerate and discuss the causes of developmental delay and disability including intellectual disability in children	3.5, 3.6
PE3.2:	Discuss the approach to a child with developmental delay	3.5
PE3.3:	Assessment of a child with developmental delay–Elicit document and present history	3.5
PE3.4:	Counsel a parent of a child with developmental delay	3.5
PE3.5:	Discuss the role of the child developmental unit in management of developmental delay	3.5
PE3.6:	Discuss the referral criteria for children with developmental delay	3.5
PE3.7:	Visit a child developmental unit and observe its functioning	3.5
PE3.8:	Discuss the etiopathogenesis, clinical presentation and multi-disciplinary approach in the management of cerebral palsy	18.11
TOPIC: Common Problems Related to Development–2 (Scholastic Backwardness, Learning Disabilities, Autism, ADHD)		
PE4.1:	Discuss the causes and approach to a child with scholastic backwardness	3.10
PE4.2:	Discuss the etiology, clinical features, diagnosis and management of a child with learning disabilities	3.7
PE4.3:	Discuss the etiology, clinical features, diagnosis and management of a child with attention deficit hyperactivity disorder (ADHD)	3.12
PE4.4:	Discuss the etiology, clinical features, diagnosis and management of a child with autism	3.11
PE4.5:	Discuss the role of child guidance clinic in children with developmental problems	4.9
PE4.6:	Visit to the child guidance clinic	–
TOPIC: Common Problems Related to Behavior		
PE5.1:	Describe the clinical features, diagnosis and management of thumb sucking	4.4
PE5.2:	Describe the clinical features, diagnosis and management of feeding problems	4.2
PE5.3:	Describe the clinical features, diagnosis and management of nail biting	4.4
PE5.4:	Describe the clinical features, diagnosis and management of breath holding spells	4.6
PE5.5:	Describe the clinical features, diagnosis and management of temper tantrums	4.6
PE5.6:	Describe the clinical features, diagnosis and management of Pica	4.2
PE5.7:	Describe the clinical features, diagnosis and management of fussy infant	4.1
PE5.8:	Discuss the etiology, clinical features and management of enuresis	4.3
PE5.9:	Discuss the etiology, clinical features and management of encopresis	4.3
PE5.10:	Discuss the role of child guidance clinic in children with behavioral problems and the referral criteria	4.9
PE5.11:	Visit to child guidance clinic and observe functioning	4.9

Contd...

Contd...

TOPIC: Adolescent Health and Common Problems Related to Adolescent Health		
PE6.1:	Define adolescence and stages of adolescence	13.1
PE6.2:	Describe the physical, physiological and psychological changes during adolescence (Puberty)	13.1
PE6.3:	Discuss the general health problems during adolescence	13.2
PE6.4:	Describe adolescent sexuality and common problems related to it	13.1, 13.3
PE6.5:	Explain the adolescent nutrition and common nutritional problems	13.2
PE6.6:	Discuss the common adolescent eating disorders (anorexia nervosa, bulimia)	13.3
PE6.7:	Describe the common mental health problems during adolescence	13.3
PE6.8:	Respecting patient privacy and maintaining confidentiality while dealing with adolescence	13.4
PE6.9:	Perform routine adolescent health check-up including eliciting history, performing examination including SMR (sexual maturity rating), growth assessments (using growth charts) and systemic exam including thyroid and breast exam and the HEADSS screening	13.4
PE6.10:	Discuss the objectives and functions of AFHS (adolescent friendly health services) and the referral criteria	13.5
PE6.11:	Visit to the adolescent clinic	-
PE6.12:	Enumerate the importance of obesity and other NCD in adolescents	13.2
PE6.13:	Enumerate the prevalence and the importance of recognition of sexual drug abuse in adolescents and children	13.3
TOPIC: To Promote and Support Optimal Breastfeeding for Infants		
PE7.1:	Awareness on the cultural beliefs and practices of breastfeeding	5.2
PE7.2:	Explain the physiology of lactation	5.2
PE7.3:	Describe the composition and types of breast milk and discuss the differences between cow's milk and human milk	5.2
PE7.4:	Discuss the advantages of breast milk	5.2
PE7.5:	Observe the correct technique of breastfeeding and distinguish right from wrong techniques	5.2
PE7.6:	Enumerate the baby friendly hospital initiatives	5.3
PE7.7:	Perform breast examination and identify common problems during lactation such as retracted nipples, cracked nipples, breast engorgement, breast abscess	5.2 5.2
PE7.8:	Educate mothers on ante natal breast care and prepare mothers for lactation	5.2
PE7.9:	Educate and counsel mothers for best practices in breastfeeding	5.2
PE7.10:	Respects patient privacy	5.2
PE7.11:	Participate in breastfeeding week celebration	-
TOPIC: Complementary Feeding		
PE8.1:	Define the term complementary feeding	5.5
PE8.2:	Discuss the principles, the initiation, attributes, frequency, techniques and hygiene related to complementary feeding including IYCF	5.5
PE8.3:	Enumerate the common complimentary foods	5.5
PE8.4:	Elicit history on the complementary feeding habits	5.5
PE8.5:	Counsel and educate mothers on the best practices in complimentary feeding	5.5., 5.6
TOPIC: Normal Nutrition, Assessment and Monitoring		
PE9.1:	Describe the age related nutritional needs of infants, children and adolescents including micronutrients and vitamins	5.1
PE9.2:	Describe the tools and methods for assessment and classification of nutritional status of infants, children and adolescents	5.9
PE9.3:	Explains the calorific value of common Indian foods	5.8
PE9.4:	Elicit document and present an appropriate nutritional history and perform a dietary recall	5.9
PE9.5:	Calculate the age related calorie requirement in health and disease and identify gap	5.1
PE9.6:	Assess and classify the nutrition status of infants, children and adolescents and recognize deviations	5.9
PE9.7:	Plan an appropriate diet in health and disease	Relevant chapters
TOPIC: Provide Nutritional Support, Assessment and Monitoring for Common Nutritional Problems		
PE10.1:	Define and describe the etio-pathogenesis, classify including WHO classification, clinical features, complication and management of severe acute malnourishment (SAM) and moderate acute malnutrition (MAM)	6.1
PE10.2:	Outline the clinical approach to a child with SAM and MAM	6.1
PE10.3:	Assessment of a patient with SAM and MAM, diagnosis, classification and planning management including hospital and community based intervention, rehabilitation and prevention	6.1
PE10.4:	Identify children with under nutrition as per IMNCI criteria and plan referral	6.1, 29.1
PE10.5:	Counsel parents of children with SAM and MAM	6.1
PE10.6:	Enumerate the role of locally prepared therapeutic diets and ready to use therapeutic diets	6.1

Contd...

Contd...

TOPIC: Obesity in Children		
PE11.1:	Describe the common etiology, clinical features and management of obesity in children	3.2
PE11.2:	Discuss the risk approach for obesity and discuss the prevention strategies	3.2
PE11.3:	Assessment of a child with obesity with regard to eliciting history including physical activity, charting and dietary recall	3.2
PE11.4:	Examination including calculation of BMI, measurement of waist hip ratio, identifying external markers like acanthosis, striae, pseudogynecomastia, etc.	3.2
PE11.5:	Calculate BMI, document in BMI chart and interpret	3.2
PE11.6:	Discuss criteria for referral	3.2
TOPIC: Micronutrients in Health and Disease-1 (Vitamins ADEK, B Complex and C)		
PE12.1:	Discuss the RDA, dietary sources of Vitamin A and their role in health and disease	6.2
PE12.2:	Describe the causes, clinical features, diagnosis and management of deficiency/excess of Vitamin A	6.2
PE12.3:	Identify the clinical features of dietary deficiency/excess of Vitamin A	6.2
PE12.4:	Diagnose patients with Vitamin A deficiency, classify and plan management	6.2
PE12.5:	Discuss the Vitamin A prophylaxis program and their recommendations	6.2
PE12.6:	Discuss the RDA, dietary sources of Vitamin D and their role in health and disease	6.5
PE12.7:	Describe the causes, clinical features, diagnosis and management of deficiency/excess of Vitamin D (Rickets and hypervitaminosis D)	6.5
PE12.8:	Identify the clinical features of dietary deficiency of Vitamin D	6.5
PE12.9:	Assess patients with Vitamin D deficiency, diagnose, classify and plan management	6.5
PE12.10:	Discuss the role of screening for Vitamin D deficiency	6.5
PE12.11:	Discuss the RDA, dietary sources of Vitamin E and their role in health and disease	6.6
PE12.12:	Describe the causes, clinical features, diagnosis and management of deficiency of Vitamin E	6.6
PE12.13:	Discuss the RDA, dietary sources of Vitamin K and their role in health and disease	6.7
PE12.14:	Describe the causes, clinical features, diagnosis management and prevention of deficiency of Vitamin K	6.7
PE12.15:	Discuss the RDA, dietary sources of Vitamin B and their role in health and disease	6.3
PE12.16:	Describe the causes, clinical features, diagnosis and management of deficiency of B complex Vitamins	6.3, 19.4
PE12.17:	Identify the clinical features of Vitamin B complex deficiency	6.3, 19.4
PE12.18:	Diagnose patients with Vitamin B complex deficiency and plan management	6.3, 19.4
PE12.19:	Discuss the RDA , dietary sources of Vitamin C and their role in health and disease	6.4
PE12.20:	Describe the causes, clinical features, diagnosis and management of deficiency of Vitamin C (scurvy)	6.4
PE12.21:	Identify the clinical features of Vitamin C deficiency	6.4
TOPIC: Micronutrients in Health and Disease -2: Iron, Iodine, Calcium, Magnesium		
PE13.1:	Discuss the RDA, dietary sources of iron and their role in health and disease	19.4
PE13.2:	Describe the causes, diagnosis and management of Fe deficiency	19.4
PE13.3:	Identify the clinical features of dietary deficiency of Iron and make a diagnosis	19.4
PE13.4:	Interpret hemogram and Iron Panel	19.2, 19.4
PE13.5:	Propose a management plan for Fe deficiency anemia	19.4
PE13.6:	Discuss the National Anemia Control Programme and its recommendations	19.4
PE13.7:	Discuss the RDA, dietary sources of iodine and their role in health and disease	22.3
PE13.8:	Describe the causes, diagnosis and management of deficiency of iodine	22.3
PE13.9:	Identify the clinical features of Iodine deficiency disorders	22.3
PE13.10:	Discuss the National Goiter Control Programme and their recommendations	22.3
PE13.11:	Discuss the RDA, dietary sources of calcium and their role in health and disease	7.4
PE13.12:	Describe the causes, clinical features, diagnosis and management of Ca deficiency	7.4
PE13.13:	Discuss the RDA, dietary sources of magnesium and their role in health and disease	7.5
PE13.14:	Describe the causes, clinical features, diagnosis and management of magnesium deficiency	7.5
TOPIC: Toxic Elements and Free Radicals and Oxygen Toxicity		
PE14.1:	Discuss the risk factors, clinical features, diagnosis and management of lead poisoning	27.6
PE14.2:	Discuss the risk factors, clinical features, diagnosis and management of kerosene ingestion	27.6
PE14.3:	Discuss the risk factors, clinical features, diagnosis and management of organophosphorous poisoning	27.6
PE14.4:	Discuss the risk factors, clinical features, diagnosis and management of paracetamol poisoning	27.6
PE14.5:	Discuss the risk factors, clinical features, diagnosis and management of oxygen toxicity	27.1, 26.2

Contd...

Contd...

TOPIC: Fluid and Electrolyte Balance		
PE15.1:	Discuss the fluid and electrolyte requirement in health and disease	7.1
PE15.2:	Discuss the clinical features and complications of fluid and electrolyte imbalance and outline the management	7.1-7.5
PE15.3:	Calculate the fluid and electrolyte requirement in health	7.7
PE15.4:	Interpret electrolyte report	7.2-7.5
PE15.5:	Calculate fluid and electrolyte imbalance	7.7
PE15.6:	Demonstrate the steps of inserting an IV cannula in a model	32.2
PE15.7:	Demonstrate the steps of inserting an interosseous line in a mannequin	32.2
TOPIC: Integrated Management of Neonatal and Childhood Illnesses (IMNCI) Guidelines		
PE16.1:	Explain the components of Integrated Management of Neonatal and Childhood Illnesses (IMNCI) guidelines and method of risk stratification	29.1-2
PE16.2:	Assess children <2 months using IMNCI guidelines	29.2
PE16.3:	Assess children >2 to 5 years using IMNCI guidelines and stratify risk	29.1
TOPIC: The National Health Programmes: NHM		
PE17.1:	State the vision and outline the goals, strategies and plan of action of NHM and other important national programs pertaining to maternal and child health including RMNCH A+, RBSK, RKSK, JSSK, Mission Indradhanush and ICDS	9.5, 28.3
PE17.2:	Analyse the outcomes and appraise the monitoring and evaluation of NHM	28.3
TOPIC: The National Health Programmes: RCH		
PE18.1:	List and explain the components, plan, outcome of Reproductive Child Health (RCH) Programme and appraise its monitoring and evaluation	28.3
PE18.2:	Explain preventive interventions for child survival and safe motherhood	28.3
PE18.3:	Conduct antenatal examination of women independently and apply at-risk approach in antenatal care	12.3
PE18.4:	Provide intra-natal care and conduct a normal delivery in a simulated environment	12.4
PE18.5:	Provide intra-natal care and observe the conduct of a normal delivery	12.4
PE18.6:	Perform postnatal assessment of newborn and mother, provide advice on breastfeeding, weaning and on family planning	12.5-12.6
PE18.7:	Educate and counsel caregivers of children	12.6-12.7
PE18.8:	Observe the implementation of the program by visiting the rural health centre	-
TOPIC: National Programmes, RCH - Universal Immunizations Programme		
PE19.1:	Explain the components of the Universal Immunization Programme and the National Immunization Programme	9.5
PE19.2:	Explain the epidemiology of Vaccine preventable diseases	10.4-7, 10.9-11, 10.13, 10-15, 10.18-21, 10.23, 10.25-27, 10.33
PE19.3:	Vaccine description with regard to classification of vaccines, strain used, dose, route, schedule, risks, benefits and side effects, indications and contraindications	9.2
PE19.4:	Define cold chain and discuss the methods of safe storage and handling of vaccines	9.6
PE19.5:	Discuss immunization in special situations – HIV positive children, immunodeficiency, pre-term, organ transplants, those who received blood and blood products, splenectomized children, adolescents, travellers	9.4
PE19.6:	Assess patient for fitness for immunization and prescribe an age appropriate immunization schedule	9.8
PE19.7:	Educate and counsel a patient for immunization	9.8
PE19.8:	Demonstrate willingness to participate in the national and sub-national immunization days	-
PE19.9:	Describe the components of safe vaccine practice – patient education/ Counseling; adverse events following immunization, safe injection practices, documentation and medico-legal implications	9.8
PE19.10:	Observe the handling and storing of vaccines	9.6
PE19.11:	Document immunization in an immunization record	9.8
PE19.12:	Observe the administration of UIP vaccines	9.8
PE19.13:	Demonstrate the correct administration of different vaccines in a mannequin	9.8
PE19.14:	Practice infection control measures and appropriate handling of the sharps	9.8
PE19.15:	Explain the term implied consent in immunization services	9.8
PE19.16:	Enumerate available newer vaccines and their indications including pentavalent pneumococcal, rotavirus, JE, typhoid IPV and HPV	9.2

Contd...

Contd...

TOPIC: Care of the Normal Newborn, and High-risk Newborn	
PE20.1: Define the common neonatal nomenclatures including the classification and describe the characteristics of a normal term neonate and high-risk neonates	12.1, 12.5.12.8
PE20.2: Explain the care of a normal neonate	12.6
PE20.3: Perform neonatal resuscitation in a manikin	12.4
PE20.4: Assessment of a normal neonate	12.5
PE20.5: Counsel/educate mothers on the care of neonates	12.6
PE20.6: Explain the follow-up care for neonates including breastfeeding, temperature maintenance, immunization, importance of growth monitoring and red flags	12.5, 9.8, 2.5
PE20.7: Discuss the etiology, clinical features and management of birth asphyxia	12.10
PE20.8: Discuss the etiology, clinical features and management of respiratory distress in newborn including meconium aspiration and transient tachypnea of newborn	12.13
PE20.9: Discuss the etiology, clinical features and management of birth injuries	12.10
PE20.10: Discuss the etiology, clinical features and management of hemorrhagic disease of newborn	12.17
PE20.11: Discuss the clinical characteristics, complications and management of low birth weight (preterm and Small for gestation)	12.11
PE20.12: Discuss the temperature regulation in neonates, clinical features and management of neonatal hypothermia	12.12
PE20.13: Discuss the temperature regulation in neonates, clinical features and management of neonatal hypoglycemia	12.12, 12.18
PE20.14: Discuss the etiology, clinical features and management of neonatal hypocalcemia	12.18
PE20.15: Discuss the etiology, clinical features and management of neonatal seizures	12.16
PE20.16: Discuss the etiology, clinical features and management of neonatal sepsis	12.15
PE20.17: Discuss the etiology, clinical features and management of perinatal infections	12.15
PE20.18: Identify and stratify risk in a sick neonate using IMNCI guidelines	29.2
PE20.19: Discuss the etiology, clinical features and management of neonatal hyperbilirubinemia	12.14
PE20.20: Identify clinical presentations of common surgical conditions in the newborn including TEF, esophageal atresia, anal atresia, cleft lip and palate, congenital diaphragmatic hernia and causes of acute abdomen	14.5-7, 14.13
TOPIC: Genito-urinary System	
PE21.1: Enumerate the etiopathogenesis, clinical features, complications and management of urinary tract infection in children	21.15
PE21.2: Enumerate the etiopathogenesis, clinical features, complications and management of acute post-streptococcal glomerular nephritis in children	21.6
PE21.3: Discuss the approach and referral criteria to a child with proteinuria	21.7
PE21.4: Discuss the approach and referral criteria to a child with hematuria	21.5
PE21.5: Enumerate the etiopathogenesis, clinical features, complications and management of acute renal failure in children	21.9
PE21.6: Enumerate the etiopathogenesis, clinical features, complications and management of chronic renal failure in children	21.10
PE21.7: Enumerate the etiopathogenesis, clinical features, complications and management of Wilms Tumor	20.5
PE21.8: Elicit, document and present a history pertaining to diseases of the Genitourinary tract	21.2
PE21.9: Identify external markers for Kidney disease, like Failing to thrive, hypertension, pallor, Ichthyosis, anasarca	21.2
PE21.10: Analyse symptom and interpret the physical findings and arrive at an appropriate provisional/differential diagnosis	21.2
PE21.11: Perform and interpret the common analytes in a urine examination	21.2
PE21.12: Interpret report of Plain X Ray of KUB	21.2
PE21.13: Enumerate the indications for and Interpret the written report of Ultra sonogram of KUB	21.2
PE21.14: Recognize common surgical conditions of the abdomen and genitourinary system and enumerate the indications for referral including acute and subacute intestinal obstruction, appendicitis, pancreatitis, perforation intussusception, phimosis, undescended testis, chordee, hypospadias, torsion testis, hernia hydrocele, vulval Synechiae	14.9, 14.13-14 14.16, 21.16
PE21.15: Discuss and enumerate the referral criteria for children with genitourinary disorder	21.3-16
PE21.16: Counsel/educate a patient for referral appropriately	21.3-16
PE21.17: Describe the etiopathogenesis, grading, clinical features and management of hypertension in children	17.12
TOPIC: Approach to and Recognition of a Child with Possible Rheumatologic Problem	
PE22.1: Enumerate the common rheumatological problems in children. Discuss the clinical approach to recognition and referral of a child with Rheumatological problem	24.1
PE22.2: Counsel a patient with chronic illness	24.1-4
PE22.3: Describe the diagnosis and management of common vasculitic disorders including Henoch-Schönlein purpura, kawasaki disease, SLE, JIA	24.2-4

Contd...

Contd...

TOPIC: Cardiovascular System–Heart Diseases		
PE23.1:	Discuss the hemodynamic changes, clinical presentation, complications and management of acyanotic heart diseases –VSD, ASD and PDA	17.5
PE23.2:	Discuss the hemodynamic changes, clinical presentation, complications and management of cyanotic heart diseases – Fallot's physiology	17.5
PE23.3:	Discuss the etiopathogenesis, clinical presentation and management of cardiac failure in infant and children	17.4
PE23.4:	Discuss the etiopathogenesis, clinical presentation and management of acute rheumatic fever in children	17.6
PE23.5:	Discuss the clinical features, complications, diagnosis, management and prevention of acute rheumatic fever	17.6
PE23.6:	Discuss the etiopathogenesis, clinical features and management of infective endocarditis in children	17.8
PE23.7:	Elicit appropriate history for a cardiac disease, analyse the symptoms, e.g. breathlessness, chest pain, tachycardia, feeding difficulty, failing to thrive, reduced urinary output, swelling, syncope, cyanotic spells, suck rest cycle, frontal swelling in infants. Document and present	17.2
PE23.8:	Identify external markers of a cardiac disease, e.g. cyanosis, clubbing, dependent edema, dental caries, arthritis, erythema rash, chorea, subcutaneous nodules, Oslers node, Janeway lesions and document	17.2
PE23.9:	Record pulse, blood pressure, temperature and respiratory rate and interpret as per the age	17.2, 31
PE23.10:	Perform independently examination of the cardiovascular system – look for precordial bulge, pulsations in the precordium, JVP and its significance in children and infants, relevance of percussion in pediatric examination, auscultation and other system examination and document	17.2
PE23.11:	Develop a treatment plan and prescribe appropriate drugs including fluids in cardiac diseases, anti-failure drugs, and inotropic agents	17.4
PE23.12:	Interpret a chest X-ray and recognize cardiomegaly	
PE23.13:	Choose and interpret blood reports in cardiac illness	17.3
PE23.14:	Interpret pediatric ECG	17.3
PE23.15:	Use the ECHO reports in management of cases	17.3
PE23.16:	Discuss the indications and limitations of cardiac catheterization	17.3
PE23.17:	Enumerate some common cardiac surgeries like BT shunt, Potts and Waterston's and corrective surgeries	17.5
PE23.18:	Demonstrate empathy while dealing with children with cardiac diseases in every patient encounter	-
TOPIC: Diarrheal Diseases and Dehydration		
PE24.1:	Discuss the etiopathogenesis, classification, clinical presentation and management of diarrheal diseases in children	14.10
PE24.2:	Discuss the classification and clinical presentation of various types of diarrheal dehydration	14.10
PE24.3:	Discuss the physiological basis of ORT, types of ORS and the composition of various types of ORS	14.10
PE24.4:	Discuss the types of fluid used in pediatric diarrheal diseases and their composition	14.10
PE24.5:	Discuss the role of antibiotics, antispasmodics, anti-secretory drugs, probiotics, anti-emetics in acute diarrheal diseases	14.10
PE24.6:	Discuss the causes, clinical presentation and management of persistent diarrhea in children	14.11
PE24.7:	Discuss the causes, clinical presentation and management of chronic diarrhea in children	14.12
PE24.8:	Discuss the causes, clinical presentation and management of dysentery in children	10.8
PE24.9:	Elicit, document and present history pertaining to diarrheal diseases	14.10
PE24.10:	Assess for signs of dehydration, document and present	14.10, 7.1
PE24.11:	Apply the IMNCI guidelines in risk stratification of children with diarrheal dehydration and refer	29.1-2
PE24.12:	Perform and interpret stool examination including hanging drop	14.3
PE24.13:	Interpret RFT and electrolyte report	21.2,7.2-5
PE24.14:	Plan fluid management as per the WHO criteria	14.10
PE24.15:	Perform NG tube insertion in a manikin	32.7
PE24.16:	Perform IV cannulation in a model	32.3
PE24.17:	Perform interosseous insertion model	32.3
TOPIC: Malabsorption		
PE25.1:	Discuss the etiopathogenesis, clinical presentation and management of malabsorption in children and its causes including celiac disease	14.12
TOPIC : Acute and Chronic Liver Diseases		
PE26.1:	Discuss the etiopathogenesis, clinical features and management of acute hepatitis in children	15.4
PE26.2:	Discuss the etiopathogenesis, clinical features and management of fulminant hepatic failure in children	15.5
PE26.3:	Discuss the etiopathogenesis, clinical features and management of chronic liver diseases in children	15.7
PE26.4:	Discuss the etiopathogenesis, clinical features and management of portal hypertension in children	15.8
PE26.5:	Elicit document and present the history related to diseases of gastrointestinal system	14.2
PE26.6:	Identify external markers for GI and liver disorders, e.g. Jaundice, pallor, gynecomastia, spider angioma, palmar erythema, ichthyosis, caput medusa, clubbing, failing to thrive, Vitamin A and D deficiency	14.2,15.2-3, 15.5, 15.7

Contd...

Contd...

PE26.7:	Perform examination of the abdomen, demonstrate organomegaly, ascites, etc.	14.2
PE26.8:	Analyse symptoms and interpret physical signs to make a provisional/ differential diagnosis	14.2, 15.2-3
PE26.9:	Interpret liver function tests, viral markers, ultra sonogram report	15.1
PE26.10:	Demonstrate the technique of liver biopsy in a perform liver biopsy in a simulated environment	32.6
PE26.11:	Enumerate the indications for upper GI endoscopy	14.3
PE26.12:	Discuss the prevention of Hep B infection – universal precautions and immunization	15.4
PE26.13:	Counsel and educate patients and their family appropriately on liver diseases	15.4-8
TOPIC: Pediatric Emergencies – Common Pediatric Emergencies		
PE27.1:	List the common causes of morbidity and mortality in the under five children	1.2-3, 28.2
PE27.2:	Describe the etiopathogenesis, clinical approach and management of cardiorespiratory arrest in children	27.1
PE27.3:	Describe the etiopathogenesis of respiratory distress in children	16.4, 27.2
PE27.4:	Describe the clinical approach and management of respiratory distress in children	16.4, 27.2
PE27.5:	Describe the etiopathogenesis, clinical approach and management of shock in children	27.3
PE27.6:	Describe the etiopathogenesis, clinical approach and management of status epilepticus	18.6
PE27.7:	Describe the etiopathogenesis, clinical approach and management of an unconscious child	18.3
PE27.8:	Discuss the common types, clinical presentations and management of poisoning in children	27.6
PE27.9:	Discuss oxygen therapy, in pediatric emergencies and modes of administration	27.1, 32.4
PE27.10:	Observe the various methods of administering oxygen	24.1, 32.4
PE27.11:	Explain the need and process of triage of sick children brought to health facility	29.1-2
PE27.12:	Enumerate emergency signs and priority signs	29.1-2, 27.4
PE27.13:	List the sequential approach of assessment of emergency and priority signs	27.1.1
PE27.14:	Assess emergency signs and prioritize	27.1.1
PE27.15:	Assess airway and breathing: Recognize signs of severe respiratory distress. Check for cyanosis, severe chest indrawing, grunting	27.1-3, 16.4
PE27.16:	Assess airway and breathing. Demonstrate the method of positioning of an infant and child to open airway in a simulated environment	27.1
PE27.17:	Assess airway and breathing: Administer oxygen using correct technique and appropriate flow rate	27.1
PE27.18:	Assess airway and breathing: Perform assisted ventilation by bag and mask in a simulated environment	27.1, 32.4
PE27.19:	Check for signs of shock, i.e. pulse, blood pressure, CRT	27.3
PE27.20:	Secure an IV access in a simulated environment	32.3
PF27.21:	Choose the type of fluid and calculate the fluid requirement in shock	27.3
PE27.22:	Assess level of consciousness and provide emergency treatment to a child with convulsions/coma	
	• Position an unconscious child	18.3
	• Position a child with suspected trauma	18.3, 27.1
	• Administer IV/per rectal diazepam for a convulsing child in a simulated environment	18.6, 27.1
PE27.23:	Assess for signs of severe dehydration	7.1, 14.10
PE27.24:	Monitoring and maintaining temperature: Define hypothermia. Describe the clinical features, complications and management of hypothermia	12.12
PE27.25:	Describe the advantages and correct method of keeping an infant warm by skin to skin contact	12.12
PE27.26:	Describe the environmental measures to maintain temperature	12.12
PE27.27:	Assess for hypothermia and maintain temperature	12.12
PE27.28:	Provide BLS for children in manikin	27.1
PE27.29:	Discuss the common causes, clinical presentation, medico-legal implications of abuse	28.4
PE27.30:	Demonstrate confidentiality with regard to abuse	28.4
PE27.31:	Assess child for signs of abuse	28.4
PE27.32:	Counsel parents of dangerously ill/terminally ill child to break a bad news	27.4
PE27.33:	Obtain informed consent	32.1
PE27.34:	Willing to be a part of the ER team	-
PE27.35:	Attends to emergency calls promptly	-
TOPIC: Respiratory System		
PE28.1:	Discuss the etiopathogenesis, clinical features and management of Nasopharyngitis	16.5
PE28.2:	Discuss the etiopathogenesis of pharyngo tonsillitis	16.5
PE28.3:	Discuss the clinical features and management of pharyngo tonsillitis	16.5
PE28.4:	Discuss the etiopathogenesis, clinical features and management of acute otitis media (AOM)	16.5
PE28.5:	Discuss the etiopathogenesis, clinical features and management of epiglottitis	16.6
PE28.6:	Discuss the etiopathogenesis, clinical features and management of acute laryngo- tracheo-bronchitis	16.6
PE28.7:	Discuss the etiology, clinical features and management of Stridor in children	16.4, 16.6

Contd...

Contd...

PE28.8:	Discuss the types, clinical presentation, and management of foreign body aspiration in infants and children	27.5
PE28.9:	Elicit, document and present age appropriate history of a child with upper respiratory problem including Stridor	16.4-6
PE28.10:	Perform otoscopic examination of the ear	16.5
PE28.11:	Perform throat examination using tongue depressor	16.5
PE28.12:	Perform examination of the nose	16.5
PE28.13:	Analyse the clinical symptoms and interpret physical findings and make a provisional/differential diagnosis in a child with ENT symptoms	16.5
PE28.14:	Develop a treatment plan and document appropriately in a child with upper respiratory symptoms	16.5
PE28.15:	Stratify risk in children with stridor using IMNCI guidelines	29.1
PE28.16:	Interpret blood tests relevant to upper respiratory problems	16.3
PE28.17:	Interpret X-ray of the paranasal sinuses and mastoid; and /or use written report in case of management. Interpret CXR in foreign body aspiration and lower respiratory tract infection, understand the significance of thymic shadow in pediatric chest X-rays	16.3
PE28.18:	Describe the etiopathogenesis, diagnosis, clinical features, management and prevention of lower respiratory infections including bronchiolitis, wheeze associated LRTI pneumonia and empyema	16.7, 16.9, 16.12
PE28.19:	Describe the etiopathogenesis, diagnosis, clinical features, management and prevention of asthma in children	16.8
PE28.20:	Counsel the child with asthma on the correct use of inhalers in a simulated environment	16.8, 32.5
TOPIC: Anemia and Other Hemato-oncologic Disorders in Children		
PE29.1:	Discuss the etiopathogenesis, clinical features, classification and approach to a child with anemia	19.2
PE29.2:	Discuss the etiopathogenesis, clinical features and management of iron deficiency anemia	19.4
PE29.3:	Discuss the etiopathogenesis, clinical features and management of Vit B12, Folate deficiency anemia	19.4
PE29.4:	Discuss the etiopathogenesis, clinical features and management of hemolytic anemia, thalassemia major, sickle cell anemia, hereditary spherocytosis, autoimmune hemolytic anemia and hemolytic uremic syndrome	19.5
PE29.5:	Discuss the National Anemia Control Programme	19.4
PE29.6:	Discuss the cause of thrombocytopenia in children: describe the clinical features and management of idiopathic thrombocytopenic purpura (ITP)	19.11
PE29.7:	Discuss the etiology, classification, pathogenesis and clinical features of hemophilia in children	19.12
PE29.8:	Discuss the etiology, clinical presentation and management of acute lymphoblastic leukemia in children	20.2
PE29.9:	Discuss the etiology, clinical presentation and management of lymphoma in children	20.3
PE29.10:	Elicit, document and present the history related to hematology	19.2, 19.10
PE29.11:	Identify external markers for hematological disorders, e.g. jaundice, pallor, petechiae purpura, ecchymosis, lymphadenopathy, bone tenderness, loss of weight, mucosal and large joint bleed	19.2, 19.10, 19.17
PE29.12:	Perform examination of the abdomen, demonstrate organomegaly	14.2, 15.2, 19.16
PE29.13:	Analyse symptoms and interpret physical signs to make a provisional/ differential diagnosis	19.2, 19.10
PE29.14:	Interpret CBC, LFT	19.2, 15.1
PE29.15:	Perform and interpret peripheral smear	19.2
PE29.16:	Discuss the indications for hemoglobin electrophoresis and interpret report	19.2, 19.5
PE29.17:	Demonstrate performance of bone marrow aspiration in manikin	32.6
PE29.18:	Enumerate the referral criteria for hematological conditions	19.2,4-15
PE29.19:	Counsel and educate patients about prevention and treatment of anemia	19.2,4-6
PE29.20:	Enumerate the indications for splenectomy and precautions	19.16.1
TOPIC: Systemic Pediatrics–Central Nervous System		
PE30.1:	Discuss the etiopathogenesis, clinical features , complications, management and prevention of meningitis in children	18.12
PE30.2:	Distinguish bacterial, viral and tuberculous meningitis	18.12
PE30.3:	Discuss the etiopathogenesis, classification, clinical features, complication and management of hydrocephalus in children	18.10
PE30.4:	Discuss the etiopathogenesis, classification, clinical features, and management of microcephaly in children	18.10,23.2
PE30.5:	Enumerate the neural tube defects. Discuss the causes, clinical features, types, and management of neural tube defect	18.10
PE30.6:	Discuss the etiopathogenesis, clinical features, and management of infantile hemiplegia	18.7-8
PE30.7:	Discuss the etiopathogenesis, clinical features, complications and management of febrile seizures in children	18.6
PE30.8:	Define epilepsy. Discuss the pathogenesis, clinical types, presentation and management of epilepsy in children	18.6
PE30.9:	Define status Epilepticus. Discuss the clinical presentation and management	18.6
PE30.10:	Discuss the etiopathogenesis, clinical features and management of mental retardation in children	3.6

PE30.11: Discuss the etiopathogenesis, clinical features and management of children with cerebral palsy	18.11
PE30.12: Enumerate the causes of floppiness in an infant and discuss the clinical features, differential diagnosis and management	18.19
PE30.13: Discuss the etiopathogenesis, clinical features, management and prevention of poliomyelitis in children	10.21
PE30.14: Discuss the etiopathogenesis, clinical features and management of Duchenne muscular dystrophy	18.18
PE30.15: Discuss the etiopathogenesis, clinical features and management of ataxia in children	18.9
PE30.16: Discuss the approach to and management of a child with headache	18.5
PE30.17: Elicit document and present an age appropriate history pertaining to the CNS	18.1
PE30.18: Demonstrate the correct method for physical examination of CNS including identification of external markers. Document and present clinical findings	18.1
PE30.19: Analyse symptoms and interpret physical findings and propose a provisional /differential diagnosis	18.1, 18.3-9, 18.17, 18.19
PE30.20: Interpret and explain the findings in a CSF analysis	18.2
PE30.21: Enumerate the indication and discuss the limitations of EEG, CT, MRI	18.2
PE30.22: Interpret the reports of EEG, CT, MRI	18.2
PE30.23: Perform in a mannequin lumbar puncture. Discuss the indications, contraindication of the procedure	18.2, 32.6
TOPIC: Allergic Rhinitis, Atopic Dermatitis, Bronchial Asthma, Urticaria Angioedema	
PE31.1: Describe the etiopathogenesis, management and prevention of allergic rhinitis in children	16.5
PE31.2: Recognize the clinical signs of allergic rhinitis	16.5
PE31.3: Describe the etiopathogenesis, clinical features and management of atopic dermatitis in children	25.8
PE31.4: Identify atopic dermatitis and manage	25.8
PE31.5: Discuss the etiopathogenesis, clinical types, presentations, management and prevention of childhood asthma	16.8
PE31.6: Recognise symptoms and signs of asthma	16.8
PE31.7: Develop a treatment plan for asthma appropriate to clinical presentation and severity	16.8
PE31.8: Enumerate criteria for referral	16.8
PE31.9: Interpret CBC and CX-ray in asthma	16.8
PE31.10: Enumerate the indications for PFT	16.3, 16.8
PE31.11: Observe administration of nebulization	16.8,32.5
PE31.12: Discuss the etiopathogenesis, clinical features and complications and management of urticaria angioedema	25.5
TOPIC: Chromosomal Abnormalities	
PE32.1: Discuss the genetic basis, risk factors, complications, prenatal diagnosis, management and genetic counseling in Down's syndrome	11.3
PE32.2: Identify the clinical features of Down's syndrome	11.3
PE32.3: Interpret normal Karyotype and recognize Trisomy 21	11.3
PE32.4: Discuss the referral criteria and multidisciplinary approach to management	11.3
PE32.5: Counsel parents regarding 1. Present child 2. Risk in the next pregnancy	11.3
PE32.6: Discuss the genetic basis, risk factors, clinical features, complications, prenatal diagnosis, management and genetic Counseling in Turner's syndrome	11.3
PE32.7: Identify the clinical features of Turner syndrome	11.3
PE32.8: Interpret normal Karyotype and recognize the Turner karyotype	11.3
PE32.9: Discuss the referral criteria and multidisciplinary approach to management of Turner syndrome	11.3
PE32.10: Counsel parents regarding 1. Present child, 2. Risk in the next pregnancy	11.3
PE32.11: Discuss the genetic basis, risk factors, complications, prenatal diagnosis, management and genetic Counseling in Klinefelter syndrome	11.3
PE32.12: Identify the clinical features of Klinefelter syndrome	11.3
PE32.13: Interpret normal karyotype and recognize the klinefelter karyotype	11.3
TOPIC: Endocrinology	
PE33.1: Describe the etiopathogenesis clinical features, management of hypothyroidism in children	22.3
PE33.2: Recognize the clinical signs of hypothyroidism and refer	22.3
PE33.3: Interpret and explain neonatal thyroid screening report	22.3
PE33.4: Discuss the etiopathogenesis, clinical types, presentations, complication and management of diabetes mellitus in children	22.7
PE33.5: Interpret blood sugar reports and explain the diagnostic criteria for Type 1 Diabetes	22.7
PE33.6: Perform and interpret urine dip stick for sugar	22.7
PE33.7: Perform genital examination and recognize ambiguous genitalia and refer appropriately	22.6
PE33.8: Define precocious and delayed puberty	22.6
PE33.9: Perform sexual maturity rating (SMR) and interpret	13.1
PE33.10: Recognize precocious and delayed puberty and refer	22.6
PE33.11: Identify deviations in growth and plan appropriate referral	2.4-5

PE34.1:	Discuss the epidemiology, clinical features, clinical types, complications of tuberculosis in children and adolescents	10.13
PE34.2:	Discuss the various diagnostic tools for childhood tuberculosis	10.13
PE34.3:	Discuss the various regimens for management of tuberculosis as per national guidelines	10.13
PE34.4:	Discuss the preventive strategies adopted and the objectives and outcome of the National Tuberculosis Control Programme	10.13
PE34.5:	Able to elicit, document and present history of contact with tuberculosis in every patient encounter	10.13
PE34.6:	Identify a BCG scar (Photograph)	10.13, 9.2
PE34.7:	Interpret a Mantoux test	10.13
PE34.8:	Interpret a chest radiograph	10.13
PE34.9:	Interpret blood tests in the context of laboratory evidence for tuberculosis	10.13
PE34.10:	Discuss the various samples for demonstrating the organism, e.g. gastric aspirate, sputum, CSF, FNAC	10.13
PE34.11:	Perform AFB staining	10.13
PE34.12:	Enumerate the indications and discuss the limitations of methods of culturing M. tuberculi	10.13
PE34.13:	Enumerate the newer diagnostic tools for tuberculosis including BACTEC, CBNAAT and their indications	10.13
PE34.14:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of fever in children	10.1
PE34.15:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of child with exanthematous illness like Measles, Mumps, Rubella and Chickenpox	10.1, 10.18-20
PE34.16:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of child with Diphtheria, Pertussis, Tetanus.	10.1, 10.5-6, 10.15
PE34.17:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of child with typhoid	10.1, 10.7
PE34.18:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of child with Dengue, Chikungunya and other vector born diseases	10.1, 10.23
PE34.19:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of children with common parasitic infections, malaria, leishmaniasis, filariasis, helminthic infestations, amebiasis, giardiasis	10.1, 10.33-37
PE34.20:	Enumerate the common causes of fever and discuss the etiopathogenesis, clinical features, complications and management of child with Rickettsial diseases	10.1, 10.17
TOPIC: The Role of the Physician in the Community		
PE35.1:	Identify, discuss and defend medicolegal, socio-cultural and ethical issues as they pertain to health care in children (including parental rights and right to refuse treatment)	27.4, 28.4, 32.1

CHAPTER 1

Child Health in India

Mukesh Agrawal

Childhood is the formative period in human life, subjected to various intrinsic and extrinsic influences affecting their survival, health and disease. State of child health in a community reflects its overall socioeconomic development and health concerns.

Constitutionally, a child has been defined as an individual <18 years of age, though conventionally, pediatricians in India looks after the health of children till 12–14 years. In some countries, the scope of pediatrics extends up to 19 years, i.e. including the period of adolescence.

From the health perspectives, childhood is not a homogeneous period but includes various phases of growth and development with unique physical, mental and social health dimensions during each phase **(Table 1.1)**.

According to the Sample Registration Survey (SRS) 2022, children constitute ~24.8% of India's population, including 7.5% infants and pre-schoolers (0–4 years) and 17.3% school children (5–14 years). Another 10.2% population is adolescents in the age-group of 15–19 years.

TABLE 1.1: Various periods in childhood

Prenatal (intrauterine life or IUL)	
Ovum	0–14th day of IUL
Embryo	3rd–8th week of IUL
Fetus	9th week of IUL–till birth
Postnatal	
Neonate	0–28 days
Infant	28 days–1 year
Toddler	1–3 years
Preschool	3–5 years
School age	5 years–till onset of puberty
Adolescence	
Early adolescence	12–14 years (10–12 years in females)
Mid adolescence	14–16 years (12–14 years in females)
Late adolescence	16–18 years (14–16 years in females)

Present chapter provides an overview of current status of child health in India and its determinants as well as leading causes of morbidity and mortality and interventional strategies, while more specific aspects have been discussed in Ch 28.

1.1 INDICATORS OF CHILD HEALTH

Status of child health in a country is reflected in various morbidity and mortality indicators and their changes over a period of time.

Morbidity indicators are more reliable pointers of community health than mortality indicators. Although community data regarding patterns of childhood morbidity in India is limited due to poor reporting system, hospital data identifies three major causes of post-neonatal morbidity in Indian children—acute respiratory tract infections (~30%), acute diarrheal diseases (~20%) and other infectious disease including tuberculosis and measles (~20%), with underlying malnutrition in over 25% of these children. Many of these problems are inter-related and co-exist in the same child seeking health care.

NFHS-5 (2021) found that 7.3% and 2.8% of under-five children had history of diarrhea and respiratory infections within 2 weeks before the survey visit. It also reveals that 32.1% and 67.1% of all under-five children were underweight and anemic.

Morbidity profile is not static and keeps on changing with changes in socioeconomic and environmental status as well as health care awareness/facilities in the community. Recent years have seen substantial decline in incidence of infections and nutritional disorders, with simultaneous rise in non-infective illnesses and accidents due to changing lifestyle and other ecological factors.

Mortality indicators are relatively better defined and documented. SRS 2022 reveals that ~11.2% of all deaths in India occur during childhood, including 9.1% in infants, 0.9% in pre-schoolers (1–4 years) and 1.4% in school children (5–14 years), apart from another 1.3%

TABLE 1.2: Current mortality indicators in children	
Perinatal mortality rate (PNR)	18
Stillbirth rate (SBR)	03
Neonatal mortality rate (NMR)	20
Early NMR	15
Late NMR	05
Post-neonatal mortality rate (PNMR)	08
Infant mortality rate (IMR)	28
Under-five mortality rate (U5MR)	32

Source: SRS report 2022.

in adolescents (15–19 years). In brief, ~85% of all childhood deaths occur in first five years, ~80% in infancy, 50% in first month and 30% in first week of life.

Considering variable risk of mortality and causative factors in different age groups, many mortality indicators **(Table 1.2)** are used to assess the status of child health and efficacy of interventional programs, some of which are as follows:

Infant mortality rate (IMR), i.e. total number of deaths during first year of life compared to total number of live births in the given year, expressed as a rate per 1000 live births, is considered as the single best indicator of child health and effectiveness of health care system in a community.

According to SRS 2022, current IMR in India is 28/1000 live births (35.3 as per NFHS-5, 2021), much higher than that in developed countries (<10/1000). Within India too, IMR differs widely in urban *vs* rural population (19 *vs* 31 respectively) and from state to state - being lowest in Puducherry and Kerala, moderate in Maharashtra and highest in Bihar and Chhattisgarh (Table 28.4).

Leading causes of IMR include *neonatal problems* (53%), *pneumonia* (17%), *diarrheal disease* (5%) and other *severe infections* (4%). (SRS-COD report 2017-19)

Infancy includes two crucial phases of human life-neonatal and post-neonatal period, with diverse health problems. Sharp fall in IMR during last century (204 in 2011 to 28 in 2020) is predominantly due to decline in post-neonatal mortality after better control of exogenous factors, e.g. infection and malnutrition.

Perinatal mortality rate (PMR), i.e. total number of late fetal (>28 weeks) and early neonatal (<7 days) deaths compared to total number of live births in given year, expressed as a rate per 1000 live births, is the best indicator of care available to pregnant mother and her newborn in a given community (Ch 12.2).

According to SRS 2022, current PMR in India is 18/1000 live births, with wide geographic variations. Despite the declining trends, it is still much higher than that in most developed countries.

Neonatal mortality rate (NMR), i.e. total number of neonatal deaths <28 days of life, expressed as a rate per 1000 live births in a given year, currently stands at 20 (SRS, 2022). NMR, is mainly related to biological factors, e.g. low birth weight, birth asphyxia and congenital malformations, etc. and continues to be high in most parts of our country. Interestingly, NMR is higher in males (? biologically fragile sex).

Leading causes of NMR in India include prematurity and LBW (46%), birth asphyxia/trauma (15%), and neonatal pneumonia in 13% (SRS-COD report 2017-19).

Under-five mortality rate is a sensitive indicator of the overall development of the community, as majority of its causes, e.g. malnutrition and infection, depend on the socioeconomic status, environmental hygiene and health awareness in population. It is defined as total annual deaths <5 years of age and total live births in the same year, expressed as a rate per 1000 live births.

According to SRS 2022, current under-five mortality rate in India is 32 (41.9 as per NFHS 2021), substantially lower than 242 in 1960, due to overall socioeconomic development, easier access to health care and control of infectious diseases.

Leading causes of childhood mortality beyond infancy include injuries (21.8%), pneumonia (18%), non-communicable diseases (14%) and diarrheal diseases 13% (SRS-COD report 2017-19).

1.2 CHANGING PROFILE OF DISEASES

Etiology of childhood morbidity and mortality varies with age and may be divided into two major groups– **endogenous causes,** e.g. low birth weight, predominantly responsible for neonatal morbidity; and **exogenous causes,** e.g. infections and malnutrition, which usually affect beyond the neonatal period **(Table 1.3)**.

Trends in last three decades (1992-2020) have witnessed a sharp drop of ~67% in post-NMR (22 to 8) as compared to only 32% improvement in NMR (34 to 20). This observation suggests that improvement in these mortality indicators during recent years are largely attributable to better control of exogenous factors (dominant cause of post-NMR) than endogenous causes (dominant in newborns) are more difficult to control and need holistic strengthening of antenatal, intranatal and postnatal services.

With relative control of common illnesses, new causes are emerging as important contributors of childhood morbidity and mortality in India, e.g. congenital malformations, immunological disorders, accidents and mental health problems.

1.3 DETERMINANTS OF CHILD HEALTH

Child health in a community is influenced by various environmental factors, which account for geographic and demographic differences in morbidity and mortality.

TABLE 1.3: Leading causes of childhood morbidity and mortality in India

Prenatal/intranatal	*Neonatal*	*Post-neonatal*	*1–4 years*
Maternal nutrition Maternal illness/infections Obstetric complications Fetal malformations Fetal hypoxia	LBW and prematurity Birth asphyxia/injury Neonatal sepsis Congenital malformations	Acute respiratory infections Acute diarrheal diseases Malnutrition Congenital malformations	Acute respiratory infections Acute diarrheal diseases Malnutrition VPDs—TB, measles Accidents/poisoning
28 weeks ← PNR → 7 days		—	—
—	NMR	PNMR	—
—	← IMR →		—
—	← Under-five mortality rate →		

VPD: Vaccine preventable diseases; **LBW:** Low birth weight; **PNR:** Perinatal mortality rate; **NMR:** Neonatal mortality rate; **PNMR:** Post-neonatal mortality rate; **IMR:** Infant mortality rate.

Important adverse factors for child health in India include:

- *Maternal factors*, e.g. young maternal age, maternal malnutrition and illnesses, repeated pregnancies, short birth spacing, etc.
- *Socioeconomic factors*, e.g. poverty, urbanization, large family size, female illiteracy, girl child, illegitimate pregnancies, etc.
- *Cultural factors*, e.g. early marriage, improper infant feeding practices, e.g. top feeding, harmful child care customs/taboos, etc.
- *Environmental factors*, e.g. overcrowding, unsafe water supply and excreta disposal, poor personal and environmental hygiene, stressful family environment, e.g. broken families, etc.
- *Health care factors*, e.g. inadequate antenatal care, unsafe/untrained deliveries, poor immunization coverage, inadequate access to health services, etc., specially in rural areas.

Table 1.4 depicts status of some important health determinants in India, including perinatal care, early infant feeding, immunization and utilization of health care services in children.

1.4 INTERVENTIONAL STRATEGIES IN CHILD HEALTH

Globally, the needs and rights of children have been recognized since long with celebration of ***Universal children day*** on 14th November every year since 1954. Year 1979 was also celebrated as the ***UN international year of the child***.

Indian constitution has acknowledged the needs and rights of children under following articles:

- Article 24—prohibits employment of children <14 years in factories
- Article 39—prevents abuse of children of tender age
- Article 45—provides free and compulsory education until 14 years of age.

TABLE 1.4: Current status of child health determinants (NFHS-5, 2019-2021)

Antenatal care	
Adequate number (4) of ANC visits	58.1%
Iron-folic supplements for 100 days	44.1%
Tetanus immunization	92.0%
Perinatal care	
Institutional deliveries	88.6%
Unsafe deliveries	10.6%
LSCS deliveries	21.5%
% LBW or low birth weight	18.0%
Infant feeding practices	
Early breastfeeding (within <1 hour)	41.8%
Exclusive breastfeeding till 6 months	63.7%
Initiation of complementary feeds @ 6 months	45.9%
Adequate diet in breastfed (6–23 mo)	11.1%
Adequate diet in non-breastfed (6–23 mo)	12.7%
Immunization coverage	
Complete immunization till 23 months	76.4%
BCG	95.2%
DPT/Penta V (3 doses)	86.7%
OPV (3 doses)	80.5%
Measles 1 and 2	87.9%/31.9%
Rotavirus	36.4%
Vitamin A supplement in last 6 months	71.2%
Health care utilization	
% ARI cases visiting health care facility	69.0%
% Diarrhea visiting health care facility	68.9%
% use of ORS in diarrhea	60.6%
% use of zinc in diarrhea	30.5%

Source: NFHS-5 Fact sheet 2021 (reference 2019-21 data)

To fulfil these constitutional provisions, Government of India adopted a ***national policy for children (1974),*** which affirms that *"It shall be the policy of the state to provide adequate services to children, both before and after birth and through the period of growth, to ensure their full physical, mental and social development. The state shall progressively increase the scope of such services so that, within a reasonable time, all children in the country enjoy optimum conditions for their balanced growth."*

To achieve this objective, Government of India has proposed and revised some health targets to be achieved in a time-bound manner, aligned to global goals, e.g. millennium development goals (MDGs), sustainable development goals (SDGs) and WHO recommendations. *National health policy 2017* has established certain health goals to be achieved in time-bound manner, some of whom are related to child health as enlisted in **Table 1.5**.

Since independence, a plethora of targeted child health programs were launched in India with periodic reviews and modifications (Ch 28.4). While earlier programs were largely unisectorial, inter-sectorial coordination and integration with universal health care is hallmark of current strategies in child health strategies. Some important aspects of these efforts are as follows:

- **General population measures**
  - Socioeconomic development
  - Population control (family planning)
  - Safe water supply
  - Environmental sanitation
  - Promotion of female literacy
- **Reproductive female health measures**
  - Nutritional/health care of reproductive females
  - Adequate birth spacing
- **Antenatal care**
  - Regular antenatal care
  - *'At-risk approach'* for high-risk pregnancies
- **Perinatal care**
  - Safe/clean delivery by trained attendants
  - Essential newborn care
  - Promotion of breastfeeding
- **Postnatal care**
  - Universal immunization
  - Growth monitoring and promotion
  - Early diagnosis and treatment of common illnesses
  - Promotion of low-cost tools, e.g. ORS
- **Strengthening of health care system**
  - Low-cost medical care
  - General health programs, e.g. RCH, ICDS
  - Disease-targeted programs, e.g. NTEP, NVBDCP
  - Group-targeted programs, e.g. street children.

To conclude, child health in India is currently at the crossroads. Despite all efforts, status of Indian child is still far behind than that of a child in developed countries. Country has largely failed to achieve child health targets set time to time.

While lessons have been learnt from the past and strategies are being revised accordingly, achievement of these targets remains a function of political will, community participation, efforts of health workers and above all, acceptance of interventions by recipients.

TABLE 1.5 National Health Policy 2017: Targets with (proposed year of achievement)

Mortality indicators	
IMR	28 (2019)
Under-5 MR	23 (2025)
MMR	100 (2020)
NMR	16 (2025)
SBR	Single digit (2020)
Disease elimination/control	
HIV	90:90:90* (2020)
Malaria (annual incidence)	<1: 1000 (2020)
Leprosy elimination	<1: 10000 (2018)
Kala-azar elimination	<1: 10000 (2017)
Lymphatic filariasis elimination	2017**
TB cure rate/elimination	85% (2025)
Health services	
Antenatal coverage	90% (2025)
Full immunization till 1 yr	90% (2025)
Stunting (under-5 children)	Reduce by 40% (2025)
Safe water and sanitation	100% by 2020

*90% PLHA know their HIV status, 90% receive sustained antiretroviral therapy and 90% on antiretroviral therapy will have viral suppression.
**<1% microfilaria prevalence in all districts.

CHAPTER

2

Normal Growth and Development

Surbhi Rathi, Priyanka Bote, Mukesh Agrawal

Growth and development is the essence of childhood that leads to transition of a fertilized ovum into an independent adult through different stages of anatomical growth and physiological maturation. While the terms *growth* and *development* are not interchangeable, both processes are largely interdependent.

Growth is *an anatomical process involving increase in the physical size of an organ, tissue and body, by multiplication or enlargement of cells*. It can be easily measured in terms of increase in anthropometric parameters.

Development denotes *physiological or functional maturation of various organs or systems, acquisition of newer functions or skills and adaptation to the environment*. Unlike growth, precise measurement of development is difficult, though the achievement of various neurological milestones may be used as general indicator of development.

2.1 DETERMINANTS OF GROWTH AND DEVELOPMENT

Growth and development is a complex process that depends on the inherent biological potential as well as various environmental influences including social, emotional and pathological factors **(Table 2.1)**. Important factors affecting growth and development in children are as follows:

I. Intrinsic (biological) factors determine the inherent pace, pattern and ultimate potential for growth and development, achievable under best environmental situations and include:

- ***Age:*** General pace of growth is highest in intrauterine life and early infancy, decelerates gradually with advancing childhood, followed by a second growth-spurt with onset of puberty.
- ***Sex:*** Boys are usually heavier and taller than girls in early childhood but puberty begins and completes earlier in girls.
- ***Ethnicity*:** Caucasians and children of developed countries have better growth, not only due to inherent potential but also due to favorable environmental factors, e.g. good nutrition and lesser infections.

TABLE 2.1: Factors affecting growth and development

I. Intrinsic (biological) factors
- Age, sex and ethnicity
- Hereditary trends
- Genetic/chromosomal disorders

II. Extrinsic (organic) factors
- *Prenatal*
  - *Maternal nutrition:* Malnutrition and anemia
  - Intrauterine (TORCH) infections*
  - *Maternal diseases:* Hypertension and diabetes
  - *Teratogens:* Drugs, radiation, smoking
  - Placental disorders/insufficiency
- *Perinatal*
  - Gestational age and birth weight
  - *Complications:* Birth asphyxia and kernicterus
- *Postnatal*
  - *Nutrition:* Malnutrition and anemia
  - *Chronic infections:* TB, worm infestations
  - *Systemic illnesses:* CHDs and asthma
  - *Trauma:* Head injury
  - *Drugs:* Steroids and cytotoxic agents

III. Extrinsic (environmental) factors
- Socioeconomic factors
- Cultural factors/practices
- Emotional stimulation
- Climatic factors

*TORCH: Toxoplasmosis, rubella, cytomegalovirus, herpes simplex.

- ***Hereditary:*** Children of taller parents are usually tall and *vice versa*. Age of menarche in daughters usually correlates well with that in their mothers.
- ***Genetic disorders*** are associated with inherently altered growth potential, e.g. short stature in Turner syndrome, Achondroplasia, etc. and tall stature in Marfan syndrome, etc.
- ***Secular trends*** suggests very small but consistent rise in normal weight/height values of the children at different ages over the decades, perhaps due to better environmental factors, e.g. nutrition and freedom from infections. Similar trends are noticed in terms of better final adult height and earlier age of menarche in girls. These secular trends are more marked in developing

countries due to the scope for improvement and underline the need for periodic revision of reference values.

II. Extrinsic (organic) factors are prime determinants of growth and development in developing countries, which directly facilitate or limit the achievement of inherent growth potential. The exact effect of these factors depends on the age, quantum and duration of exposure in relation to the period of growth. Important organic factors affecting growth/development include:

- ***Prenatal factors*** involving maternal health, e.g. malnutrition, infections and systemic diseases affects growth of offsprings in three different ways: (a) during the period of organ differentiation, i.e. *embryogenesis*, leading to higher risk of abortions or congenital malformations, (b) during late fetal phase of anatomical and functional maturation, leading to intrauterine growth retardation (IUGR) or stillbirths, (c) during postnatal life, when maternal ill-health may affect emotional attention and quality of baby care during critical phase of growth.
- ***Obstetrical or perinatal factors:*** Preterms and IUGR babies behave differently than term babies during postnatal growth period—while preterms grow faster in late infancy (*catch up growth)* than the term babies, IUGR babies are unlikely to show significant catch-up growth and have limited growth potential throughout the life. Other perinatal events, e.g. asphyxia, injuries, sepsis, kernicterus, etc. may also have disastrous effects on subsequent growth and development.
- ***Postnatal factors:*** Postnatal growth is largely governed by hormonal influences, e.g. growth hormone in pre-pubertal period and sex-steroids during puberty; apart from adequate supply of substrates, e.g. nutrition, oxygen, etc. and freedom from infections. Malnutrition, chronic infections, e.g. tuberculosis and systemic illnesses, e.g. asthma, heart diseases, etc. are important adverse factors influencing postnatal growth and development. Head injury may lead to intellectual disability while growth of a particular limb may be affected after fractures of long bones. Prolonged steroid/cytotoxic therapy are important causes of iatrogenic growth suppression.

III. Extrinsic (environmental) factors are important hindrances for normal growth in developing countries, which indirectly affect nutrition, infection rate and quantum of health care. These include:

- ***Socioeconomic factors:*** Children of affluent parents have better growth due to better nutrition and hygienic conditions than those of low socio-economic status.
- ***Cultural factors*****:** Child-rearing practices vary indifferent communities, which may significantly impact child's growth. Routine practice of breast-feeding is a positive growth-promoting factor, while delayed weaning, food taboos and unhygienic living conditions are important adverse cultural influences in India.
- ***Emotional factors:*** Adequate emotional stimulation is essential not only for psychosocial and linguistic development of a child but also for growth. Lower growth hormone levels are well documented in emotionally deprived children like orphans.
- ***Climatic factors:*** Growth is slower in summer than in spring season, probably as infections are common and appetite is poor in hot and humid climate. Climate also affects the food productivity.

2.2 LAWS AND PATTERNS OF GROWTH

Although each child has a unique pace of growth, certain principles are applicable to all children, as follows:

- **Growth is a continuous and orderly process** that begins with fertilization of ovum and continues at *every moment* of intrauterine and postnatal life till puberty, in a fairly consistent order.
- **Pace of growth in not uniform throughout childhood**, with intermittent periods of rapid growth, also termed as *critical periods*. Various *phases or periods of growth* **(Table 1.1)** may be broadly classified as follows:
  - ***Embryonic period*** (0–8 weeks) is the period of explosive growth in the number of cells following fertilization and implantation of the ovum in uterus as well as organ differentiation, i.e. formation of various tissues and organs. Any insult in first trimester is more likely to cause congenital malformations. By the end of this period, a fetus is structurally similar to an adult, except the differences in organ size and function.
  - ***Fetal growth*** (9^{th} week to birth) is characterized by increase in size of organs (anatomical development) and functional maturation of various systems (physiological development). Intrauterine fetal growth follows an S-shaped curve with maximum growth in terms of weight gain during 24–37 weeks of life (15 gm/day) followed by gradual decline to ~6 gm/day between 37–40 weeks. However, growth in fetal length peaks at ~20 weeks with a gain of ~1 cm/month followed by gradual slow-down.

    Any insult in late pregnancy leads to restrictions in body size and organs, termed intrauterine growth retardation or IUGR. While a fetus is usually capable to survive *ex-utero* beyond 28^{th} weeks of life (*age of viability*), adequate functional maturation is achieved only by 37 weeks (*full term*).
  - ***Postnatal growth*** during childhood (birth to onset of puberty) involves further physiological maturation and anatomical growth, though the pattern and pace of these changes differ in different

body tissues and in different individuals, discussed later (see next law below).

– ***Adolescent growth and development*** from onset to completion of puberty, is the transitional phase between child and adult, characterized by (a) *physical growth* spurt to attain adult dimensions, (b) *sexual maturity*, and (c) *psychological changes* in order to gain emotional and functional independence (Ch 13.3). Girls have an earlier onset of physical growth spurt during adolescence (9–12 years) than boys (12–15 years).

- **Pattern of growth is different in different body tissues.** All tissues or organs do not grow at the same velocity at same age. Mainly four types of growth patterns are seen in different body tissues **(Fig. 2.1)**.
  – ***Somatic growth*** is maximum in intrauterine life and follows a sigma-shaped curve in postnatal life, with two distinct growth spurts - during infancy and during adolescence. In mid-childhood, child grows slowly but steadily. Somatic growth completes at 16–18 years (earlier in females) with achievement of adult height.
  – ***Neurological growth*** is maximum in late intrauterine and early postnatal life, followed by rapid deceleration in late infancy and is nearly complete by two years of age. Head circumference reaches to ~95% of adult value by 2–3 years of age and any further increase is due to the increase in bony thickness rather than the brain size.
  – ***Gonadal growth*** is negligible till the onset of puberty, when gonads grow rapidly under endocrinal influences to achieve adult size and function during next 3–4 years of adolescence.
  – ***Lymphoid growth*** is maximum in mid-childhood, during 4–8 years of age. Thus, lymph nodes, tonsils and adenoids are physiologically enlarged in this age group, often confused with a diseased state. Subsequently, these tissues partially regress to adult size after 8–9 years of age.
- **Pace of growth is unique for every child**, despite comparable growth potential, determined by familial and racial characteristics. Each child experiences intermittent periods of growth spurts and stagnation. While some children grow rapidly in early life followed by slower pace, others have initially slower growth followed by late catch-up growth.
- **Growth progresses in cephalocaudal direction:** During intrauterine life, head and upper torso grows faster than limbs as evident from higher upper *vs* lower segment (US:LS) ratio at birth (1.7:1) and the head being larger than the chest. Postnatally, trunk and limbs grow more rapidly with equalization of Head : Chest circumference at 1 year and US:LS ratio at 7 years. Chest circumference exceeds head circumference beyond first year of life.

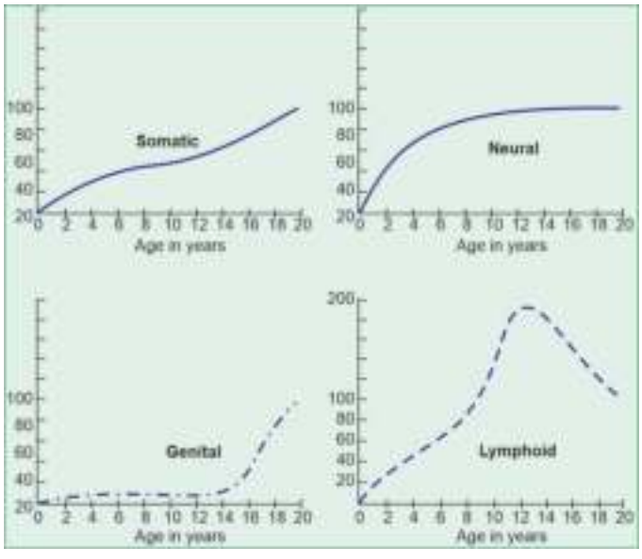

Fig. 2.1: **Growth patterns in different body tissues.**

2.3 NORMAL CHILDHOOD GROWTH

Physical growth during childhood is evident in many dimensions by chronological changes in body size and appearance, i.e. anthropometric indicators **(Table 2.2)** as well as in others tissues, e.g. dentition, skeletal maturation, and internal body composition. Despite individual variations, most of these changes follow a predictable pattern and any significant deviation from this pattern may be the earliest or only indicator of ill health.

TABLE 2.2: Anthropometric indicators

I. Anthropometric

Primary
- Weight[1]
- Length or height[1]
- Head circumference[1]
- Chest circumference[1]
- Mid-arm circumference[1]
- Arm span[3]
- Sitting Height[3]
- Skin-fold thickness[2]

Derived
- Weight for height[2]
- US: LS ratio (CR:RH ratio)[3]
- Stem stature index[3]
- Body mass index (BMI) [2]

II. Clinical
- Body build
- Dentition
- Sexual maturity rating (SMR)

III. Radiological:
- Bone age

Should be recorded in: [1]in all children, [2]in malnourished/obese children, [3]in short/tall stature

US: Upper segment; **LS:** Lower segment; **CR:** Crown to rump; **RH:** Rump to heel.

This chapter deals with some important patterns of growth during childhood, while adolescent growth and sexual maturity has been discussed in later chapter 13.2.

2.3.1 SOMATIC (ANTHROPOMETRIC) GROWTH

Change in the body size and appearance is most obvious dimension of growth, which can be easily measured by various anthropometric parameters as follows:

Weight is the most sensitive indicator of physical growth, used not only for regular monitoring but also for early detection of diseases/recovery and calculation of drug dosages. While precise values of body weight in normal children depend on the sex, race and other factors, as reflected in growth norms/charts discussed later, a general pattern is as follows:

A normal baby weighs ~3.3 kg at birth and looses ~10% of birth weight during first 7 days of life, which is regained by 10th day. Subsequently, they gain ~20–30 gm/day during first 3 months, ~400 gm/month during 3–12 month, ~2 kg/year till 7 years and then, ~3 kg/year subsequently till end of puberty.

Birth weight usually doubles at five months (~6.5 kg), triples at one year (~10 kg), quadruples at two years (~12 kg) and becomes seven times by 7 years (~21 kg) of age. A simple method to calculate normal Wt at different ages is given in **Table 2.3** (for precise values, *see* **Table 2.6A and B)**.

Stature, i.e. cephalocaudal distance is measured in terms of recumbent ***length*** up to two years of age and *standing* ***height*** in older children. Stature is an indicator of long-term growth, affected only after prolonged growth insult for many months. While precise values of stature in normal children depend on the sex, race and other factors, as reflected in growth norms/charts discussed later, a general idea is as follows:

At birth, a term newborn measures ~50 cm. Subsequently, the length increases by ~4 cm/month till 3 months (~62 cm at 3 months), then ~2 cm/month till 6 months (~69 cm at 6 months) and then ~1 cm/month till one year (~75 cm at one year).

A child gains about half of the birth length, i.e. ~25 cm in first year of life (~75 cm), half of the first-year gains, i.e. ~12.5 cm in second year (~ 87.5 cm), half of the second year gains, i.e. ~6.5 cm in third year (~94 cm) and then ~5–6 cm/year till the onset of puberty. A simple method to calculate normal length/height at different ages is given in **Table 2.4** (For precise values, *see* **Table 2.6A and B)**.

Parental height is an important determinant of children's height. Height of a boy at 2 years and girls at 2.5 years is nearly half of the adult height (+ 5 cm). It is possible to predict the adult height in children from parental heights, using the following formulas:

Adult Ht* (boy) = {(Mother's Ht +13) + Father's Ht}/2
Adult Ht* (girl) = {(Father's Ht – 13) + Mother's Ht}/2
(predicted adult Ht + 8 cm)*

Head circumference is the indirect indicator of brain growth and must be measured in all children up to 5 years of age. Brain growth is nearly complete by then and any further increase in head circumference of older children is minor and due to thickening of calvarium rather than changes in brain size. While precise values of head circumference in normal children depend on the sex, race and other factors, as reflected in growth norms/charts discussed later, a general idea is as follows:

At birth, normal head circumference is ~33 cm, increases by ~2 cm/month till 3 months (~39 cm at 3 months), ~1.5 cm/month in next 3 months (~43 cm at 6 months) and ~0.5 cm/month in next 6 months (~47 cm at 1 year). Subsequently, it increases by only ~2 cm in second year (~49 cm at 2 years), ~1 cm in third year (~50 cm at 3 years) and <1 cm/year afterwards. For precise values of head circumference up to 5 years, *see* **Table 2.6A and B**.

Dine's formula may be used in first 400 days of life to express relationship between length and head circumference with accuracy of ~95%, as follows:

Head circumference ± 2.5 = Length/2 + 9.5
(all values in cm)

Smaller head size (<3rd percentile) indicates microcephaly or craniosynostosis, while larger head (> 97th percentile) is seen in hydrocephalus, macrocephaly, rickets, or chondrodystrophies.

Mid-upper arm circumference (MUAC) is a measure of circumferential growth of soft tissue including fat and muscles. After rapid growth in first 6 months of life,

TABLE 2.3: Simplified weight calculations

Birth weight (BW)	:	3.3 kg
0–4 months	:	BW + (age in months × 0.8)
4–8 months	:	BW + (age in months × 0.7)
8–12 months	:	BW + (age in months × 0.6)
1–9 years	:	(Age in years + 4) × 2
9–12 years	:	Age in years × 3

TABLE 2.4: Simplified length/height calculations

At birth	50 cm
Gains in first year	
0–3 months	4 cm/month
3–6 months	2 cm/month
6–12 months	1 cm/month
At 1 year	75 cm
At 2 years	87.5 cm
At 3–12 years	(Age in years × 6) + 77*

*Weech's formula

MUAC remains largely constant (~16–17 cm) between 2–5 years of age, due to replacement of body fat with muscle mass.

A MUAC <13.5 cm between 1–5 years of age indicates acute malnutrition, forming the basis of its diagnosis and classification (severe <11.5 cm,/moderate 11.5–12.4 cm).

Chest circumference is ~3 cm less than the head circumference at birth, equals at one year and exceeds afterwards. It needs to be measured only in children <2 years at nipple level during mid-expiration by encircling the non-stretchable measuring tape perpendicular to chest using cross-over technique.

Persistence of chest circumference less than head circumference beyond infancy indicates larger head, e.g. hydrocephalus or smaller chest, e.g. malnutrition.

Body proportions, i.e. ratio between torso and limbs may be altered in some disorders with short/tall stature. Various terms are used to denote these proportions, e.g. upper-segment *vs* lower-segment ratio (*US:LS ratio*), crown-to-rump *vs* rump-to-heel ratio (*CR:RH ratio*) and *stem-stature index* (sitting Ht/standing height × 100).

To calculate these ratio/index, measure lower-segment height in standing position from pubic symphysis to the floor and deduct it from total standing height to derive upper-segment height.

At birth, upper segment is longer than the lower-segment. Postnatally, lower-segment grows more rapidly to equalize upper segment by 7–10 years. Thus,

- *Normal US: LS ratio* is ~ 1.7:1 at birth, 1.3:1 at three years and 1:1 at seven years onwards.
- *Normal stem-stature index* is ~70 at birth, 66 at six months, 64 at one year, 61 at two years, 58 at three years, 55 at 5 years, and 52 at 7 years.

US:LS ratio is *increased* in short-limb dwarfism, e.g. achondroplasia, cretinism and severe rickets; and decreased or reversed in short-trunk dwarfism, e.g. spondyloepiphyseal dysplasia, spinal deformities and Marfan syndrome.

Limb span, i.e. the distance between tips of middle fingers of outstretched hands, is another measure of body proportions, being normally 1–2 cm less than the height till 10 years of age and equals or more afterwards. Disproportionate increase or decrease in limb span as compared to height indicates short-trunk or short-limb dwarfism respectively.

Skin-fold thickness is an indicator of body fat and must be measured in selected children over the left triceps area by a *Lange* or *Harpenden's* skin-fold calipers. A skin-fold thickness of <10 mm after infancy indicates malnutrition (<6 mm in severe malnutrition).

Body mass index (BMI) is an indicator of subcutaneous fat, calculated as weight in kg/Ht in m^2. Normal BMI ranges between ~18.5–23 kg/m^2 after first 5 years of life.

Rather than growth assessment, BMI is more useful for the diagnosis of obesity or overweight in children >2 years and undernutrition in children >5 years of age. Nutritional status may be classified on the basis of BMI as follows: obesity (>27), overweight (>23), normal (18.5–22.9), thinness (<18.5) and moderate/severe thinness (<17). For precise values, *see appendix 2.11–2.12.*

Body Build (Somatotypes)

Body build (somatotype) refers to visual physical appearance of normal children (excluding craniofacial features), which is often determined by hereditary and racial characteristics. Three main types of normal body build or somatotypes, as per *Sheldon's classification* are:

a. ***Ectomorphic:*** Tall and linear build, with small musculature and lighter bone structure.

b. ***Endomorphic:*** Stocky-rounded build, with large amount of soft tissue.

c. ***Mesomorphs:*** Heavy muscular physique, between the ectomorphs and endomorphs.

2.3.2 DENTAL DEVELOPMENT (DENTITION)

Dental development may be divided into 3 chronological stages—(a) eruption of primary or deciduous teeth, (b) exfoliation of these teeth, and (c) eruption of permanent teeth **(Table 2.5)**, though the timings of these events are too variable to be useful for growth assessment.

Normal dentition: Important events in normal dentition include:

- Total numbers of deciduous and permanent teeth are 20 and 32 respectively. *There are no deciduous premolars and third molars.*
- Primary dentition begins at 5–8 months with eruption of *lower central incisor* (first deciduous teeth) and completes by 2–2.5 years with eruption of second molars. A baby has ~6 primary teeth at one year and ~12–16 teeth at 2 years.
- Exfoliation of deciduous teeth begins at ~6 years, usually with loss of *first molar*. Delayed shedding of deciduous teeth may lead to dental mal-alignment.

TABLE 2.5: Chronology of dentition

Deciduous teeth		*Permanent teeth*	
Age (months)	***Erupting teeth***	***Age (years)***	***Erupting teeth***
5–8	Central incisors	6–7	First molars
7–11	Lateral incisors	6–8	Central incisors
10–16	First molars	7–9	Lateral incisors
16–20	Canines	9–12	Canines
20–30	Second molars	10–12	First premolars
–	–	10–13	Second premolars
–	–	12–13	Second molars
–	–	17–23	Third molars

- Permanent dentition begins ~2–4 months after exfoliation of first deciduous tooth (usually first molar) and continues well beyond the childhood till eruption of third molars (*wisdom teeth*) at 17–23 years.

Abnormal dentition: Common developmental abnormalities in dentition include:

Natal teeth are occasionally present at birth as supernumerary or prematurely erupted deciduous teeth. These teeth are usually harmless and should be extracted only if loose or interfere with feeding.

Delayed dentition, i.e. no primary tooth till 12 months of age, may be due to: (a) familial tendency, (b) nutritional deficiency, e.g. PEM or rickets, (c) local gingival disease, e.g. gum fibrosis, (d) inherited defects of dentin, e.g. osteogenesis imperfecta, and (e) endocrinal disorders, e.g. hypothyroidism or hypoparathyroidism.

Anodontia, i.e. absolute non-eruption of teeth, is seen in ectodermal dysplasia.

Discolored teeth usually indicate tetracycline therapy in early childhood (yellow staining), malnutrition, prolonged illness (discrete pit lines) or poor oral hygiene.

Premature exfoliation of tooth is common in dental caries, trauma and gingivitis. Rarely, recurrent tooth loss may also indicate histiocytosis or cyclic neutropenia.

2.3.3 SKELETAL MATURATION

Skeletal maturation begins *in utero* with formation of endochondral bones, followed by appearance of ossification centers and completion of ossification, which continue in postnatal life.

Normal maturation: It is important to note that:

- Earliest epiphyseal centers to appear are for *os calcis* and *talus*, at 22–26 weeks of intrauterine life.
- *At birth*, a term newborn has total *five* ossification centers for distal end of femur, proximal end of tibia, head of humerus, calcaneus and talus.
- Clavicle, mandible and membranous bones of skull are already ossified at birth.
- Skeletal maturation is faster in girls than in boys.
- Ossification centers appear earlier on left side of body.

Appearance, maturation and fusion of various epiphyseal centers for ossification is commonly used as the determinant of skeletal maturation or bone age.

Indications for bone age determination are – (a) evaluation of short stature; (b) prediction of adult height in cases with early/late onset of puberty, and (c) medico-legal purposes.

Assessment of bone age requires the knowledge of normal skeletal maturation, its variability and selection of proper X-ray (conventionally of left side) for assessment, as follows:

- *Bone age in newborn* is assessed by knee X-ray, to see the presence of epiphyseal centers for lower end of femur and upper end of tibia. Absence of these centers at birth usually indicates *prematurity* or *hypothyroidism.*
- *Bone age in infancy* is difficult to determine due to extreme variability in early skeletal maturation.
- Postnatally, first ossification centers appear for: (a) two carpal bones, i.e. capitate and hammate at ~6 months, and (b) upper end of humerus at ~ 5 months of age. X-ray of left wrist joint and shoulder is preferred to determine bone age in late infancy.
- *Bone age beyond infancy* may be assessed by number of carpal ossification centers in X-ray of left wrist, i.e. *Bone age = Number of centers – 1.* Thus, a six years old child has ~7 carpal centers, while the last or eight carpal center (for pisiform) appears only at 12–13 years.
- *Bone age in early adolescence* is determined by X-ray of left elbow to see the centers for distal end of ulna and lesser trochanter, which appear at ~ 12 years of age. Fusion of capitulum with the shaft at elbow predicts onset of puberty within one year.
- *Bone age in late adolescence* is assessed on X-ray of left hip to see the center for iliac crest, which appears at ~ 16 years.

Commonly, *Greulich-Pyle atlas* or *Tanner-Whitehouse-2 individual bone method* is used for assessment of bone age.

Common abnormalities in skeletal maturation include:

- ***Delayed bone age in:*** (a) prematurity (physiological), (b) nutritional deficiency, e.g. severe malnutrition, rickets, (c) endocrinal disorders, e.g. hypothyroidism, hypopituitarism, and (d) genetic disorders, e.g. Down syndrome, epiphyseal dysplasias, etc.
- ***Advanced bone age*** in endocrinal disorders, e.g. thyrotoxicosis, adrenal hyperplasia, precocious puberty, gigantism, pseudohypothyroidism. Bone age may be advanced *only in affected bones* in rheumatoid arthritis and arteriovenous malformations.

2.3.4 BODY COMPOSITION

Although of little importance in assessment of growth, it is noteworthy to remember following changes in body composition with age:

- *Decrease in total body wate*r from ~75% at birth to ~60% in adults, as well as its redistribution with gradual decrease in extracellular water and increase in intracellular water.
- *Increase in skeletal muscle mass*, from ~25% at birth to ~45% in adults.
- *Changes in adipose tissue mass*, which is higher in infancy and adolescence, i.e. ~25%, as compared to mid-childhood, i.e. ~20%.
- *Changes in chemical composition* of lean body mass, due to accumulation of various minerals.
- *Changes in visceral size*, which usually follow the changes in body size with some exceptions, e.g. postnatal regression of thymus.

2.4 GROWTH NORMS AND GROWTH CHARTS

Normal or reference values for common growth parameters in healthy children are obtained by longitudinal or cross-sectional surveys of the selected population with an appropriate sample size. However considering individual variations even in healthy population, data obtained during these surveys is further analyzed by various statistical methods to disregard normal variations, in terms of medians, percentiles and Z-scores.

Medians, Percentiles and Z-scores: When a parameter, e.g. weight of the large number of children is recorded in a given population with comparable age and sex, values are expected to differ from each other but all variations are not abnormal. When this data is arranged in an ascending or descending order, it is expected to form a bell-shaped curve (Gaussian distribution) with maximum values clustered around the center of this curve and fewer values at both ends.

Median value: *If the data, (e.g. weight/height) from a sample population of 100 children is arranged in ascending or descending order, the weight/height of the 50th child is likely to be essentially normal and reflects the median value.* On the other hand, children at the extremes of this arrangement are more likely to be abnormal.

Percentiles *mean the location of a child's value in above arrangement.* For example, the anthropometric value of 3rd, 25th, 50th, 75th or 97th child in this series is designated as 3rd, 25th, 75th and 97th percentile respectively. Values between 3rd and 97th percentile cover 95% of children and correspond with 2 standard deviations (SD) of mean value on Gaussian distribution—a universally acceptable limit for variations. For information, one SD covers 68% of values (16th-84th percentile) and three SD covers 97% of values in this data series (2nd-98th percentile).

In practice, 50th percentile is considered as ideal value, 3rd percentile as the lowest acceptable limit of normal value and 97th percentile as highest acceptable normal value. Thus, children with weight, height or other parameters below the 3rd percentile or above the 97th percentile are considered as potentially abnormal, while those within these limits are considered as potentially normal.

Z-score is another common term used to denote *deviation of observed value from the median value* and calculated as follows–

Observed value - Median value/standard deviation.

A Z-score of 2 means that the difference between observed value and expected reference value is 2 times of standard deviation in reference population, with prefix +/- sign (+1,+2,+3 Z-score or -1,-2,-3, Z-score) denoting the observed value being more or less than the reference values. A Z-score between +2 and -2 covers 95.4% of observations and is generally considered as limits of normalcy.

Growth norms and Growth charts: Results of these surveys, after statistical analysis, are depicted eiher in numerical tabular form *(Growth norms)* or visual graphic form *(Growth charts)*. Thus, growth norms or charts reflect normal anthropometric values in healthy children of different ages and gender, within the acceptable limits of individual variations.

Standard vs Reference norms: While the term *standard norms* and *reference norms* for growth are often used interchangeably, two terms have different connotations.

- *Reference norms for growth* are derived from the local population with similar environmental, socioeconomic and nutritional characteristics and represent that - *'how does the concerned population grow ?'.*
- *Standard norms for growth,* on the other hand, are derived from the much healthy population, relatively free from common constraints, e.g. malnutrition of infections. And denote that '*How should the child grow?',* If not constrained by other factors.

WHO vs IAP Growth norms: WHO, in 2006, published Standard growth norms for children below 5 years, derived from a multicenteric study of six countries in different regions of the world – Brazil, India, Ghana, Norway, Oman and United States. Study included populations with healthy practices, e.g. breastfeeding and no maternal smoking during pregnancy.

WHO standard growth norms are available for many anthropometric parameters including those for weight, length/height, weight for height, head circumference and body mass index in the tabular as well as graphic forms ***(Appendix 2.1–2.8)***. Government of India has adopted WHO growth standards for use in children <5 years. These standards are aspirational models, which define *how the under-five children of the world should grow*, rather than *how they actually grow ?*

For older children, WHO suggests use of country-specific growth standards, as growth in this age-group is often influenced by local environmental factors and timing of the puberty.

Indian Academy of Pediatrics (IAP) in 2015, published reference growth norms for Indian children between 5–18 years, for many anthropometric parameters, e.g. weight, height, and body mass index; in tabular as well as graphic forms ***(Appendix 2.9–2.12)***. Recently in 2021, IAP has also published WHO and IAP charts in combination for use in children from birth to 18 years.

Tables 2.6A and B provide abridged versions in tabular form of WHO norms for children < 5 years and IAP norms for those aged 5–18 years, for selected anthropometric parameters for quick reference.

TABLE 2.6A: WHO child growth standards for weight (kg), height (cm) and head circumference (cm)

Boys							Girls					
Weight		Height		Head		Age	Weight		Height		Head

Source: Modified from: Revised IAP growth charts for height, weight and body mass index for 5– to 18–year–old Indian children.

2.5 GROWTH ASSESSMENT AND MONITORING

Growth assessment and monitoring is the essential component of child health surveillance, even in the absence of apparent abnormality.

While *growth assessment* may be considered as one-point process, *growth monitoring* is more important and requires serial data, e.g. weight, to detect changes in growth parameters over a period of time. Growth monitoring helps in early identification of high-risk children for growth-faltering and institute early remedial measures.

Indian Academy of Pediatrics (IAP) recommends periodic growth assessment at – (a) birth, (b) during each immunization visits at 6, 10, 14 weeks and 6, 9 and 15 months, (c) every 6 months from 18 months to 8 years of age and then d) annually during 9–18 years. While weight and length/height must be recorded during all visits, head circumference should be recorded till 3 years, body mass index (BMI) from 6 year onwards and sexual maturity rating (SMR) from 9 year onwards.

Growth assessment is a four-step process including:

a. Recording of appropriate anthropometric growth parameter (*Observed value*).
b. Comparing this observed value with standard or reference growth norms for corresponding age and sex (*Expected value*).
c. Serial recording of assessed parameters (observed values) on growth charts to assess growth velocity.
d. Interpretation and conveying the information to parents as well as suitable remedial action (*growth monitoring and promotion*).

Step I. Selecting and recording appropriate growth parameter, depends on the purpose of assessment. In regular practice, three growth parameters are commonly recorded in children – *weight*, *length/height* and *head circumference*.

Weight is the best indicator of acute growth insult, though rapid fluctuations during health and disease render it unsuitable for long-term growth assessment. It should be measured on a *digital balance* or *beam balance* with minimum accuracy of 20 gm in infants and 100 gm in older children **(Figs. 2.2, 2.3)**. Spring balances, e.g. bathroom scale or salter-spring balance tend to provide false values due to loss of spring elasticity after repeated use and should be avoided.

Length/height is a better indicator of long-term growth, affected only after prolonged illnesses and remains abnormal for a long time after recovery. It should be recorded in recumbent position (length) in infants <2 years using an *Infantometer* **(Fig. 2.4)** and in standing position in older children, using a *Stadiometer* **(Fig. 2.5)**.

Fig. 2.2: Weighing an infant.

- Place the beam/digital balance on a firm and stable surface to avoid toppling while weighing.
- Check the zero error and correct, if necessary, using the calibrating screw.
- Remove clothing, including diapers, of the infant and place him/her in the center of pan.
- Allow the time to stabilize him/her on the pan, to avoid errors due to swaying.
- Read the scale with eyes perpendicular to the display/dial to avoid errors.

Fig. 2.3: Weighing an older child.

- Place the weighing scale on a firm, even and stable surface.
- Check the zero error and correct, if necessary, using the calibrating screw.
- Ask the child to remove heavy cloths/footwear and stand on the platform.
- Read the weight with eyes perpendicular to the display/scale to avoid errors.

Head circumference is an indicator of brain growth and must be recorded till 5 years of age, using a non-stretchable plastic tape with an accuracy of 0.1 cm **(Fig. 2.6)**.

Mid upper-arm circumference (MUAC) is a useful anthropometric parameter for assessment of nutritional status, which should be recorded using a non-stretchable plastic tape with an accuracy of 0.1 cm **(Fig. 2.7)**.

Fig. 2.4: Measuring length (below 2 years) on infantometer.

- Place the infantometer on a firm and stable surface to avoid toppling.
- Place the infant on the platform in supine position, after comforting him/her.
- Position the head gently straight with crown firmly touching the headboard, and an imaginary line from external auditory meatus to lower orbit being perpendicular to the platform.
- Ensure that shoulders, spine and hips are touching the platform with fully extended legs.
- Slide the soleboard to bring in contact with soles at right angle and toes pointing upward.
- Read the length up to 0.1 cm with eyes perpendicular to scale to avoid errors.

Fig. 2.5: Measuring height (above 2 years) on stadiometer.

- Ensure that stadiometer is placed on a firm, even and stable surface.
- Ask to child to remove shoes/hair-braid etc and stand erect on the platform.
- Ask him/her to look straight with head in Frankfurt plane and external auditory meatus with lower border of orbit in a straight horizontal line.
- Ensure that heels, buttocks, shoulder and back of the head are in same line, touching the scale.
- Slide down the headboard/stick down to bring it in firm contact of the crown.
- Read the length up to 0.1 cm with eyes perpendicular to the scale to avoid errors.

Fig. 2.6: Measuring head circumference.

- Ensure that baby is comfortable in mother's lap or sitting/standing quietly.
- Encircle the measuring tape around forehead to simultaneously touch the nasion anteriorly and inion posteriorly.
- Pull the tap gently to overlap both ends in parietal region and read the measurement at cross-over point (Cross-over technique).

Fig. 2.7: Measuring mid-upper arm circumference.

- Palpate and mark two landmarks on the right arm—Tip of acromion process of scapula and olecranon process of ulna.
- Mark the mid-point of arm between these two landmarks, using a measuring tape/scale.
- Encircle the measuring tape perpendicular to the long axis of arm at this mid-point, gently compressing the muscles.
- Pull the tape gently to overlap both ends and read the measurement at cross-over point (Cross-over technique).

Other anthropometric parameters may be recorded in selected cases to assess nutritional status (skin fold thickness), or investigate cause of short stature (body proportions, bone age), etc.

Step II. Comparing these observed values with standard or reference norms: Observed anthropometric value of the child under assessment are then compared with corresponding expected values in normal children of the same age/gender, using WHO standard norms for those < 5 years of age and IAP reference norms for those 5–18 years, discussed in chapter 2.4.

While this comparison may be done directly using growth tables, it is always preferable to plot individual observed values on appropriate growth charts not only for quick comparison but also to monitor the growth velocity over time by drawing the child's personal growth curve.

To plot the actual measurements on growth chart, following steps are required:

- Select the age and gender appropriate WHO/IAP chart from the parameter under assessment, e.g. weight.
- Plot the observed value of child on this chart as a dot, aligning with X and Y axis.
- Compare the location of this dot (observed value) with the expected value on standard/reference percentile or Z-score curves above and below the value and read as, e.g. *between 25th and 50th percentile or 1 and 2 Z-scores*.
- An observed value between 3rd and 97th percentile of the reference curve, roughly corresponding with (± 2 Z or SD scores) is considered as normal, while values beyond this range are most likely abnormal. Values below –3 Z or SD score indicate more severe abnormality **(Fig. 2.8A to C)**. However, for head circumference, a value <-3Z or SD score is considered as abnormal, i.e. microcephaly **(Fig. 2.8D)**.

Several mobile applications are also available at present to directly compare the observed anthropometric values in a child and plot his/her growth curve, with WHO/IAP reference norms.

Step III. Serial record of assessed parameters on growth chart aims to evaluate the trend of growth over a period of time and identify a deviation from normal growth as early as possible, even in children with previous borderline values. This objective is achieved by plotting the serial anthropometric values on a *growth chart* and joining all the dots to develop a child-specific growth curve.

Location and shape of this *child's growth curve* as compared to *reference curves* provides important information about the trend of growth in child under assessment. Any child's growth curve, which runs flatly below the lowest reference curve or plateaus/dips after initially being above the reference curve is a cause of concern.

Growth velocity is defined as *"rate of growth or change in a growth parameter over unit period of time."* For example, since length at birth is 50 cm and at one year is 75 cm, growth velocity in first year is 25 cm/yr. Growth velocity is not uniform throughout the childhood and a baby has different growth velocity at different ages and for different parameters.

Growth velocity is calculated by serial recording of selected parameter at different time intervals, i.e. monthly or yearly and then dividing the change in parameter by the time, interval. Reference values for different growth velocities at various age intervals are also available, termed as *reference velocity norms* in tabular form and *reference velocity curves* in graphic form.

Step IV. Interpretation of growth records, conveying the information to parents and taking suitable remedial actions: The main objective of growth assessment is not only to detect the growth abnormality, but also to make the mother (and family) realize its significance and take timely action. This process of continuous check and timely action is strategically described as *growth monitoring and promotion*, discussed later.

Growth monitoring and promotion (GMP): Growth monitoring aims not only to track the growth of a child over time but also to enable mother/caregiver to visualize growth or lack of growth in their children and to provide specific, relevant and practical guidance for remedial measures, also termed as growth monitoring and promotion).

While WHO/IAP growth charts may be used for growth monitoring in facility setting, many simplified growth charts are also available for field use, including the widely popular one "Road-to-health card". However, recently, *Mother-to child protection card* has replaced most of them, being used routinely in all national health programs.

Mother to Child Protection Card

Since the adoption of WHO growth standards in 2009, a new *mother and child protection card* has been developed under National Health Mission, which also includes two gender-specific growth charts for boys and girls below 3 years of age **(Fig. 2.9A and B)**.

These charts have three differently colored zones based on weight-for-age as per WHO standard norms – top green zone between 50th percentile and – 2 SD values (***normal***), second yellow zone between –2 SD and –3 SD values (***underweight***) and bottom red zone for values <– 3 SD (***severe underweight***).

In addition, these cards also serve as immunization card, development charts (Ch 2.7) and provide parenting tips, e.g. breastfeeding, weaning, etc.

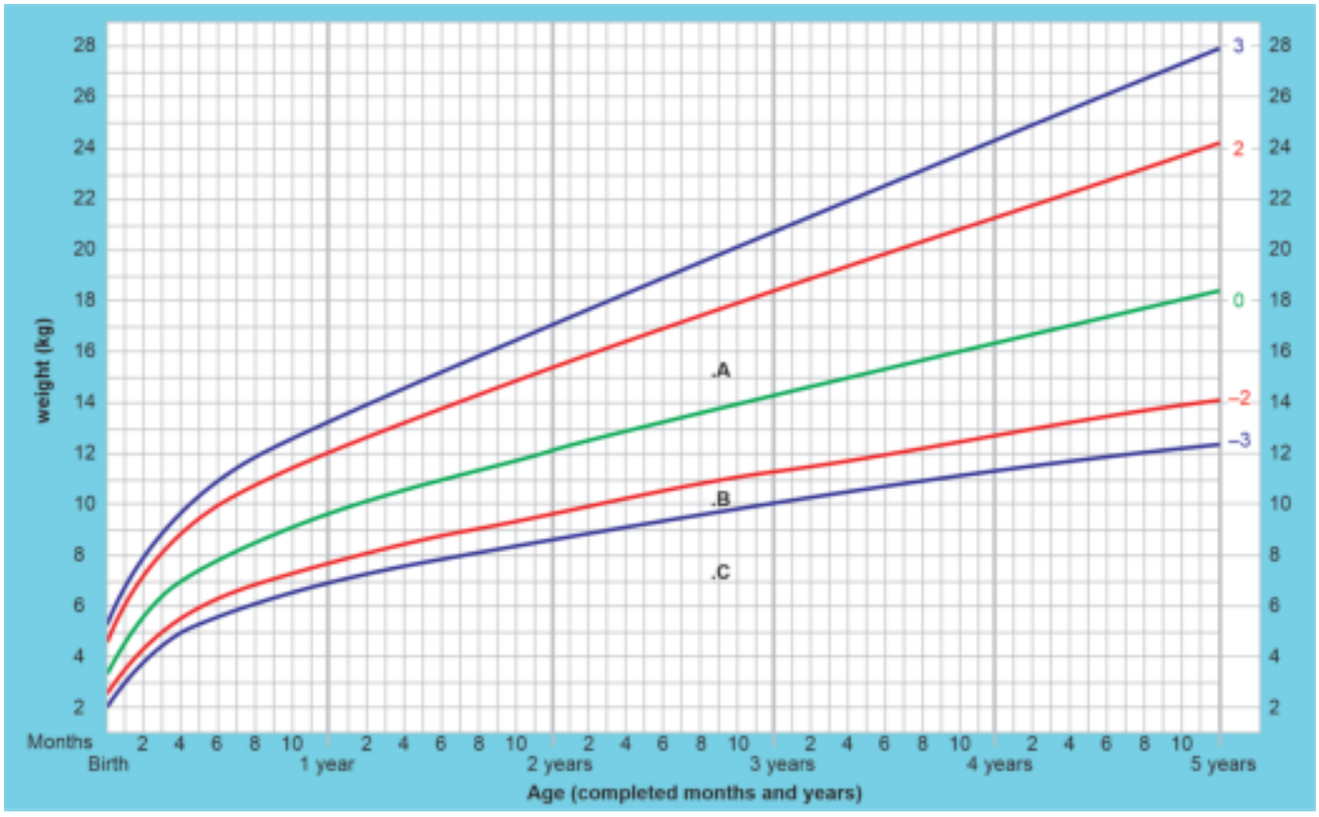

Fig. 2.8A: **Interpretation for weight for age (WFA). A:** Normal, **B:** Undernutrition, **S:** Severe undernutrition

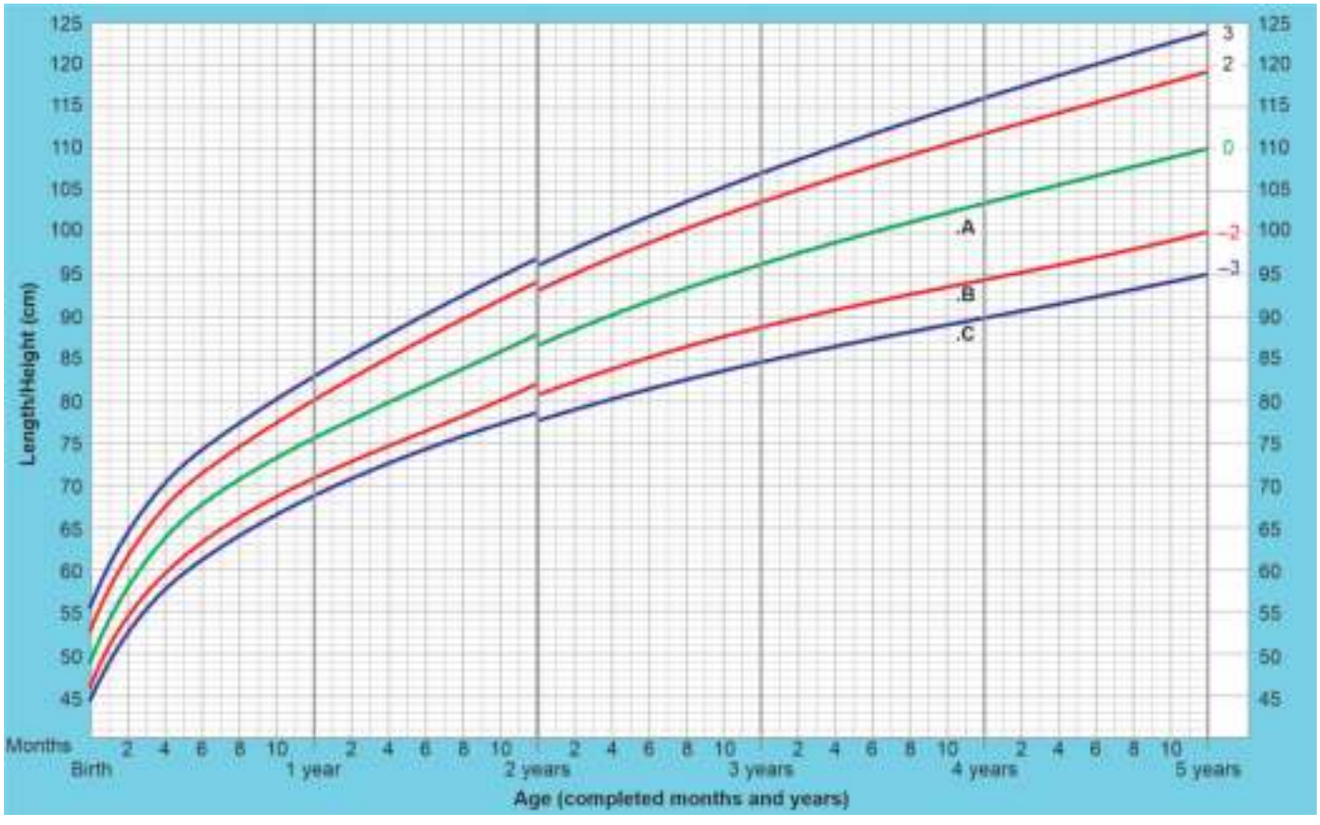

Fig. 2.8B: **Interpretation for length/height for age (L/HFA). A:** Normal, **B:** stunted, **C:** Severely stunted

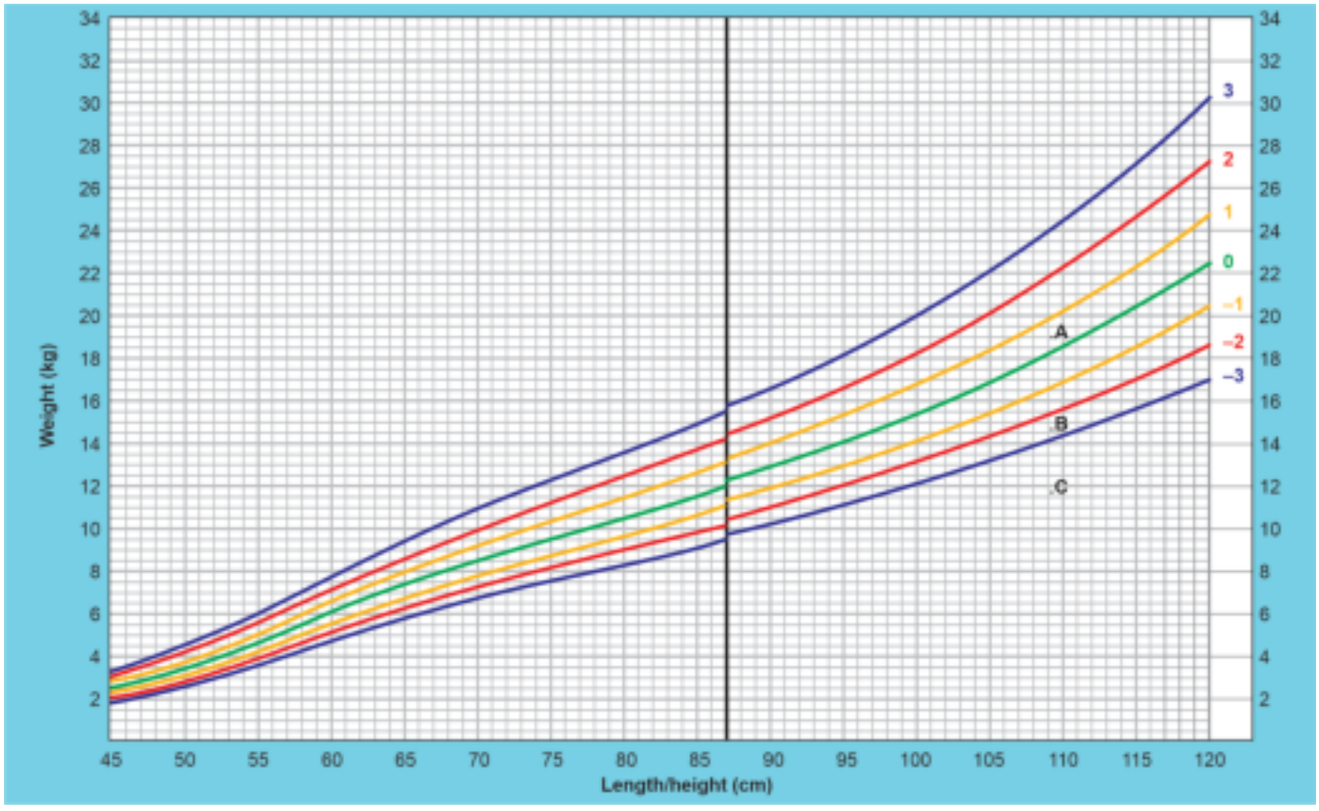

Fig. 2.8C: Interpretation for weight for length/height (WFL/H). A: Normal, **B:** Wasted, **S:** Severely wasted

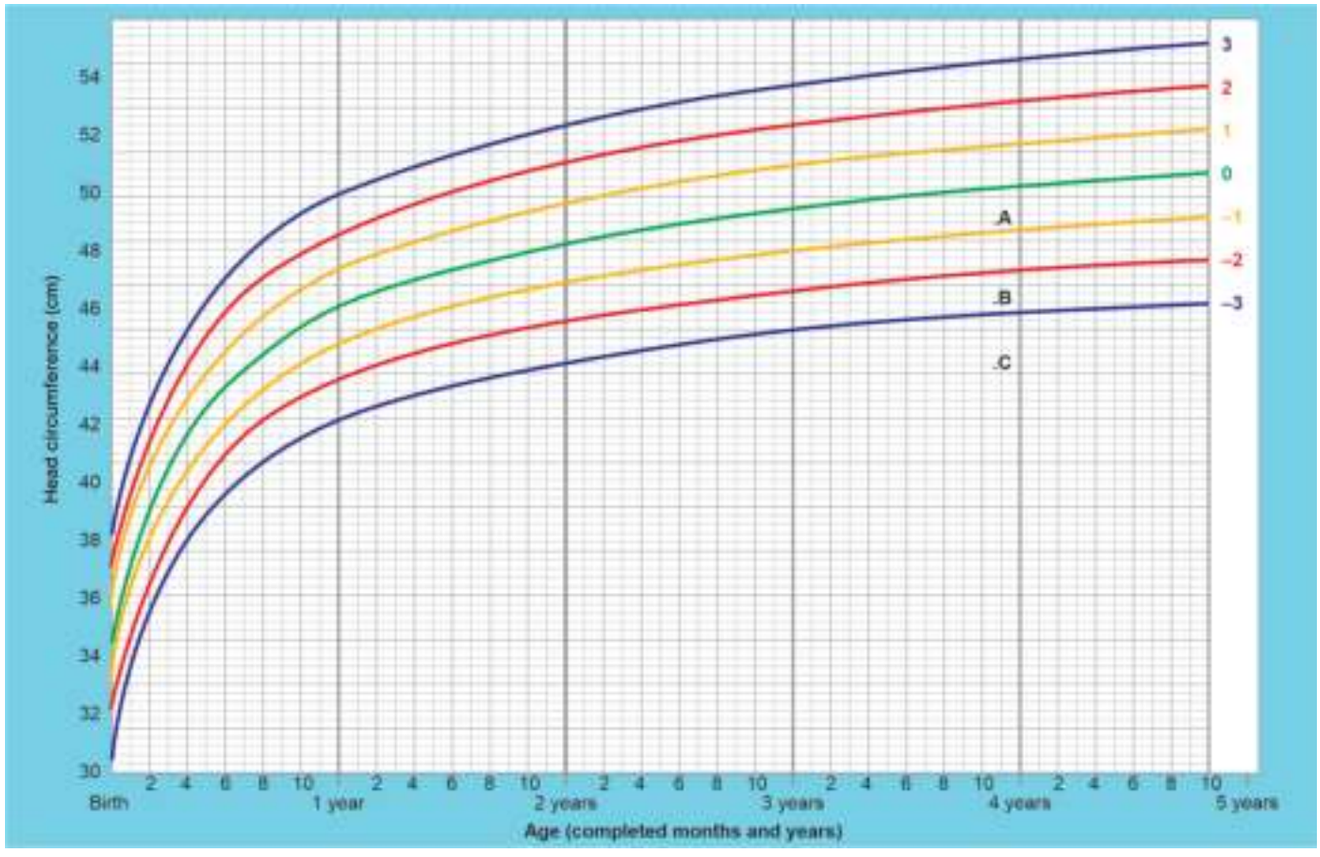

Fig. 2.8D: Interpretation for head circumference. A: Normal, **B:** Borderline, **C:** Microcephaly

2.6 NORMAL CHILDHOOD DEVELOPMENT

Development denotes *physiological or functional maturation of various organs or systems, acquisition of newer functions or skills and adaptation to the environment.* While it is multi-dimensional process, the term development is popularly used in connection to neurological and psychosocial maturation.

Factors, which affect growth, also affect development (Ch 2.1). However, two most important factors for appropriate development are – (a) normal brain growth and (b) adequate emotional stimulation.

Most critical period for brain growth extends from mid-gestation till 2 years of age, characterized by explosive growth in neuronal cells, neuroglial proliferation and progressive myelination. Nearly 90% of brain growth is complete by two years of age. Any neurological insult during early childhood, e.g. hypoxia, infections or trauma, often leaves severe and irreversible neurological sequelae.

Emotional stimulation is another major determinant of development in early childhood, dependent on many factors, e.g. parenting practices, exposure to abuse and violence, institutionalization, etc.

Early Childhood Development (ECD)

The term *early childhood development* refers to physical, cognitive, social-emotional and linguistic development during early childhood, specially in *first three years of life*, which determines the learning outcomes in later life.

Nurturing care for ECD refers to the five components of care during first three years of life to achieve optimal development, including: *(1) good health, (2) appropriate nutrition, (3) safety and security, (4) responsive parenting, and (5) early learning opportunities*.

2.6.1 GENERAL LAWS (PRINCIPLES) OF DEVELOPMENT

Like growth, development also follows the laws discussed earlier in Chapter 2.2, as follows:

- **Development is a continuous and qualitative process,** starting from conception and continuing till maturity or even beyond. However unlike growth, precise measurement of development is difficult as a baby may be able to perform the same milestone, e.g. sitting, with variable degrees of maturity at different ages. Developmental assessment consist not so much of observing *what* a child does, but *how* he does it.
- **Development progresses in cephalocaudal direction,** head control is achieved earlier than sitting and further followed by standing. Fine motor functions generally mature from proximal to distal manner, e.g. voluntary lifting of hands to reach-out for an object appears before development of fine finger movements to grasp it, e.g. pincer-grasp.
- **Individual pace of development is variable and unique for every child.** Some children are *rapid-developers*, while others are *slow-developers*. Hence, it is important to exercise caution, before declaring a child as developmentally delayed.

Further, pace of development may also differ in different domains, e.g. gross-motor, fine-motor, psychosocial and language. Some children develop slowly in certain fields and faster in others. However, significant differences in development among different domains are abnormal and are termed as *developmental dissociation*. Generally, girls have a faster speech development, while boys develop faster in motor fields.

- **General sequence of achieving developmental milestones is fairly consistent**, despite individual variations in the pace of development. It is extremely unlikely to achieve a later milestone, e.g. sitting, until the earlier milestone, e.g. neck holding, has been achieved.
- **Disappearance of primitive reflexes is also a part of development:** Certain primitive neonatal reflexes, e.g. grasp or stepping reflex, must disappear before the corresponding voluntary function, e.g. voluntary grasp or standing is achieved. Persistence of a neonatal reflex beyond the expected age of its disappearance, by itself indicates developmental problem, as seen in cerebral palsy.
- **Generalized mass activity is gradually replaced by more specific and purposive response,** e.g. while an infant of 3–4 months squeals and excitedly moves all the limbs when offered a toy, an older child may simply smile and reach-out to it with one hand.

2.6.2 DEVELOPMENTAL MILESTONES

Neurological development is assessed in terms of the *milestones*, i.e. *easily identifiable events representing maturation of certain physical functions*, e.g. sitting or smiling, which are expected to be achieved by a normal child within certain age limits. Milestones may be broadly divided into five major domains:

1. *Gross motor* milestones, e.g. sitting, standing, etc.
2. *Fine motor* milestones, e.g. handling of objects, feeding himself, etc.
3. Personal-social milestones, e.g. interacting with others, expression of emotions, etc.
4. Adaptive (Cognitive) milestones, e.g. ability to explore environment and learn from experiences.
5. *Linguistic* milestones, e.g. development of speech.

A. Gross motor milestones reflect maturation of locomotor functions and require normal neurological development as well as adequate muscle mass and tone. These functions may be delayed in grossly malnourished children, despite adequate neurological functions.

While lifting the chin momentarily from bed in prone position is the earliest recognizable gross motor milestone (4 weeks), persistent neck (head) holding is not achieved before 3 months and may be considered as the first key gross motor milestone for practical purpose.

TABLE 2.7: Key gross motor milestones

Age	*Gross motor milestone*
1 mo	Lifts chin momentarily in prone position
3 mo	Neck-holding
4 mo	Roll-over from supine to prone position
5 mo	Roll-over from prone to supine position
6 mo	Sits with support (Tripod position)
8 mo	Sits without support
9 mo	Crawls, pulls to stand
10 mo	Stands with support, creeps
12 mo	Walks without support
15 mo	Walks, creeps upstairs
18 mo	Runs, walks backward
24 mo	Walks up and down-stairs (two-feets/step)
36 mo	Rides tricycle, climb stairs one-foot/step
48 mo	Hops on one foot, goes down-stairs one-foot/step
60 mo	Skips with both feet

Table 2.7 enlists key gross-motor milestones till 5 years of age.

B. Fine motor milestones reflect development of certain fine skills, required for day-to-day functions like play, eat, draw, etc. These milestones are more reliable indicators of neurological maturity, as such skills are governed by large cerebral area and usually not affected in nutritional disorders. Isolated delay in maturation of these milestones indicates cerebral palsy or peripheral nerve injury, e.g. Erb's paralysis.

Important components of fine motor development in order of maturity include – (i) hand-eye coordination, e.g. reaching out for objects, (ii) hand coordination, e.g. grasping an object voluntarily, (iii) hand-hand coordination, e.g. transfer of objects, and (iv) hand-mouth coordination, e.g. feeding himself/herself.

Holding an object when offered in hand (voluntary grasp) at 4 months of age may be considered as the earliest and easily identifiable fine motor milestone, which is possible to achieve only after disappearance of neonatal grasp reflex. **Table 2.8** enlists key fine-motor milestones till 5 years of age.

C. Adaptive milestones, also termed as *cognitive milestones*, denote the development of the ability to explore environment and learn from new experiences. Achievement of adaptive milestones needs normal cognitive functions as well as normal special senses, e.g. vision and hearing.

Visual fixation to a moving object (4–6 weeks) may be considered as the earliest adaptive milestone, checked by observing infant's eye movements in response to a bright moving object, e.g. a red-ring tied to a string. Other adaptive milestones include visual exploration (hand-regard) or oral exploration of body parts (mouthing) and learning from experiences, e.g. searching for a hidden toy

TABLE 2.8: Key fine motor milestones

Age	*Fine motor milestone*
4 mo	Voluntary grasp (hold objects when given),
5 mo	Bidextrous reach for an object (both hands)
6 mo	Unidextrous reach, transfer of objects between hands
9 mo	Immature pincer-grasp (probes with forefinger)
10 mo	Mature pincer-grasp, release of object on request
12 mo	builds tower of 2 cubes
18 mo	Scribbles, tower of 3–4 cubes
24 mo	Tower of 6 cubes, imitates vertical and horizontal lines
30 mo	Tower of 8 cubes
36 mo	Tower of 8–10 blocks, copies 'circle'
48 mo	Builds bridge, copies 'cross'
60 mo	Copies 'Triangle'

TABLE 2.9: Key adaptive (cognitive) milestones

Age	*Adaptive (Cognitive) milestones*
4 wks	Fixes vision on moving object up to 45°
2 mo	Follows a moving person
4 mo	Hand-regard, excited to see a toy/food
5 mo	Mouthing, hand-regard disappears
6 mo	Searches for a dropped toy
8 mo	Finds partially-hidden objects
12 mo	Mouthing stops, looks at pictures
15 mo	Turns 2–3 pages at a time
18 mo	Turns single page at a time
24 mo	Points to 4–6 body parts, matches shapes
36 mo	Knows name and gender
48 mo	Right-left discrimination
60 mo	Counts till 10, identifies coins

or matching the shapes. **Table 2.9** enlists key adaptive milestones till 5 years of age.

Many adaptive milestones tend to disappear after the learning process is complete. *Hand-regard*, i.e. exploration of own hand appears at 3–4 months and disappears by 6 months **(Fig. 2.10)**. Similarly, mouthing appears at 5–6 months and disappears by the end of infancy. Persistence of hand-regard beyond 6 months or mouthing beyond 12 months suggests delayed neurological development.

D. Psychosocial milestones, i.e. development of interpersonal relationship and social skills, depend on higher cerebral functions as well as external inputs, e.g. normal vision and social stimulation. Social smile (~6 weeks) may be considered as the earliest psychosocial milestone. **Table 2.10** enlists key psychosocial milestones till 5 years of age.

Isolated delay in these milestones indicates intellectual disability, autism, visual impairment and emotionally deprived child, e.g. orphans.

Fig. 2.10: Hand regard.

TABLE 2.10: Key personal-social milestones

Age	*Personal-social milestones*
6 wks	Social smile
3 mo	Recognizes mother
4 mo	Smiles at mirror image
6 mo	Stranger's anxiety, enjoys 'peek-a-boo'
9 mo	Waves 'bye-bye'
12 mo	Responds to name, plays simple ball game, parallel play
15 mo	Jargon, points to desired object
18 mo	Domestic mimicry (copies parents, e.g. sweeping)
24 mo	Dry by day, asks for food, show toys to others
30 mo	Washes hands, brushes teeth
36 mo	Dry by night, share toys
48 mo	Goes to toilet alone, group-play
60 mo	Dresses/undresses independently

TABLE 2.11: Key Linguistic milestones

Age	*Linguistic milestones*
6 wks	Turns head towards sound
3 mo	Makes cooing sounds
4 mo	Laughs aloud
6 mo	Says monosyllables (ma, da)
9 mo	Says bi-syllables (mama, dada)
12 mo	Speaks with vocabulary of two meaningful words
18 mo	has vocabulary of 8–10 words
24 mo	Speaks 2–3 word sentences, uses pronouns (I,You)
36 mo	Asks questions, tells name and gender
48 mo	Sing songs, tells stories
60 mo	Speaks grammatically correct sentences

E. Linguistic milestones require normal hearing, normal central functions as well as healthy organs of phonation. Hearing impairment is the most common cause of delayed language development. Startle response to a sudden sound in newborns suggests hearing ability. Appearance of monosyllables (6 months) may be considered as earliest proper linguistic milestone, though a younger infant is also able to make non-specific vocalizations, e.g. cooing sounds or laughs aloud. **Table 2.11** enlists key linguistic milestones till 5 years of age. Some other important aspects of language development are also discussed in Chapter 3.8.

It is re-emphasized that pin-pointing the precise age of appearance for a particular milestone is neither possible nor desirable, due to continuous maturation of these functions.

2.7 DEVELOPMENTAL ASSESSMENT

Developmental assessment is an integral part of every child's health check-up, even if apparently normal. However, it is not necessary to perform exhaustive developmental assessment in every child and the depth of assessment must vary, according to perceived risk of abnormality.

In practice, developmental assessment must be conducted in a step-wise manner, as follows:

a. Informal *developmental surveillance* of all children during health care visits;
b. *Development screening* of all children at scheduled intervals;
c. *Formal developmental assessment* in children with abnormal screening results.

This chapter deals with *informal developmental surveillance* of all under-five children during regular well-baby clinic/immunization/health-care visits, as well as *development screening* of all children at scheduled age-intervals, in order to identify children who need in-depth formal assessment, discussed in Ch 3.5.

Development surveillance is a continuous and informal process, not to draw a line between normal and abnormal, but merely to identify high-risk children, who need referral for early developmental screening and/or follow-up. Three important components of informal development surveillance include:

- *Ask the* parents about age of achieving milestones (developmental history);
- *Observe the* baby's performance and behavior in the clinic (developmental observation);
- *Elicit* common age-appropriate milestones (developmental examination).

Developmental history must be obtained by a reliable caretaker, preferably mother, to find out the age of achieving common milestones in different domains, with following principles:

- Record achievement of various milestones in all domains with the age of attainment.
- Compare actual age of attainment with expected age of attainment **(Table 2.8 to 2.12)** with due consideration for normal variations. In preterm, corrected age should be used to assess adequacy of milestones till the end of infancy.
- Denote the results as developmental age in different fields separately, rather than averaging out to calculate developmental quotient on this informal assessment.
- Record all milestones sequentially, starting from neonatal period irrespective of the age, in cases with suspected neurodevelopmental problems to get an idea about the age from which milestones began to falter.

However in apparently normal children, it is time-saving to begin with last few milestones that the child should have achieved at present chronological age in each domain and go backwards *only* if the last expected milestone/s have not been achieved.

- In cases with abnormal development, find out if a milestones was never achieved (Delay) or has been lost after the initial achievement (Regression). Regression of milestones is an important clue to neurodegenerative disorders.

Mother and child protection (MCP) card, used by ASHA/Anganwadi workers throughout India, includes a simple tool for monitoring of the child's development. On this card, ASHA/AWW/other field health workers have to simply mark a tick or cross against the pictorially depicted milestones at different ages (2–3, 4–6, 7–9, 10–12, 18, 24, and 36 months). This chart also provides parenting tips to stimulate development as well as red-flag signs **(Table 2.12)** to identify children for referral for formal developmental assessment.

Developmental observation involves observing the child's behavior and interaction with others while waiting in the clinic or approached by mother/doctor. Some important milestones which can be assessed by simple observations are as follows:

- *Observe an infant from a distance in the waiting room* for behavior for *personal-social milestones*, e.g. social smile (6 weeks), eye-contact (3 months) enjoys mirror image (4 months) hand-regard, (4–6 months) mouthing (5–12 months), searching for a dropped rattle/toy (6 months), attempting to find a partly-hidden toy (8 months) and waving *bye-bye* (9 months).
- *Observe an older child while playing for interaction with others*, e.g. enjoying peek-a boo (6 months), plays/throws ball (12 months), parallel play despite presence of other children (12 months), pointing to a desired toy or object (15 months), mimicry (18 months) showing toys to others (24 months) and sharing toys with others (36 months).
- *Observe for gross-motor milestones*, e.g. sitting with/without support, standing with/without support. Crawling/creeping, walking, going up/down stairs, etc.
- *Observe when approached by mother/others, e.g.* excitement with limb movement when approached by mother, i.e. recognition of mother (3 months) or crying when approached by the examiner, i.e. stranger anxiety (6 months), etc.
- *Listen him/her for linguistic milestones* cooing sounds (3 months), laugh aloud (4 months), monosyllables (6 months), bisyllables (9 months) jargon (15 months), two meaningful words (12 months), 8–10 meaningful

TABLE 2.12: Red-flag signs for development delay on informal developmental surveillance*

At 3 months	***At 6 months***
No social smile	No head control
No Startle response to sounds	Cannot sit up with support
No eye to eye contact when fed/ cuddled	Does not grasp things within reach
Persistent squinting >2 months	Does not track a moving object with head/eyes
Persistent limb stiffness/arching of head	Does not vocalize, e.g. *'ah, ..eh, ..oo..'*
Cortical thumb	Unable to raise head in prone position
At 9 months	***At 12 months***
No roll-over	No pincer-grasp
Cannot sit without support	Does not stretch hands to be picked up
Does not turn towards the sound (Out of sight)	Does not respond to own name
Does not utter monosyllables, e.g. *'ma.. pa.. ba'.*	Does not search for half-hidden toys
Tilts head always to one side, whenlooking at objects	Does not play social games, e.g. Peek-a-boo
At 18 months	***At 24 months***
Cannot stand without support	Does not walk steadily while pulling a toy
No response to gestures, lives in *own world*	Does not respond to gestures. e.g. *bye-bye*
Cannot put small objects in a container	Cannot scribble
Does not use both hands for everyday activity	Does not point to body parts
Does not point finger to a named object,	Does not use two word phrases – *'give milk'*
Does not say single words, e.g. *'mama, papa'*	Does not understand/ follow simple instructions
At 36 months	
Has troubles climbing up/down stairs	
Cannot play "pretend" games	
Cannot eat without help	
Continuous drooling/ unclear speech	
Does not communicate meaningfully, repeats others' speech	
Does not speak simple 3-word sentences, e.g. *'mummy give milk'*	

*Based on Mother and Child protection card (MCP)

words (18 months), 2–3 word sentences (24 months) and complete sentences (60 months).

Developmental examination of a young child is tricky and must be performed before the systemic examination, when child is playful and not apprehensive. Information already obtained by developmental history (if reliable) and simple observation needs not be elicited. No rigid pattern should be followed for developmental examination, which may begin informal assessment of vision and hearing, eliciting fine motor and adaptive/cognitive milestones and lastly, gross-motor milestones, which might disturb the child. A short list of items required for developmental assessment is given in **Table 2.13**.

TABLE 2.13: Development assessment kit

- Red ring on a string (6–7 cm diameter)
- Small bell
- Paper pellets
- Nine red cubes ~1'' each
- Paper and crayon
- Picture-book with thick pages
- Doll and mirror
- Plastic cup with spoon (Small)
- Shape-board with common shapes

A tentative protocol of developmental examination of a child is as follows:

- *Elicit or check vision* by dangling a red-ring attached to a string in the visual field (follows till 45° at 4 weeks and 180° at 8 weeks), and following the mother's movement (2 months)
- *Elicit or check hearing* using a small bell for turning the head towards sound (6 weeks) or response to the name-call (12 months).

Fig. 2.11: **Pincer grasp.**

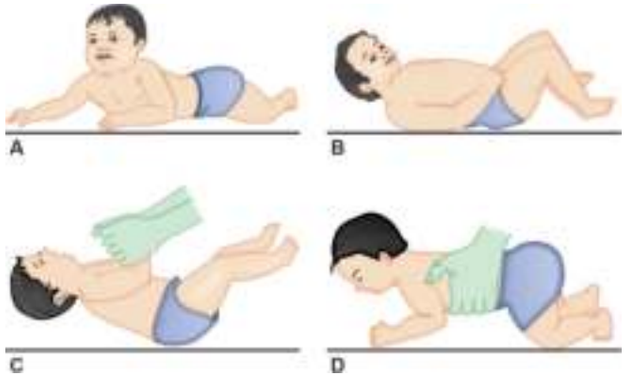

Fig. 2.12: **Head holding in different positions. (A) Prone position; (B) Supine position; (C) Pull to sit position; (D) Ventral suspension.**

- *Elicit fine motor milestones* in an infant by:
  - Offer a red ring to observe for voluntary grasp (4 months), bidextrous approach with both hands (5 months) unidextrous approach with one hand (6 months), transfer of object (6 months) and release of object on request (10 months).
  - Offer a paper pellet to observe for the maturity of pincer grasp (9–10 months) **(Fig. 2.11)**.
- *Elicit fine motor milestones in an older child* by:
  - Offer a cube to see stacking, e.g. tower of 2 cubes (12 months), 3 cubes (18 months), 6 cubes (24 months) 8 cubes (30 months), 9–10 cubes (36 months) and making a bridge (48 months).
  - Offer a paper and crayon to see for scribbling (18 months) and imitating vertical/horizontal lines (24 months), circle (36 months), cross (48 months) and triangle (60 months).
  - Offer a bright picture-book with thick pages to see whether he looks at pictures (12 months), turns 2–3 pages at a time (15 months) or turns single page at a time (18 months)
  - Check/ask mother for the ability to feed with a spoon (15 months) or cup (18 months), pulling out of shoes (18 months), attempts to undress (24 months), brush (30 months) and helps to dress (36 months).
- *Elicit adaptive/cognitive milestones* by:
  - Ask him/her to point body parts (18–24 months), name and gender (36 months), right/left side discrimination (48 months), to sing a nursery rhyme (48 months) or tell a story (48 months) and count up to 10 coins (60 months).
  - Offer a doll and ask to point 4–6 parts of the doll (24 months).
- *Elicit gross-motor milestones by history as well as:*
  - Assess the neck-control in infants <3 months in different positions, e.g. supine, prone, pull-to-sit and ventral suspension **(Fig. 2.12)**.
  - Ask the history or elicit other gross-motor milestones, e.g. roll-over, sitting with/without support, standing, crawling, pulled to sit walking, go up/down stairs, etc.

In addition, thorough physical examination should follow the developmental assessment to search for neuromuscular abnormalities, e.g. abnormal posture, tone or power, etc. and vision/hearing impairment, which might hinder to achieve full potential of development.

Developmental screening: Developmental screening denotes administration of standard, validated and locally appropriate screening tests to identify high-risk children who needs detailed developmental assessment.

IAP recommends that:

a. *All children should be screened using standardized tools at the age of 9–12 months, 18–24 months and at school entry, with timing coinciding with immunization visits, and*
b. *High-risk children should also be additionally screened at 4–6 months.*

Many developmental screening tests are available for screening purpose, including widely used Denver developmental screening test (DDST), or locally developed *Phatak's Baroda development screening test* or *Trivandrum development screening test. Please note that these tests are screening tests and should not be used to assign development quotient/intelligence quotient (DQ/IQ).*

- *Denver development screening test* (DDST) and its modification (DDST II) are widely used to assess development till 6 years of age in four domains—gross motor, fine motor or adaptive, language and personal-social behavior. DDST II contains 125 items of simple nature and a child's development is considered as delayed if he/she cannot perform an item, which can be done by 90% of children with comparable age.
- *Baroda development screening test*, developed in 1991, by Phatak *et al* at child development unit of Baroda University, is an Indian adaptation of *Bayley's scale of infant development (BSID)* to screen children up to 30 months of age. Test assesses child's performance on different milestones (53 items) and is available as

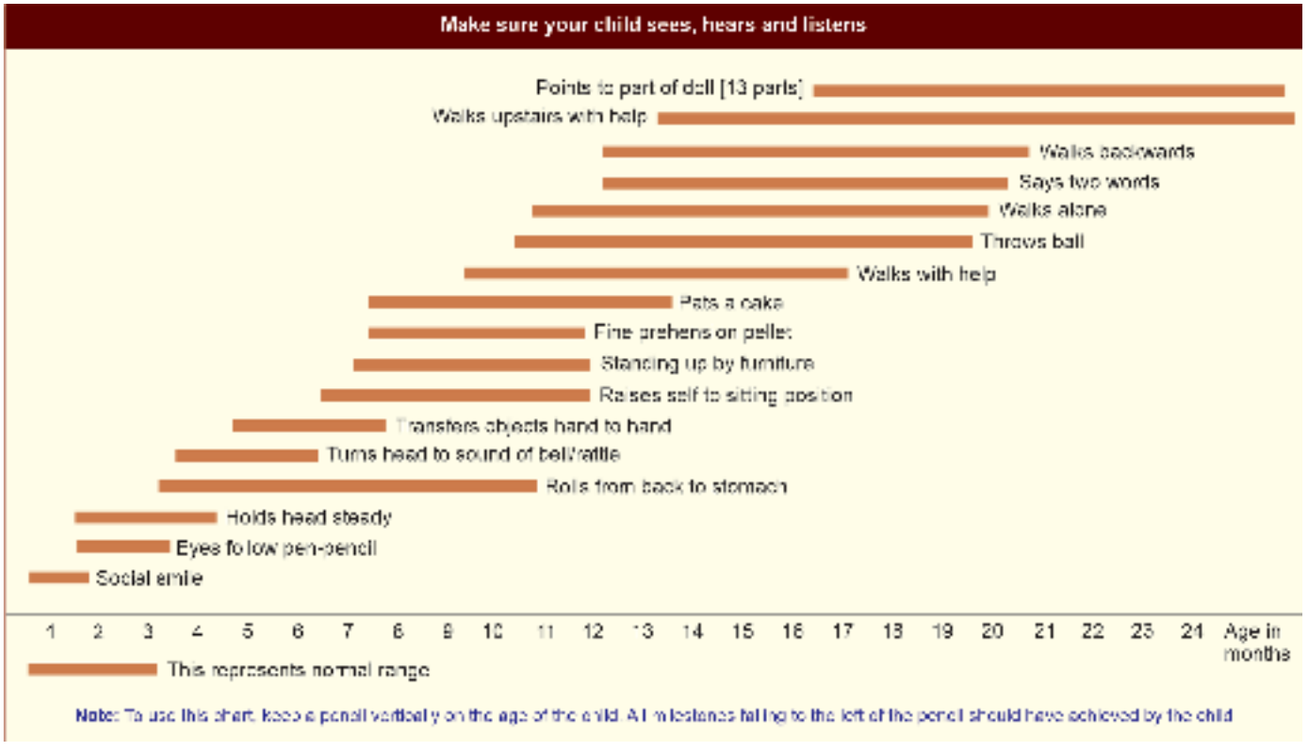

Fig. 2.13: **Trivandrum development chart.**

commercial kit including several objects and tools for the assessment.

- *Trivandrum development screening test*, a simple and most popular development screening test in India, based on Baroda norms, using 17 test milestones **(Fig. 2.13)**. This test provides the upper (97th percentile) age-limits for development of test milestones, beyond which a baby may be considered as developmentally retarded. It is designed for easy to use by community level health worker for mass screening and takes around 5 minutes to complete.

Other commonly used development screening tests include *Age and stage questionnaire* (ASQ-3)- a parent-completed questionnaire, *Rashtriya Bal swasthya Karyakram (RBSK) screening* tool, and Goodenough-Harris *Draw-a-man* test, etc.

CHAPTER 3

Growth and Development Disorders

Samir H Dalwai, Surbhi Rathi, Mukesh Agrawal

Growth and developmental problems in children are common causes of parental concerns, though all are not necessarily pathological. This chapter aims to distinguish normal variations from pathological disorders, as well as to discuss diagnostic and therapeutic approach in some common problems of growth and development.

3.1 FAILURE TO THRIVE

Failure to thrive (FTT) is a clinical state of growth failure due to any cause, characterized by any one or more of the following features:

a. Lack of growth, i.e. weight for age < 3rd percentile
b. Failure to gain weight over time on serial monitoring
c. Deceleration in growth velocity, i.e. weight dropping at least two major percentiles below the previous values over a short period, (e.g. from 75th to 25th percentile).

While *weight* is the defining criteria for FTT, other anthropometric parameters, e.g. length/height for age and body mass index, are also frequently affected and may be used for diagnosis.

Etiologically: FTT may be due to non-organic, organic or mixed causes **(Table 3.1)**.

TABLE 3.1: Causes of failure to thrive

Non-organic
a. Emotional deprivation • Maternal death/chronic illness/separation • Family disharmony • Unwanted child
b. *Nutritional:* Protein-energy malnutrition
Organic
a. *Infections:* TB, chronic malaria, kala-azar, AIDS
b. *GIT:* Cleft palate, GER, malabsorption syndrome
c. *Hepatic:* Chronic liver disease, cystic fibrosis
d. *Resp:* Recurrent infections, asthma, chronic lung disease
e. *CVS:* CCF, cyanotic CHDs, infective endocarditis
f. *CNS:* Cerebral palsy, mental retardation
g. *Renal:* Chronic UTI, renal failure, renal tubular acidosis
h. *Endocrinal:* GH deficiency, cong. adrenal hyperplasia
i. *Collagen disorders:* Rheumatoid arthritis, SLE
j. *Hematological:* Severe anemia, malignancy

GER: Gastroesophageal reflux; **GH:** Growth hormone

a. ***Non-organic FTT*** is more common (80%), usually seen in under-five children due to dietary deficiencies or emotional deprivation.
b. ***Organic FTT*** may develop at any age due to identifiable causes, e.g.
   – *Decreased food intake due to difficulties* in sucking, eating or swallowing.
   – *Impaired digestion/absorption* of nutrients, e.g. malabsorption syndromes.
   – *Increased metabolic requirements*, e.g. chronic diseases or infections.
   – *Increased losses of ingested food*, e.g. chronic diarrhea or vomiting.

Clinically these children present with:

- *Malnutrition*, e.g. growth failure, anemia, vitamin and mineral deficiencies,
- *Behavioral changes*, e.g. apathy, social withdrawal, poor eye contact/response to cuddling,
- Developmental retardation,
- Recurrent or persistent infections,
- *Signs of primary disease*, e.g. chronic infections, illnesses, emotional deprivation, etc.

Diagnostic assessment of a child with FTT may be divided into three steps: (a) preliminary clinical evaluation and investigations, (b) evaluation of response to the trial feeding and (c) revaluation with more exhaustive investigations in cases, refractory to trial feeding **(Fig. 3.1)**.

Step I. Preliminary evaluation includes:

a. *Detailed history,* specially related to dietary intake, preceding infections, e.g. diarrhea, child abuse/neglect and developmental history. Available case records, e.g. growth charts should be reviewed to confirm the presence of FF and assess the age of onset.
b. *Physical examination,* specially related to anthropometric values and signs of malnutrition, vitamin/mineral deficiencies, systemic infections/illnesses, etc.
c. *Developmental and psychosocial assessment* to search for the cause, e.g. emotional deprivation as well as consequence of FTT.

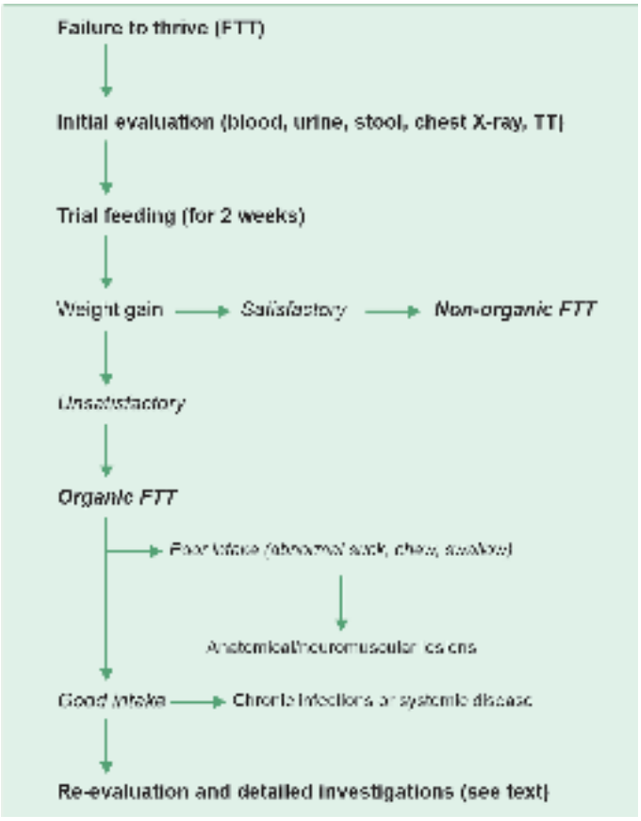

Fig. 3.1: **Diagnostic approach in failure to thrive.**

d. *Baseline investigations* to exclude common causes, i.e.
   - Complete hemogram for anemia, infections, etc.
   - Urine analysis for UTI, chronic renal disease, etc.
   - Stool analysis for malabsorption, worms, etc.
   - X-ray chest and tuberculin test for tuberculosis.
   - Skeletal survey to assess bone age.

Step II. Trial feeding: While most cases may be managed at home with nutritional counseling and periodic follow-up, hospitalization is indicated in cases with—(a) severe undernutrition with weight <60%, (b) suspected child abuse/neglect, (c) suspected organic disease, and (d) doubtful dietary intake.

In hospital, these cases should receive *trial feeding*, i.e. supervised, unlimited high caloric diet (150–200 cal/kg/day) for minimum 14 days, if necessary by nasogastric tube, along with daily weight record. A weight gain of ~50 g/day from 4–5th day onward and sustained for at least a week is considered as satisfactory, suggestive of non-organic etiology. Absence of satisfactory weight gain on trial feeding indicates organic FTT.

Step III. Re-evaluation with detailed investigations is indicated in non-responsive cases to trial feeding and includes:

- *Biochemical investigations*, e.g. blood sugar, serum proteins, liver/renal function tests, screening tests for renal tubular acidosis/aminoaciduria.
- *Endocrinal studies*, e.g. thyroid function tests, growth hormone assays including somatomedin C levels, cortisol levels, etc.
- *Genetic studies* for inborn errors of metabolism, including enzyme assays in selected cases.

In addition, all cases of FTT must.

Management of FTT aims not only to nutritional rehabilitation but also to resumption of appropriate emotional environment and treatment of the underlying organic cause. A multi-disciplinary approach is necessary in most cases, including:

a. *Nutritional management* to correct the dietary deficit and allow catch-up growth, with: (a) increasing volume, frequency and caloric density of meals, (b) avoidance of low-caloric foods and (c) dietary and micronutrient supplementation;
b. *Psychological support* and modification of home environment;
c. *Treatment of underlying cause* and associated problems, e.g. vitamin deficiencies, anemia, etc. All children should be immunized to their age-appropriate level;
d. *Parental counseling* regarding: (a) correct nutritional practices including dietary requirements, (b) use of local nutritious foods, (c) correct cooking practices, (d) maintenance of dietary hygiene, (e) inculcation of good food habits in their children, (f) myths and misconceptions about foods, and (g) Psychosocial and emotional support to the child. They should be actively involved in nutritional rehabilitation process to ensure compliance with treatment and follow-up.
e. *Periodic growth monitoring and regular follow-up* after discharge, as FTT frequently recurs due to continuance of etiological factors.

Prognosis: While initial catch-up growth is excellent in most of the adequately treated cases, it tends to slow-down over time and recurrence of FTT is not uncommon. Long-standing FTT in early life may lead to persistence of development problems, e.g. cognitive, behavioral and language disorders.

3.2 OBESITY

Body fat content changes from high adiposity state in infancy to the lowest level at 5–6 years of age, followed by gradual increase till adolescence. Obesity is a complex multi-factorial disorder characterized by an excess of adipose tissue, adversely affecting the health. While frequently used interchangeably, the terms *overweight* and *obesity* have different connotations.

Definition: *Obesity* and *overweight* in children > 2 years is defined on the basis of body mass index (BMI) as follows:

- ***Obesity:*** BMI above +3 Z-score (adult equivalent >27 kg/m^2),
- ***Overweight:*** BMI above +2 to +3 Z-score (adult equivalent >23–27 kg/m^2),

- ***Extremely obesity:*** 120% of the 95th percentile (adult equivalent ≥35 kg/m^2).

In younger children < 2 years of age, obesity is considered when the *weight for length exceeds 97th percentile.*

Prevalence: Recent years have witnessed sharp rise in prevalence of obesity among children, reported in ~5% of those above 5 years of age, increasing with age.

Etiology: Obesity results from both *hereditary* as well as *environmental* factors. It may be either *exogenous* due to life-style factors (95%) or *endogenous* due to pathological causes (5%) **(Table 3.2)**. Pathological obesity is usually central in distribution, associated with dysmorphism, growth failure and delayed bone age.

Exogenous (constitutional) obesity denotes an imbalance in dietary intake (high-fat, high-sugar, high-salt, energy-dense diet) and physical activity (sedentary life-style). Recent trends of excessive consumption of energy-dense junc foods, high screen-time and limited outdoor play have fuelled pandemic of obesity in children.

Some children are inherent prone for constitutional obesity due to genetic factors (*Polygenic obesity)* associated with single nucleotide polymorphisms of PSMA6 and PSMA3 proteosomal genes.

Endogenous (Secondary) obesity is due to pathological causes, e.g. endocrinal disorders, hypothalamic lesions and syndromic defects, e.g. Prader-Willi syndrome. *Monogenic obesity* due to loss of function mutations in leptin (LEP) and leptin receptor (LEPR) genes is more common in consanguineous families, with earlier onset < 5 years of age.

TABLE 3.2: Causes of obesity in children

A. Exogenous (95%)
- Physiological in early adolescence
- Constitutional *or* familial
- Over-eating (behavioral)
- *Poor physical activity:*
  - Habitual
  - Pathological: Physical handicaps

B. Endogenous (<5%)
- ***Endocrinal:***
  - Hypothyroidism
  - Cushing syndrome
  - Polycystic ovaries (*Stein-Leventhal syndrome*)
- ***Genetic:***
  Laurence-Moon-Biedl syndrome*
  Prader-Willi syndrome**
- ***Monogenic:*** Leptin deficiency
- ***Hypothalamic:***
  - Post-meningitic/encephalitic sequelae
  - Fröhlich syndrome***
- ***Drugs:*** Steroids, valproate, clonazepam

*Obesity, mental retardation, hypogonadism, retinitis pigmentosa
**Obesity, short stature, hypotonia, hypogonadism
***Obesity, hyperphagia, short-stature, hypogonadism, blindness

Complications: Most children with obesity are merely overweight with complications limited to psychological stress and poor body image. However, extreme obesity may be associated with significant morbidity including:

a. Skeletal: Genu valgum, slipped femoral epiphysis,
b. Respiratory: Obstructive sleep apnea syndrome,
c. Cardiovascular: Hypertension,
d. Metabolic: Hyperlipidemia, diabetes mellitus,
e. Skin: Acanthosis nigricans, striae, etc.
f. Behavioral and social problems,
g. Obesity in later life.

Pickwickian syndrome, immortalized in the Charles Dickens's novel *Pickwickian papers*, is a rare complication of extreme obesity, characterized by persistent respiratory distress with hypoxia, cyanosis, polycythemia, cardiomegaly and congestive cardiac failure.

Diagnosis of obesity *per se* requires:

a. Calculation of BMI using weight and height (weight in kg/height in cm^2);
b. Plotting of this BMI on gender-specific BMI charts **(Appendix 2.11, 2.12)** and
c. Analysis of these charts to identify the location of child's BMI on the chart. A value above the red-line indicates obesity, while values between orange and red lines indicate overweight **(Fig. 3.2)**.

While BMI remains the preferred criteria, waist circumference or waist-hip ratio may also be used to detect obesity in older children and adults. While age-wise waist-circumference charts are available for children aged 5–18 years for comparison, Waist-hip ratio is the absolute value in adults, i.e. >1.0 in males and > 0.85 in females suggesting obesity.

Assessment of a child with obesity aims to identify the cause as well presence of complications and co-morbidities, to plan appropriate management. It includes:

a. *Detailed history* to assess:
   - Dietary intake by 24-hour dietary recall, with special reference to consumption of *junk* foods, binge-eating, frequent-snacking, etc.
   - Physical activity in preceding few days including screen time;
   - Presence of family obesity, life-style and motivation;
   - Other risk factors, e.g. maternal gestation diabetes, early infant feeding, drug consumption, delayed development, etc.
b. *Physical examination* to:
   - Confirm the presence of obesity, using anthropometric assessment and BMI charts;
   - Detect markers of underlying diseases, e.g. endocrinal or genetic disorders,

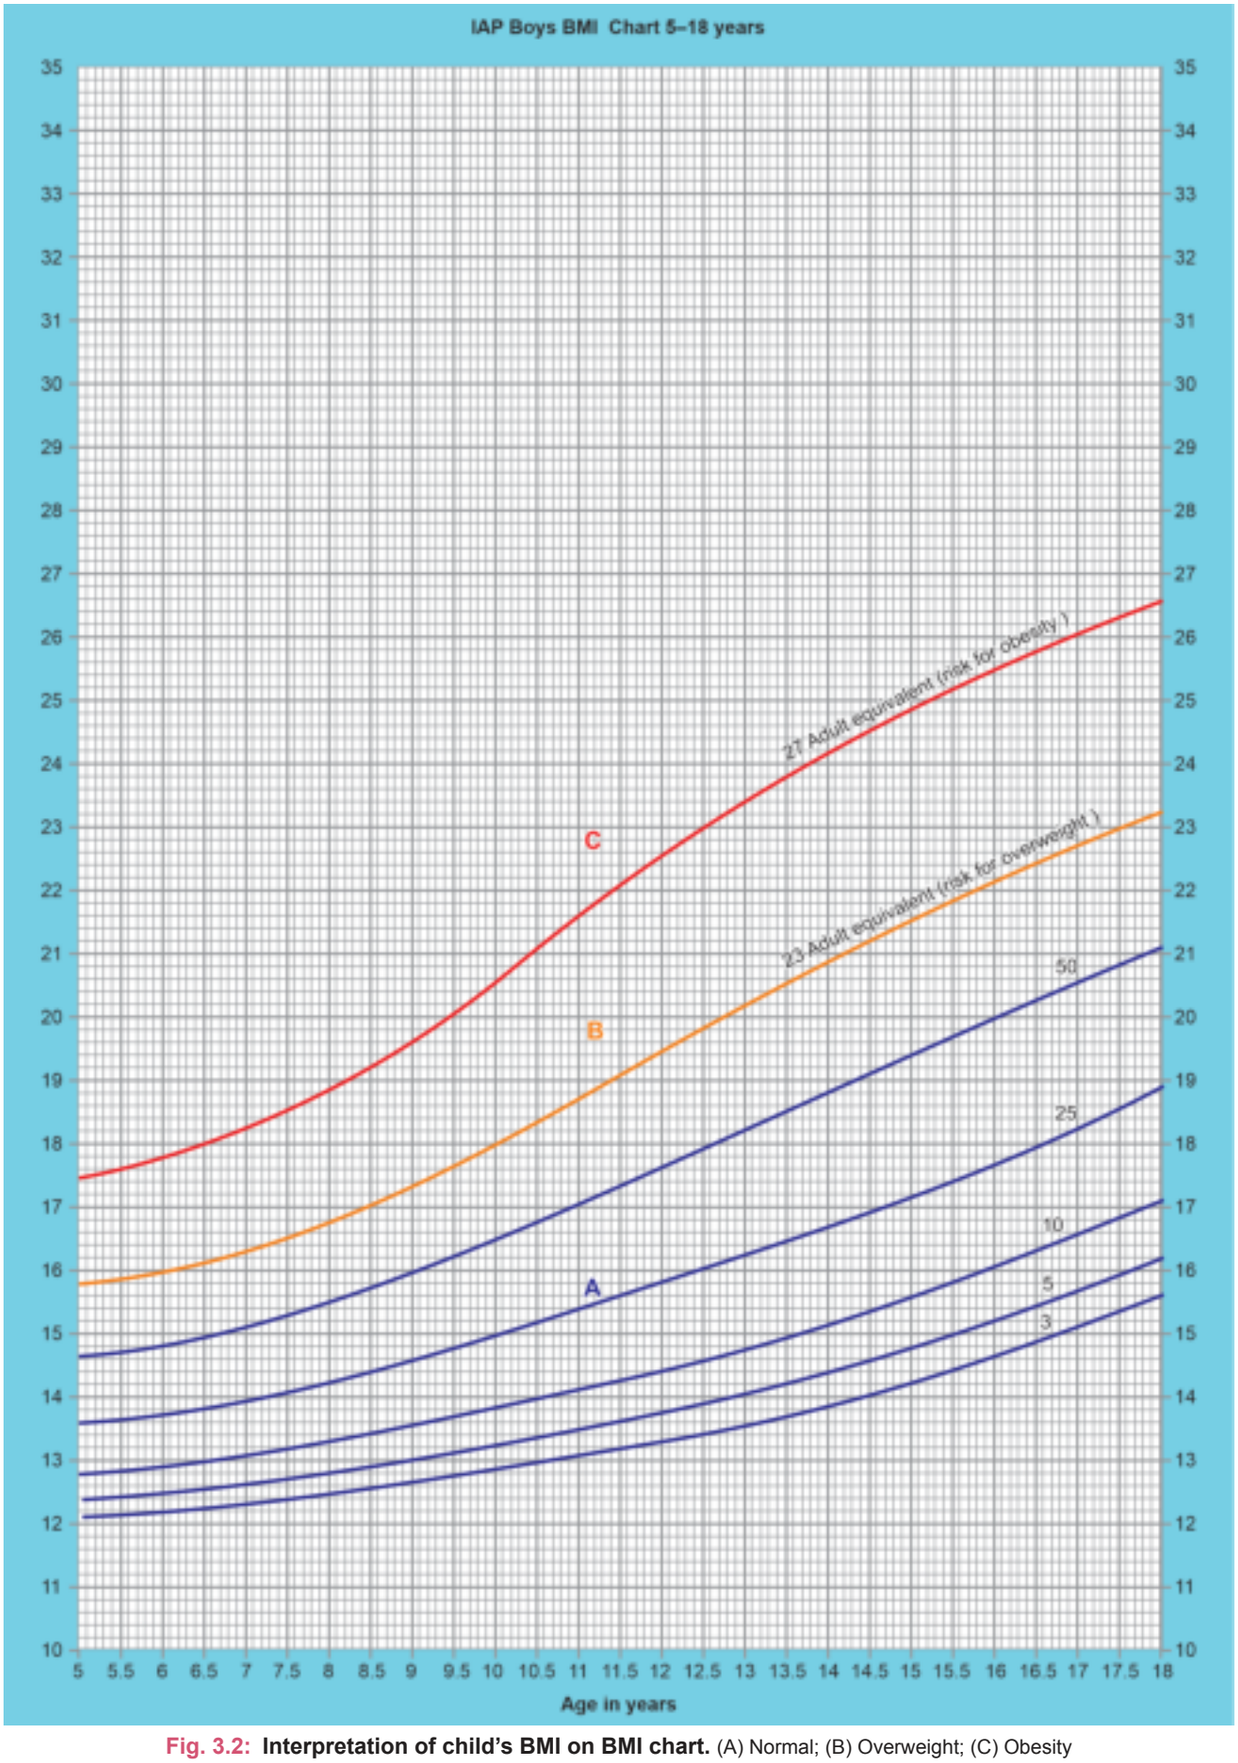

Fig. 3.2: Interpretation of child's BMI on BMI chart. (A) Normal; (B) Overweight; (C) Obesity

– Search for complications, e.g. sleep problems, hypertension, metabolic problems, etc.

c. *Psychosocial assessment* for body-image, self-esteem and secondary behavioral problems.

d. *Relevant investigations* to search for the cause of obesity as well as metabolic complications, e.g. glucose tolerance test, lipid profile, hormonal profile, etc.

Management of obesity in children should aim for gradual and sustained control with weight loss not exceeding 1.5 kg per month or >7–10% over 6 months, with a multidisciplinary approach involving pediatrician, dietician and behavioral counselor, as follows:

- ***Dietary modification,*** with low-caloric, low-fat, normal-protein, high-fiber diet, tailored to reduce the weight by ~500 g/week, is enough in most cases of overweight or mild obesity. Severe dietary restrictions and aggressive weight reduction plans are undesirable in children and may hamper normal growth. Junk foods and carbonated drinks should be avoided.
- ***Encouragement of physical activity***, e.g. outdoor games or swimming, is more acceptable to children than rigid exercise schedules.
- ***Treatment of identifiable cause.***
- ***Psychosocial support*** to the child and family.
- ***Drugs:*** General anti-obesity drugs, e.g. *orlistat* (gastric lipase inhibitor) or *sibutramine* (neurotransmitter modulator) affect growth and should be avoided in children. However, *leptin* (in leptin deficiency), o*cteotride* (in hypothalamic obesity) and *metformin* (in polycystic ovarian syndrome) may be considered in selected cases.
- ***Surgery*** like *gastric banding* or *jejuno-ileal bypass* is rarely indicated except in morbid obesity with BMI >40 kg/m^2.
- *Referral:* Children with-(a) early-onset obesity < 5 years age, (b) rapid progression, (c) delayed development, growth, and puberty, (d) neurological features and (e) abnormal metabolic workup should be referred for detailed evaluation and management under expert guidance.

Prevention: Obesity in adults usually originates in childhood and prevention should begin as early as possible with appropriate guidance and monitoring. Important preventive interventions evention of obesity in childhood include –

a. ***Dietary modifications*** to restrict high-fat, high-sugar, high-salt diet; and encourage consumption of whole grains, legumes, fruits, vegetables and nuts. JUNCS food should be avoided as per IAP guidelines **(Table 3.3)**. Fibre content in diet should be *~5 g + age in years*. Exclusive breastfeeding till 6 months followed by appropriate complementary feeding is known to curtail risk of obesity in later life.

TABLE 3.3: IAP Guidelines on consumption of JUNCS* food

- Avoid JUNCS foods or limit to one serving/ week with < 50% of total energy intake
- Limit dietary fat to <30% of total caloric intake in older children >2 years (No restriction < 2 years)
- Eliminate trans-fat from diet
- Restrict free sugar content to <5% of total energy intake
- No fruit juices/drinks below 2 years of age, and limit them to <125 ml (2–5 yrs) or <250 ml in older children with sugar content <35% w/v
- No caffeinated or carbonated drinks below 5 years of age and limit them to <100 ml/day (5–9 yrs) or <200 ml/day in older children
- Encourage seasonal fruits, vegetable, whole grains, legumes and nuts

*JUNCS: Junk food with high fat/sugar/salt content, Ultra-processed food, Nutritionally inappropriate homemade food cooked in recycled oil with high fat/salt/sugar content, Caffeinated/carbonated drinks, Sweetened sugar beverages.

Unless morbidly obese, calorie restriction is not recommended in obese children <7 years of age, rather focusing on healthy eating pattern and habits. Older children and adolescent may be advised caloric restriction to 1200–1800 cal/day, if required.

b. ***Encouragement of physical activities:*** WHO guidelines recommend average 60 minutes of moderate to vigorous physical activity, at least thrice a week in children and adolescents. Children must also be encouraged to participate in household chores. Jogging, bicycling, swimming and dancing are good calorie burners for children, apart from outdoor games (300–400 cal/hour).

c. **Limiting the screen time** as per IAP guidelines, i.e. no screen time till 2 years, less than 1 hour from 2–5 years and less than 2 hours from 5–10 years.

d. **Behavioral counseling** for parents to change their own life style as well as set realistic goals of diet and exercise in children with positive reinforcement.

e. **Periodic monitoring** to ensure success of interventional strategies and prevent recurrence of obesity.

3.3 SHORT STATURE

Short stature (SS) is a common cause of concern in school-age children, defined as the *height below the 2 Z-score or 3rd percentile for the age*. Height below the 3 Z-score indicates severe short stature.

Growth-velocity below the 10th percentile for a year indicates potential risk of SS, though many of these children in pre-pubertal age group are merely *slow-growers.*

Prevalence: While 35.5% of under-five children are stunted due to nutritional causes, ~3% of school children are estimated to be short-statured in India as per above mentioned criteria.

Types: According to the growth potential and patterns of growth, SS may be broadly classified into three types:

a. ***Normal variant SS*** (20%), i.e. children with normal growth potential, who are relatively slow grower in childhood but achieve normal adult height by more marked growth spurt during adolescence or delayed completion of puberty.
b. ***Primordial SS*** (15–20%), i.e. children with inherently low growth potential, who remain short-statured even after completion of puberty.
c. ***Secondary SS*** (50–60%), i.e. children with normal growth potential, which is hampered by exogenous factors, e.g. diseases.

Etiology: Important causes of SS are listed in **Table 3.4**, though characteristics of some common types are as follows:

- ***Familial SS*** is common in India, due to short-statured parents. These children are normal at birth but their growth velocity declines during pre-school age-group. Subsequently, they resume normal growth velocity by mid-childhood but without catch-up growth. As the onset and completion of puberty occur at normal age, ultimate adult height is short but comparable to their parents **(Fig. 3.3A)**.
- ***Constitutional SS*** is similar to familial SS, but with two differences-parents have normal height and puberty is usually delayed to enable them to grow for a longer period and attain near-normal adult height **(Fig. 3.3B)**.
- ***Primary SS*** denotes inherently low growth potential due to genetic disorders, e.g. skeletal dysplasia or intrauterine growth retardation. These children are usually low birth weight, have lower growth velocity (<4 cm/year) in childhood and remain short-statured in adulthood. Children with skeletal dysplasia also have distorted body proportions.
- ***Secondary SS*** is the commonest cause of preventable SS, in which growth velocity is hampered by prolonged illnesses, e.g. malnutrition, infections or systemic diseases during early childhood. Delayed bone age is a consistent feature in these cases, which may or may not correspond to height age. Growth hormone deficiency is an important cause of SS due to hypopituitarism, reduced somatomedian levels or receptor insensitivity, i.e. *Laron syndrome.*

Important differentiating features between common causes of short stature are shown in **Table 3.5**.

Diagnostic assessment: All short-statured children are not necessarily abnormal and a preliminary clinical evaluation with baseline investigations, periodic height monitoring and parental reassurance is enough in most pre-pubertal children with borderline SS.

Detailed evaluation and referral to specialized services is indicated in children with:

TABLE 3.4: Common causes of short stature

A. Normal variants short stature
- Familial
- Constitutional

B. Primary short stature (primordial dwarfism)
- Intrauterine growth retardation (IUGR)
- *Genetic:*
  - *Chromosomal:* Mongolism, Turner syndrome
  - *Inborn errors of metabolism:* Hurler syndrome
  - *Others:* Progeria, Silver-Russell syndrome
- *Skeletal dysplasia*
  - *Short-limb:* Achondroplasia
  - *Short-trunk:* Spondylo-epiphyseal dysplasias

C. Secondary short stature
- *Nutritional:* PEM, zinc deficiency
- *Emotional:* Psychosocial dwarfism
- *Chronic infections:* TB, AIDS, UTI, worms
- *Chronic systemic diseases:*
  - *GIT:* Malabsorption syndrome, chronic liver disease
  - *Renal:* Chronic renal failure, renal tubular acidosis
  - *Cardiac:* Cyanotic CHDs, recurrent CCF
  - *Pulmonary:* Asthma, tuberculosis
  - *CNS:* Diencephalic syndrome of infancy
  - *Blood:* Hemoglobinopathies, malignancies
- *Endocrinal disorders:*
  - Growth hormone deficiency
  - Hypothyroidism
  - Cong. adrenal hyperplasia, Cushing syndrome
- *Iatrogenic:* Steroids, cytotoxics, radiotherapy

a. Severe short stature with height <-3 Z-score,
b. Short stature with height <-2 Z-score, after adjusting MPH,
c. Downward crossing of height by two major percentiles in 6 months,
d. Pre-pubertal height velocity < 5 cm/year,
e. Disproportionate SS at any age,
f. Clinical features suggestive of genetic or secondary cause,
g. Persistent SS after the onset of puberty,

Important steps in evaluation of these children include **(Fig. 3.4)**:

Step I. Confirm the presence of SS by recording the patient's height and comparing it with reference norms. Previous personal growth charts, if available, should be reviewed for growth velocity in the past and assess the timing of the growth faltering.

In borderline cases, height velocity should be measured for next 12 months before further workup. A height velocity of <5 cm in pre-pubertal years is significant and needs further evaluation.

Step II. Exclude normal variant SS by–(a) review of previous height records and (b) evaluation of parent/

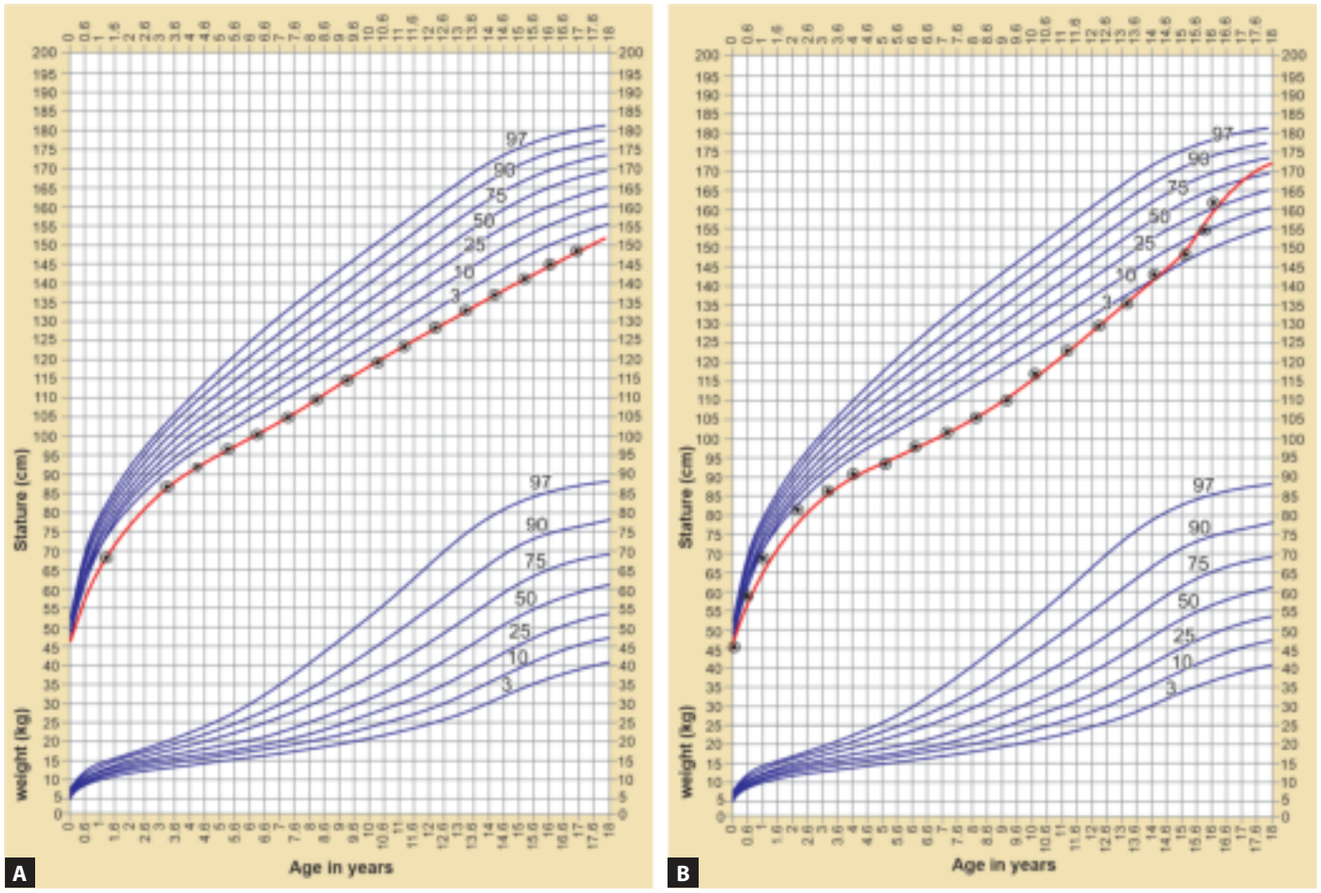

Fig. 3.3A and B: **(A) Familial SS.** Normal at birth > low growth velocity <3rd percentile throughout childhood and adolescence > normal age of onset of puberty > Low final Height, comparable to mid-parental height; **(B) Constitutional SS.** Normal at birth > low growth velocity in early childhood > late onset of puberty with pick-up (accelerated) growth > normal final height.

TABLE 3.5: Differential diagnosis of short stature

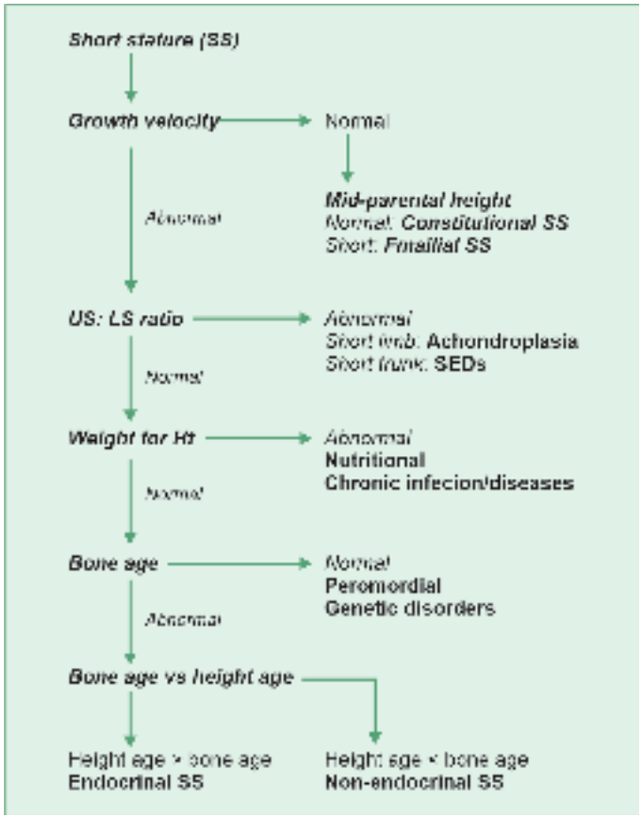
	Familial	*Constitutional*	*Genetic*	*Skeletal*	*Secondary*	*Endocrinal*
Parental height	Less	N	N	N	N	N
Birth weight	N	N	Less	N	N	N
Early GV (<3 years)	Less	Less	Less	Less	N/Less	N/Less
Late GV (>3 years)	N	N	Less	Less	Less	N/Less
Onset of puberty	N	Late	N/Late	N	N/Late	L/E
Final adult height	Less	N	Less	Less	N/Less	Less
Body proportions	N	N	N	Disproportionate	N	N
Weight for height	N	N	N	More	Less	More
Bone age vs CA	N	N	N	N	Less	Less
Bone age vs HA	More	N	More	More	More	Less

Note: Salient features are given in bold and italics, **GV:** Growth velocity, **CA:** Chronological age, **HA:** Height age.

sibling height. Adult height in familial cases may be predicted within reasonable limits (± 6.5 cm) by using standard graphs or following formula:

- Boys = {(Mother's height +13) + Father's height}/2
- Girls = {(Father's height – 13) + Mother's height}/2

Adult height may also be predicted by plotting the mid-parental height on MPH percentile growth chart. The percentile line nearest to this point is mid-parental 50th percentile and child's own percentile curve is expected to be between 10th and 90th percentile on this chart.



SED: Spondyloepiphyseal dysplasia

Fig. 3.4: Diagnostic approach to short stature.

Step III. Differentiate between proportionate and disproportionate SS by recording *upper segment: Lower segment ratio* and *arm-span*. Disproportionate SS is most obvious in skeletal dysplasia, e.g. achondroplasia (short-limb), spondyloepiphyseal dysplasia (short-trunk) and hypothyroidism (short-limb).

Step IV. Evaluate the bone age by age-appropriate skeletal X-rays and compare it with chronological as well as height age. Bone age is less than the height age in endocrinal disorders, e.g. hypothyroidism. (Height age is the age at which his/her current height would match 50th percentile curve on growth chart).

Step V. Exclude organic causes, e.g. malnutrition, chronic infection or diseases and emotional deprivation by detailed history and clinical evaluation, specially related to birth weight, dietary intake, previous illnesses and inter-family relationship.

Step VI. Relevant investigations, including:

a. *Baseline investigations in all cases*
   - Routine blood, urine and stool analysis
   - X-ray chest and tuberculin test to exclude tuberculosis
   - Skeletal survey for bone age and dysplasia

b. Selected investigations, depending on clinical suspicion
   - Chromosomal analysis (karyotyping)
   - Biochemical tests for diabetes and liver/renal functions
   - Endocrinal work-up, e.g. thyroid function tests, growth hormone assays, etc.
   - Serological tests for celiac disease.

Management of SS depends on the cause and includes:

- Adequate nutrition with high protein and caloric diet and micronutrient supplements.
- Treatment of underlying infections and infestations
- Specific treatment for identified cause, e.g. thyroxine for hypothyroidism, gluten-free diet for celiac disease, etc.
- Follow-up with periodic height monitoring till the final height is achieved.
- Growth hormone therapy, as discussed below.

Growth hormone (GH) therapy is used not only in growth hormone deficiency (Ch 22.2.2) but also in many other causes of SS, e.g. chronic renal disease, Turner/Noonan syndrome, intrauterine growth retardation and Idiopathic SS, etc. It should be started as soon as possible after confirmation of diagnosis, using a recombinant GH preparation as daily night injections (25–50 µg/kg, subcutaneously). Higher doses may be used during puberty. Maximum response is seen during first year of therapy which must be continued till height velocity drops <2.5 cm/yr or bone age reaches >14 years in girls and >16 years in boys.

Pseudotumor cerebri is a significant but rare complication of GH therapy. Rare side-effects include fluid retention, impaired glucose tolerance, worsening of scoliosis and slipped capital femoral epiphysis. Very rarely, there is increased risk of malignancy in some predisposed genetic conditions.

3.4 TALL STATURE

Tall stature, defined as *height >97th percentile for the corresponding age* is relatively uncommon.

Some children may appear taller than others in early childhood due to individual variations and ectomorphic body build. Hildren with precocious puberty are relatively taller in early puberty than others, though final adult height in them is normal due to early skeletal maturation and completion of puberty.

Etiology: Most of these cases are *normal variants* due to familial or constitutional features, though pathological tall stature indicates chromosomal, genetic or endocrinal etiology **(Table 3.6)**. Some unique causes of tall stature, not discussed elsewhere, are as follows:

Marfan syndrome is the commonest cause of pathological tall stature in children. It is an autosomal dominant connective tissue disorder, with abnormal synthesis of *fibrillin-1*, an α-glycoprotein in elastin fibers.

TABLE 3.6: Causes of tall stature

- **Familial** (tall parents)
- **Constitutional**
- **Genetic**
  - *Chromosomal:* Klinefelter or XXY syndrome
  - *Genetic:* Marfan syndrome, homocystinuria
- **Endocrinal**
  - Hyperpituitarism (pituitary gigantism)
  - Precocious puberty
  - *Others:* Thyrotoxicosis, Beckwith syndrome
- **Cerebral** gigantism *(Soto's syndrome)*

Clinically, these cases are characterized by tall stature, increased arm span (US:LS ratio), arachnodactyly (long fingers), ocular abnormalities, (e.g. lens dislocation, iridodonesis) and cardiac abnormalities, (e.g. mitral valve prolapse, aortic regurgitation).

Cerebral gigantism (Soto's syndrome) is a rare hypothalamic disorder, characterized by rapid linear growth during first 3–4 years of age, macrocrania, mental retardation, gait abnormalities and normal or precocious puberty. It may be differentiated from pituitary gigantism by normal growth hormone levels and delayed skeletal maturation as compared to height.

Diagnostic evaluation of tall stature aims to differentiate normal variants form rare pathological causes, usually based on positive family history (correlate with mid-parental height) and normal physical examination. A suspected cases of pathological tall stature needs complete clinical evaluation, including ophthalmic and cardiac assessment (for Marfan syndrome and homocystinuria) and detailed investigations, including:

a. Radiological determination of bone age.
b. Karyotyping to exclude chromosomal disorders, e.g. Klinefelter syndrome.
c. Hormonal studies, e.g. growth hormone assays and thyroid function tests.

Treatment: No treatment is usually necessary for tall stature *per se*, except the treatment of underlying cause. Hormonal therapy with sex-steroids to accelerate epiphyseal fusion and early completion of puberty is occasionally used in children with severe tall stature (with predicted adult height >3 SD) and significant psychological stress.

3.5 DEVELOPMENTAL DELAY

Developmental status of a child is usually measured and expressed either as *Developmental age*, i.e. the age for which expected milestones have been achieved or as *developmental quotient* (DQ) derived by dividing developmental age (DA) by chronological age (CA) and multiplied by 100 (DQ = DA/CA×100). DQ is an absolute value and not a percentage.

Developmental delay (DD) refers to the significant delay in achieving developmental milestones in any one or more of the following domains: (a) gross and fine motor, (b) social-personal, (c) cognition, (d) speech and language, and (e) activities of daily living, as compared to peers, i.e. *a performance of less than 2 SD for the age-appropriate norms. A DQ of less than 70 is also considered as developmental delay*.

This term is reserved only for children below 5 years of age, in whom formal intelligence quotient (IQ) testing is not possible. The term *'Intellectual disability'* is used in older children (Ch 3.6).

Types: Developmental delay may be further classified as:

a. ***Global developmental delay*** (GDD), when two or more domains are affected, and
b. ***Development dissociation***, when the delay is limited to only one domain or is disproportionately more in one domain as compared to others. DA or DQ should always be measured in different domains separately, to identify developmental dissociation, if any.

Developmental deviance, i.e. differences in the sequence of achieving different milestones in one or more domain may be innocent or sinister, e.g. some infants may not creep before they start walking and should not be construed as abnormal.

Developmental regression, refers to the loss of previously acquired milestones, usually suggestive of a neurodegenerative disorder.

Etiology of DD is identifiable only in ~70% cases and common causes include genetic disorders, intrauterine infections, e.g. congenital rubella syndrome, perinatal hypoxia at the time of birth and postnatal insults to developing brain till 2 years of life. Emotional deprivation may also lead to DD, specially in social domain while hearing impairment is the commonest cause of delay in language development **(Table 3.7)**.

Diagnostic approach for a child with suspected DD aims to-(a) confirm the presence of DD *vis a vis* individual variations and deviance, (b) differentiate global DD from developmental dissociation, deviance or regression, (c) identify the cause of DD, if possible, and (d) search for presence of co-morbidities, if any.

Early detection of developmental delay involves a step-wise approach:

a. *Informal developmental surveillance* of all children during all health-care visits;
b. *Formal development screening* of all children at scheduled intervals;
c. *Formal developmental assessment* of children with abnormal screening results.

Step I. Informal developmental surveillance, discussed earlier (Ch 2.7) is a continuous and informal process

TABLE 3.7: Causes of developmental delay

- **Idiopathic (30%)**
- **Familial**
- **Genetic disorders:**
  - *Chromosomal:* Down syndrome, Fragile X syndrome
  - Inborn errors of metabolism: Phenylketonuria
  - Mitochondrial disorders
- **Fetal brain injury:**
  - Congenital brain malformations
  - Intrauterine infections, e.g. CRS
  - *Teratogens:* Alcohol, phenytoin
  - Obstetric complications
- **Perinatal brain injury:**
  - Prematurity and/or low birth weight
  - Birth asphyxia and birth injuries
  - *Metabolic:* Hypoglycemia, kernicterus
- **Postnatal brain injury** (in first 2 years):
  - *Infections:* Meningitis, encephalitis
  - Head injury
  - *Endocrinal:* Hypothyroidism
  - *Prolonged hypoxia:* Seizures, ALTS
  - *Toxic:* Lead poisoning
  - *Metabolic:* Hypoglycemia
- **Environmental:**
  - Emotional deprivation
  - Visual/hearing disability

ALTS: Acute life threatening events

to assess the development of a child during regular health check-up/immunization visits by asking the developmental history from mother, observing his/her behavior in the clinic and examination to elicit common age-appropriate milestones. *A developmental delay* may exist when the child fails to achieve developmental milestones at the expected age, despite adjustments for individual variations. However, the purpose of this surveillance is not to draw a line between normal and abnormal, but to identify high-risk children, who need referral for formal assessment.

Mother and child protection (MCP) card also includes a check-list of red-flag signs for delayed development for different ages, which can also be used by field health workers to identify a high-risk child, who need referral for further assessment **(Table 2.12)**.

Step II. Formal developmental screening involves use of validated and locally appropriate screening tools to identify high-risk children who needs detailed developmental assessment.

IAP recommends that—

a. All children should be screened by these screening tools at the age of 9–12 months, 18–24 months and at school entry, coinciding with immunization visits, and
b. High-risk children should also be additionally screened at 4–6 months.

Many screening tests are available for this purpose, including widely used Denver developmental screening test (DDST), or locally developed *Phatak's Baroda development screening test* or *Trivandrum development screening test*, discussed in Ch 2.7.

TABLE 3.8: Referral criteria for formal developmental assessment

- Delayed development on informal surveillance
- Delayed development on formal screening
- Family h/o delayed development/intellectual disability
- Neuromuscular or neuroregression disorders
- Presence of dysmorphic features/physical stigmata **(Table 3.9)**
- Presence of vision or hearing disabilities
- Abnormal neuroimaging findings

DD: Developmental delay, **ID:** Intellectual disability

However, these screening tests should not be used to assign development quotient/intelligence quotient or to declare the developmental delay *but only* to identify high-risk children for formal assessment.

Step III: Formal development assessment tests: Developmental delay is a shattering diagnosis for parents and should not be made without formal assessment. **Table 3.8** enlists high-risk children for developmental delay, who must be referred for formal developmental assessment, including those identified on informal surveillance or screening tests.

Formal developmental assessment tests must be administered only by trained personals, usually developmental pediatricians or clinical psychologists. Many such tests are available and the choice depends on the age of the child, expected area of developmental abnormality and familiarity of the assessor with the test.

Bayley scale of infant development (BSID-IV) for children aged 16 months to 42 months and its Indian version-*developmental assessment scale of Indian infants* (DASII) for children aged 0–30 months, are commonly used in India to confirm the presence and severity of developmental delay in young children.

Other domain-specific tests are also available, e.g. Vineland adaptive behavior scale II for personal-social domain and clinical linguistic/auditory milestone scale (CLAMS) for language skills.

Step IV. Assessment of a child with confirmed DD on formal developmental assessment tests needs a detailed history, clinical examination, relevant investigations and developmental evaluations to arrive at an etiological diagnosis, to identify the line of further management, predict the expected outcome and parental counselling. Important components of this assessment include—

a. *Detailed history,* with special reference to similar family history (pedigree analysis), consanguinity, adverse antenatal or perinatal events and behavioural problems, e.g. attention-deficit.
b. *Review of the development record* to distinguish between– (a) delay from birth or later, (b) global developmental

delay from developmental dissociation, (c) developmental delay and developmental regression, and (d) non-progressive delay and progressive worsening.

Presence of developmental dissociation (selective delay in one or two domains) narrows the diagnostic possibilities, e.g. hearing impairment for speech/language domain, vision/hearing impairment for personal-social domain, neuromuscular disorders for motor domain, etc. Similarly, a non-progressive global delay indicates cerebral palsy, whereas a deviancy or regression in social and communication domains may indicate autism spectrum disorder.

c. *Physical examination* with special reference to anthropometry, physical stigmata **(Table 3.9)**, vision/hearing problems and neurological signs. Ophthalmoscopic examination is highly informative in etiological diagnosis of developmental delay, e.g. presence of chorioretinitis in intrauterine infections, cherry-red spot in neurodegenerative disorders, papilledema in hydrocephalus, etc.
d. *Relevant investigations,* depending on suspected etiology, mainly include cytogenetic, biochemical and neuroimaging tests **(Table 3.10)**.
e. *Family screening:* Once a genetic diagnosis is firmly established in the index case, parents and siblings should be screened for assessing the risk of recurrence and genetic counselling.

Management: Except for few causes, e.g. hypothyroidism, phenylketonuria and lead intoxication, majority of the disorders with developmental delay have no pharmacological cure and management *primarily aims to achieve maximum functional independence and eliminate function-limiting factors*, e.g. vision/hearing impairment or seizures.

Management and rehabilitation program of each child needs to be individualized, according to their needs and potential. A multidisciplinary team approach is essential in these cases, involving following interventions:

a. Physiotherapy and occupational therapy for neuromuscular dysfunctions.
b. Management of associated deficits, e.g. hearing, vision and speech delay, seizures, etc.
c. Psychotherapy or behavioral modification.
d. Schooling, preferably in a regular school, as far as possible.
e. Parental support and counselling

Parental counselling is an essential component of the management of development delay to help them understand the:

a. cause of developmental delay.
b. goals of diagnostic and therapeutic interventions,
c. anticipatory course and expected long-term outcome,
d. strengths of the child, and
e. potential to prevent recurrence in subsequent children.

Managing a child with developmental delay is often a frustrating task for parents, who should be counselled in clear and compassionate manner but without kindling unrealistic expectations.

TABLE 3.9: Common physical stigmata in developmental delay

- *Size :* Tall/short stature, obesity, failure to thrive
- *Head :* Microcephaly, hydrocephalus
- *Eyes :* Slanting eyes, microphthalmia, cataract
- *Ears :* Deformed or low-set ears
- *Face :* Coarse facies, retro-/prognathia
- *Mouth :* Cleft lip/palate, macroglossia
- *Hair :* Sparse, kinky, light-colored
- *Neck :* Short or webbed neck
- *Limb :* Brachy-/arachnodactyly, poly-/syndactyly
- *Skin :* Café-au-lait spots, adenoma sebaceum
- *Genitals :* Hypogonadism, hypospadias

TABLE 3.10: Investigations in developmental delay

- *Neuroimaging:* CT/MRI for structural CNS lesions
- *Electrophysiological studies:* EEG, EMG, BERA
- Serological tests for intrauterine infections
- Hormonal assays, e.g. thyroid function tests
- *Toxin screening:* Lead, uric acid
- *Cytogenetics:* Karyotyping, Chromosomal microarray, WES
- *Urinalysis for IEM:* Ferric chloride test, AA chromatography
- Enzyme assays for neurodegenerative disorders

WES: Whole exome sequencing; **AA:** Amino acid

Child Development Units (CDUs)

Child development units have been established in many large hospitals and child-health centers for early diagnosis and comprehensive management of developmental delay. These units are served by a multi-disciplinary team of pediatricians, developmental pediatricians, neurologists, psychologists, physiotherapists, occupational therapists, speech therapists and special educators.

These units not only offer diagnostic and therapeutic services for developmental delay or intellectual disability but also provide management of co-morbidities, behavioral interventions, special educational activities, and parental counselling.

3.6 INTELLECTUAL DISABILITY

Intellectual disability (ID) is defined under DSM-V criteria as follows:

1. *Deficit in intellectual functions,* e.g. reasoning, problem-solving, abstract thinking, academic learning, etc., with measured IQ score of <70 (or <-2SD for same age and culture) *(IQ = Mental age/Chronological age × 100).*
2. *Deficit in adaptive functions* needed to live in an independent and responsible manner, e.g. communication, social/interpersonal skills, self-care or

TABLE 3.11: Severity grading of intellectual disability

Severity	*Level support*
Intermittent (Mild, IQ 52–60)	No constant support needed
Limited (Moderate, IQ 36–51)	Requires occupational support, has independent home life
Extensive (Severe, IQ 20–35)	Requires occupational support as well as support for daily activity
Pervasive (Profound, IQ < 20)	Institutionalized care is often necessary

independence at home or community settings, e.g. shopping and school/work functioning.

3. Onset of these deficits or limitations during developmental phase <18 years of age.

The term ID should be used only in children above 5 years of age who meet all of the above criteria and in whom formal intelligence quotient (IQ) testing is possible.

Classification: Conventional classification of ID based on IQ scores has been largely replaced by the revised classification systems based on the need for support system necessary for daily functioning **(Table 3.11)**.

Incidence: It is estimated that ~3% of general population fulfills the diagnostic criteria for ID, though >80% of them have only mild deficits. ID is more common in males and in children with *risk factors, e.g.* similar family history, consanguinity and perinatal complications.

Etiology of ID is similar to that of developmental delay **(Table 3.7)**. It may be genetic, environmental or mixed in origin, though the exact cause is identifiable in only 40–60% cases.

Mild to moderate ID is usually idiopathic or familial (*? polygenic*), with recurrence risk of ~40% if both parents are affected and ~20% if only one parent is affected. Down syndrome is the commonest genetic cause of ID in Indian children.

Clinical presentation: Severe or profound ID is easily identified in early infancy due to delayed milestones. However, mild to moderate cases are often missed till school-entry or even later age. Important early indicators of ID include:

a. Developmental delay on early surveillance,
b. Neurosensory deficits, e.g. cerebral palsy, visual/hearing defects, language delay, etc.
c. Behavioral problems, e.g. attention-deficit, hyperactivity, impulsivity, etc.
d. Poor scholastic performance.

Presence of physical stigmata, discussed in Ch 3.5 on development delay suggests higher risk of ID and points toward the probable cause **(Table 3.9)**.

Diagnostic evaluation of ID involves: (a) confirmation of diagnosis, (b) identification of underlying etiology and (c) identification of limiting neurosensory defects.

Step I. Confirmation of diagnosis: ID is a shattering diagnosis for parents and should be made only after careful assessment. Single assessment may be abnormal due to temporary variability in performance or environmental influences and an abnormal observation needs to be re-confirmed before disclosing the diagnosis to parents. Other causes for poor performance on IQ testing, e.g. hearing or visual defects should also be considered to eliminate secondary delays in development.

Intelligence quotient (IQ) is a ratio (mental age/chronological age × 100), commonly used to denote presence and severity of ID. It may be assessed by a number of age-appropriate tests to evaluate various domains of cognitive and adaptive behavior, with due consideration for ethnic and linguistic variations as well as adequacy of sensory inputs, e.g. hearing and vision.

In India, commonly used IQ tests include *Wechsler intelligence scale for children for children aged* 6–16 years and *Wechsler adult intelligence scale for those above* >16 years. Adaptive skills are generally tested using *vineland adaptive behavior scale*.

Wechsler intelligence scale for children (WISC) is the most commonly used intelligence test for school children (6–17 years), which can be completed without needing the child to read or write. Current WISC-V version takes ~45–65 minutes to administer and generates a full scale IQ that represents a child's general intellectual ability. It also provides five primary index scores, (i.e. verbal comprehension index, visual spatial index, fluid reasoning index, working memory index and processing speed index) in separate cognitive domains. Many Indian adaptations for WISC, e.g. *Malin's* or *Mahindrika Bhat's tests* are available commercially for use in Indian children >5 years of age.

Step II. Etiological diagnosis is often difficult, though every effort should be made to identify preventable/treatable causes. Important steps in etiological diagnosis are same as for developmental delay and include:

a. *Detailed history,* with special reference to similar family history (pedigree analysis), consanguinity, adverse antenatal/perinatal events and behavioral problems.
b. *Physical examination* with special reference to anthropometry, physical stigmata **(Table 3.9)**, vision/hearing problems and neurological signs. Ophthalmic examination is highly informative in etiological diagnosis of ID, e.g. chorioretinitis in intrauterine infections, cherry-red spot in neurodegenerative disorders, papilledema in hydrocephalus, etc.
c. *Relevant investigations,* depending on suspected etiology, mainly include cytogenetic, biochemical and neuroimaging tests **(Table 3.10)**.

d. *Family screening:* Once a genetic diagnosis is firmly established in the index case, parents and siblings should be screened for computing the recurrence risk and genetic counseling.

Step III. Identification of function-limiting defects, i.e. hearing and vision defects, neuromotor problems, seizures, behavioral problems, parent–child relationship, etc.

Management: Except for a few conditions like hypothyroidism, phenylketonuria and lead intoxication, the majority of disorders with ID have no specific curative treatment. Hence, the *primary aim of management is to maximize functional independence,* e.g. activities of daily living household chores, social independence, etc., *and eliminate limiting factors*, e.g. vision or hearing correction.

Management and rehabilitation program of each child needs to be individualized, according to their needs and potential **(Table 3.11)**. A multidisciplinary team approach is essential in these cases, involving following interventions:

a. Physiotherapy/occupational therapy for neuromuscular dysfunctions
b. Management of associated deficits, e.g. hearing, vision and speech delay, seizures, etc.
c. Psychotherapy or behavioral modification
d. Family counseling and social support
e. Schooling, preferably in regular schools except in severe/profound cases.
f. Institutionalization is the last resort, often needed in severe/profound ID.

Prevention of ID and associated handicaps may be broadly divided into:

I. Primary prevention includes following interventions in all prospective mothers:

a. *Pre-conceptional* measures, e.g.
   - Control of goiter in adult population
   - MMR immunization in girls
b. *Antenatal* measures, e.g.
   - Serological screening for intrauterine infections
   - Folic acid supplements for neural tube defects
   - Anti-D prophylaxis in Rh-negative mothers
   - Appropriate obstetrical and neonatal care
c. *Neonatal screening* for hypothyroidism, PKU, etc.

II. Secondary prevention includes prenatal diagnosis and genetic counseling in cases with family history of ID in parents or previous siblings. Familial ID is usually multi-factorial in origin with recurrence risk of ~20–40%. Although prenatal diagnosis is difficult in these cases, prenatal genetic studies may be used to avoid recurrence of other genetic/chromosomal defects.

III. Tertiary prevention includes minimization of functional handicaps in established ID by early diagnosis and treatment of limiting factors.

IV. Legislative support: ID has been included as a disability under *the Disabilities Act, 1995* that provides for screening of children at-risk, awareness campaigns via mass media and improved perinatal care. It also provides for free education, research and setting up of special teacher's training institutes

3.7 LEARNING DISORDERS

Learning disorders or disabilities (LD) include a large and heterogeneous group of low severity-high incidence disorders, all characterized by "*persistent difficulties in coping with academic skills (learning) due to problems with efficient reading (Dyslexia), writing (Dysgraphia), calculations (Dyscalculia) or in other processing functions, which contribute to learning and are not caused by low intelligence quotient (IQ), visual/hearing handicaps or extraneous factors like parental education and family environment*". These children are not intellectually disabled and have normal or even above average IQ.

Prevalence: Although frequently underdiagnosed, LDs are estimated to be present in ~5–15% of Indian school children, almost six times more common in boys than in girls.

Pathogenesis: Achievement of academic skills requires normal development of many domains including: (a) attention span, (b) cognitive function, (c) memory, (d) speech and language, (e) neuromotor coordination, (f) visual-spatial capability, (g) temporal-sequential order, and (h) personal–social relationship.

Children with LDs have abnormalities in either all (*generalized learning disorders*) or some of these fields (*specific learning disabilities or SLDs*).

Etiology: Exact etiology of LDs is difficult to ascertain in majority of cases, though some inherent or environmental factors have been associated with higher risk, as follows:

a. *Prenatal factors*, e.g. maternal malnutrition, smoking, alcoholism, intrauterine infections and placental insufficiency, e.g. toxemia, etc.
b. *Perinatal complications*, e.g. birth asphyxia, hypoglycemia, hyperbilirubinemia, etc.
c. *Postnatal problems*, e.g. malnutrition, anemia, head injury, lead poisoning, drugs, e.g. anticonvulsants, chronic infections and illnesses, e.g. epilepsy.
d. *Genetic defects*, e.g. Down syndrome, Turner syndrome, Klinefelter syndrome, Fragile X syndrome, Duchenne muscular dystrophy, phenylketonuria, etc.

About 25–65% dyslexic children have a parent or sibling with dyslexia. Some of them have been identified to have under-activation of posterior brain regions and overactivation of anteroinferior frontal regions during the reading process.

Clinical presentation: LDs in children mainly include three different types of presentations-dyslexia (70–80%), dysgraphia (30–40%) and dyscalculia (15–20%), with frequent overlapping or co-existence.

Dyslexia (Reading disability) is the commonest SLD, characterized by *persistent, unexpected difficulty in reading in children or adults*, who otherwise possess normal intelligence, motivation and opportunities to learn. Proper comprehension of written and oral words requires *phonetic processing*, i.e. segmentation of each word into smaller units, before central decoding. Dyslexic children lack this ability of segmentation, leading to slow and incorrect reading, skipping words and lines or substituting common phonetic words. These children like to listen to stories but find it difficult to read them. Dyslexia usually manifests when the formal reading starts, i.e. in first standard of the school, when the focus is on reading to learn than on *learning to read*.

Dysgraphia (Writing disability) presents with problems in hand-writing, e.g. frequent errors in spellings, grammar and sentence formation and shape and size of written alphabets. Children have difficulties in copying from the board and often produce a disorganized text that is difficult to follow. Dysgraphia is almost always associated with dyslexia and is usually not recognized till II/III standard of the school, when written work increases.

Dyscalculia (Mathematical disability) is usually picked up last in V/VI grade or even later, when complex calculations are introduced in schools. Dyscalculia presents with problems in identifying numbers, retrieving arithmetic combinations and understanding language of mathematics, e.g. numbers and symbols. Students may reverse numbers or make errors while reading them aloud.

These problems are usually seen in conjunction with dyslexia or dysgraphia, Mathematical calculations require ability to understand words associated with arithmetic operations and word problems, which can aggravate difficulties in acquiring mathematical skills.

Other types of SLDs, e.g. *dysorthographia* denote spelling difficulties and *dysnomia refers to* difficulty in finding correct word/s for expression. Uncommon LDs includes *auditory processing disorders* (difficulty to comprehend sounds), *language processing disorders* (difficulty to understand spoken words), *non-verbal learning disabilities* (difficulty to understand non-verbal clues) and *visual perceptual deficits* (difficulty to understand visual clues).

Some children with LDs also have ***comorbidities,*** e.g. *problems in attention span* (attention-deficit hyperactivity disorder), *neuromuscular coordination* (Apraxia) and *personal-social adjustments* or social communication disorders (autism spectrum disorders). Many of them also develop secondary behavioral problems, e.g. frustration, low self-esteem, anxiety neurosis and ticks.

TABLE 3.12: Early indicators of learning disabilities

- **Pre-school**
  - Delayed language development
  - Difficulties in learning colors, shapes, etc.
  - Difficulties in learning alphabets, numbers, etc.
  - Problems in pronunciation
- **Early-school**
  - Slow development of vocabulary
  - Repeated spelling mistakes in reading/writing
  - Letter reversals (b/d), inversions (m/w), etc.
  - Problems with left-right discrimination
  - Illegible hand writing
- **Late-school**
  - Difficulty in rhyming words
  - Difficulty in written expression
  - Difficulty in calculations

Diagnosis: LD is a leading cause of poor school performance and the role of school-teachers is vital in early recognition and referral of these children as also the role of pediatrician to guide parents correctly. Some common indicators for suspecting LD in a child are listed in **Table 3.12**, though it can be diagnosed only after the formal education starts or later, provided there is evidence of onset during the years of formal schooling.

Assessment for LD should begin with assessment of– (a) educational history and (b) class-room activities, (c) Intelligence Quotient, (d) visual and hearing functions, followed by, (e) formal psychometric (processing and learning ability) testing.

Formal evaluation of these children involves a battery of specific tests, e.g. *Woodcock-Johnson test of achievement*, *Wechsler individual achievement test*, etc. or locally developed tests, e.g. *National Institute of Mental Health and Neurosciences (NIMHANS) index*. NIMHANS index test differs for children aged 5–7 years (Level I) and 8–12 years (Level II) and has the advantage of availability in Hindi and some regional languages apart from in English.

However, before interpreting these tests, it is important to ensure that these children have:

a. Normal Intelligence Quotient (IQ) on standard IQ tests,
b. Normal visual and hearing functions on relevant assessments,
c. Tests are administered in the language that they understand

Management of LDs requires cooperation from child, parents, peers and school teachers and should involve school counsellors, pediatricians, psychologists, psychiatrists, social workers and education consultants. Important principles of management of these cases

include (a) parental counselling, (b) remedial education, (c) curriculum modification, (d) bypass strategies with strengthening of un-affected skills, (e) accommodative provisions during teaching and examinations.

Schooling: While these children have problems in coping with routine pace of learning, it is preferable to continue regular schooling with suitable modifications, e.g. small-group teaching by specially trained teachers (Special educators) rather than to shift them in special schools. Teachers should be sensitized about the limitations and needs of a child with LD. Under the Right to Education (RTE) Act, all SLD children should be taught in regular schools with provision of a special educator in each school.

Remedial education includes: (a) assessment of the child's strengths and weaknesses in academic skills, (b) altering the pace and mode of teaching, (c) development of an individualized education program with well-defined short-term and long-term goals, (d) and monitoring the child's progress. Interventional sessions, (*i.e.*, twice-or thrice-weekly) could be offered in the school or outside regular school hours. The key is to monitor significant time-bound progress in the child's academic skills and social behavior and confidence.

Accommodation provisions help an older child with: (a) permission to use calculators, (b) *extra time* to complete the task or test, (c) *no deduction* of marks for grammar/spelling mistakes, (d) permission to use a writer during examinations, (e) provision for grace marks. Many educational boards provide these provisions to LD children which vary from one State of India to another.

Teaching strategies: Teachers as well as parents need to be adopt the some strategies in class room and at home, as follows–(a) review the information about previous lesson, before beginning a new lesson; (b) clearly state what the student is expected to learn during each lesson; (c) describe how the student is expected to behave during the lesson, *e.g.* not to talk with peers if the assigned task is found to be difficult, but to raise his/her hands to get the teacher's attention; (d) state all materials that the child will need during the lesson, e.g. crayons, scissors and colored paper for an art project rather than leaving the child to figure out the need of materials; (e) psycho-educational interventions, e.g. seating the child near the teacher to minimize classroom distractions, etc.

In recent *Rights of Persons with Disability Act 2016*, LD has been included and recognized as a disability.

Prognosis: Learning disabilities persist throughout life, though it is usually possible to achieve adequate academic skills and school performance with appropriate teaching and learning techniques. The child's social and emotional well-being should also be prioritized.

3.8 HEARING DISORDERS

Hearing is the essential sensory pathway for development of speech and presence of even mild hearing loss in early childhood may affect speech, learning and psychosocial development.

Severity of hearing loss is categorized on the basis of *unperceived* sound decibels (db), as mild (16–30 db), moderate (31–50 db), severe (50–70 db) and profound (>70 db), i.e. a child with profound hearing loss cannot hear a sound even as loud as 70 db and can hear sounds only louder than 70 db normal conversational speech produces ~55 db of sound.

Incidence: Moderate to severe hearing loss is estimated to be present in ~0.1–0.5% children, apart from a larger number of undetected cases with mild hearing impairment. Less than 10% of hearing impaired children have severe or profound deafness.

Etiology: Common causes of hearing impairment **(Table 3.13)** are broadly classified into 4 groups:

a. ***Conductive hearing loss*** (CHL) due to interference in the mechanical transmission of sounds to the inner ear. These disorders respond well to treatment.
b. ***Sensorineural hearing loss*** (SNHL) due to damage to the cochlea or the auditory nerve. These disorders are usually irreversible. Most cases of congenital hearing loss are sensorineural hearing loss in nature and genetic in origin. Mutations of a single gene GJB2 may be responsible for over 50% cases of congenital SNHL.
c. ***Mixed hearing loss,*** where early treatment of CHL is necessary to minimize the disability.

TABLE 3.13: Common causes of hearing loss

A. Conductive hearing loss
- Congenital anomalies of middle ear
- Acquired defects:
  - *Ear canal:* Otitis media, foreign body, cerumen
  - *Tympanic membrane:* Perforation, sclerosis
  - *Ossicles:* Cholesteatoma, otosclerosis, tumors

B. Sensorineural hearing loss
- *Pre-natal causes:*
  - Familial
  - *Genetic:* Pendred syndrome, Alport syndrome
  - *Congenital* cochlear anomalies
  - *Intrauterine (TORCHS) infections*
- *Post-natal causes:*
  - *CNS infections:* Meningitis, encephalitis
  - *Trauma:* Head injury, noise trauma, surgery
  - Tumors and lesions of VIII cranial nerve
  - *Drugs:* Aminogycosides, quinine
  - *Toxins:* Lead poisoning

C. Central auditory problems
- Cerebral palsy
- Mental retardation

***TORCHS:** Toxoplasmosis, rubella, CMV, herpes, syphilis

d. ***Central auditory problems:*** These children have normal propagation of auditory stimuli to central auditory areas, but further processing, i.e. comprehension of spoken words, is impaired. Audiograms are typically normal in these cases.

Clinical presentation and age of diagnosis depends on the severity and type of hearing loss as well as whether it is unilateral or bilateral. Lack of startle response in the newborn to a sound is often the earliest indicator of hearing impairment, apart from others listed in **Table 3.14**. Unilateral hearing defects lead to problems in localizing the source of the sound.

Diagnosis of hearing problems depends on routine screening of high-risk cases or on clinical suspicion of hearing impairment, with following age-appropriate tests:

a. *Oto-acoustic emissions* (OAE) *test* is a simple bed-side screening test to assess neonatal screening, though with poor sensitivity. It is performed by a special machine, placing the small probe in the newborn's ear canal. When the machine triggers a click sound, sound waves travel from the external ear to inner ear and cause outer hair cells of the cochlea to move, producing sound detected by the probe. It indicates normal cochlear function.

b. *Audiometry brain stem response (ABR)* is the more reliable screening test to assess the hearing function in infants and to differentiate the high-tone deafness (SNHL) from low-tone deafness (CDL). Various types of audiometric evaluations, suitable for different age groups include-behavioral response audiometry (<6 months), visual reinforcement audiometry (6 months–3 years), play audiometry (3–5 years) and Pure-tone audiometry for children > 5 years.

Brainstem evoked response audiometry (BERA) is the most reliable test for early diagnosis of hearing loss even in newborns.

TABLE 3.14: Indications for hearing assessment

A.	**Presence of high-risk factors** • Family history of hearing impairment • *High-risk neonates:* Preterm, asphyxia, hyperbilirubinemia • Craniofacial anomalies • Cerebral palsy or mental retardation • *CNS infections:* Meningitis, encephalitis • Chronic otitis media
B.	**Clinical suspicion of deafness** • No startle response at birth • No turning of head towards the sound by 3 months • No response to name-call by 10 months • No response to gesture-free command by 18 months • Delayed language development • Learning disabilities/poor school performance.

c. *Impedance audiometry* helps to check patency of eustachian tube, tympanic membrane and ossicles by tympanometry, acoustic impedance testing and measurement of acoustic reflex thresholds.

d. *Local examination* of ear canal and testing of air vs. bone conduction by tuning-fork tests (*Rinne's* and *Weber's tests*) helps to distinguish CHL from SNHL. In CHL, bone conduction is better than air conduction, while both are affected in SNHL.

Management: Early diagnosis and appropriate management of hearing impairment is essential for normal speech development. Children given hearing aids before 6 months of age develop better speech than untreated children or those given hearing aids later. Principles of management include:

- Correction of CHL etiology, e.g. otitis media;
- Correction of SNHL by hearing aid or cochlear implants for sound amplification;
- Communication training with use of non-verbal methods, e.g. sign-language, lip-reading, etc.;
- Modified schooling, e.g. seating them on front benches or in special schools;
- Psychological and behavioral counseling for child, parents and teachers.

Prevention: Prevention of congenital deafness has been included as a disability for early identification and remedial action under *Rashtriya Bal Swasthya Karyakram* (RBSK) by screening of infants and children under age 18 years by a mobile team and provision of appropriate treatment at District Early Intervention Centres.

Indian Academy of Pediatrics recommends universal screening of newborns for hearing impairment by a two-step process, as follows:

- All newborns should be screened before the discharge from hospital with OAE and if it 'fails', should be repeated after 4–6 weeks during first immunization visit. If OAE fails again, then, these infants should be subjected to behavioral response audiometry (BERA).
- All babies admitted to intensive care unit should be directly screened *via ABR*.
- All babies with abnormal ABR should undergo detailed evaluation, hearing aid fitting and auditory rehabilitation, before six months of age.

The goal is to screen all newborn babies before one month, diagnose hearing loss before three months and start intervention before six months of age.

3.9 SPEECH AND LANGUAGE DISORDERS

Communication is the exchange of thought, words and ideas between two or more individuals. **Speech** is the communication in an audible (verbal) form. **Language** denotes the knowledge of rules for communication.

Language is a function on which the speech is constructed. Normal development of speech requires- (a) normal hearing, (b) normal neurological functions to understand, process and formulate appropriate response, and (c) normal motor structures and neuromuscular coordination required for phonation. In addition, stimulative social and emotional nurturing in the environment is also essential for development of verbal skills and language.

Etiologically speech disorders may be primarily due to **(Table 3.15)**:

a. *Disorders of receptive language*, e.g. hearing impairment, (commonest cause in children).
b. *Disorders of central processing*, e.g. CNS disorders,
c. *Disorders of expressive language* due to orofacial or phonation problems.

Clinically, expressive speech disorders may be broadly classified as follows, though many patients have multiple defects.

a. ***Resonance disorders:*** Hyper/hyponasality.
b. ***Voice disorders***: Abnormal pitch/quality of voice.
c. ***Fluency disorders:*** Stuttering, stammering, etc.
d. ***Articulation disorders***, e.g. imprecise production of sounds, e.g.
   - *Substitution*, i.e. replacement of one sound with another, e.g. height for light.
   - *Omission*, i.e. failure to produce some sounds, e.g. boo. for book.
   - *Distortion*, i.e. inappropriate sounds replacing the correct one.
e. ***Language disorders***, i.e. problems in formulation of proper language, e.g.
   - *Telegraphic speech*, i.e. inability to form sentences.
   - *Word-finding disorders*, i.e. difficulty to name a picture or in the use of gestures to explain it.
   - *Narration disorders*, i.e. inability to describe an experience or tell a story.

TABLE 3.15: Causes of speech/language delay

- ***Hearing loss*** since birth or early infancy
- ***Central processing defects***
  - Mental retardation or learning disorders
  - Autistic spectrum disorders
  - Post-meningitic/encephalitic sequelae
- ***Phonation organ defects***
  - *Structural:* Cleft palate, adenoid hypertrophy
  - *Neuromuscular:* Cerebral palsy, bulbar palsy
  - *Breathing disorders:* Chronic lung diseases
- **Environmental factors**
  - Speech problems in parents
  - Emotional deprivation
  - Bi-lingualism

Diagnosis: *Early warning signals* for speech problems in a baby include:

1. Does not babble by 6 months
2. Does not speak monosyllables by 9 months
3. Does not speak > 3 words by 18 months
4. Does not speak 2 word meaningful phrases by 2 years
5. Excessive meaningless (jargon) speech beyond 2 years
6. Does not speak simple meaningful sentences by 3 years
7. Stutters beyond 4 years
8. Any speech sound error beyond 7 years
9. Presence of pitch abnormalities at any age.

Management: Presence of speech defects needs careful evaluation, intervention and follow-up, as many of them are easily manageable. Principles of management include:

- Correction of hearing impairment, etc.
- Speech and phonation therapy,
- Training in alternate modes of expression, e.g. sign language, etc. and
- Behavioral support and counselling.

3.10 SCHOLASTIC BACKWARDNESS

Scholastic performance of a child is the measure of achievement in academic field. Unrecognized and unresolved scholastic backwardness leaves a life-long impact on the future, affecting educational achievements, employment prospects and behavioral performance.

Prevalence of scholastic backwardness in India is uncertain due to poorly defined criteria for diagnosis but estimated to be in the range of ~20–30%, being the common cause of school drop-outs.

Etiology is multi-factorial, ranging from subtle learning disabilities to frank intellectual disability or presence of function-limiting hearing/vision impairment. Environmental factors and general health of the child are also major determinants of academic performance **(Table 3.16)**.

TABLE 3.16: Causes of scholastic backwardness

Primary (organic)

- Intellectual disability
- Learning disorders (dyslexia)
- Attention-deficit hyperactivity disorder
- Visual or hearing impairment
- *Systemic:* CNS disorders, hypothyroidism
- *Drugs:* Anticonvulsants, substance abuse
- *Toxins:* Lead or aluminium poisoning

Secondary (environmental)

- *Family:* Lack of encouragement, stress
- *School:* Inappropriate teaching methods poor student–teacher relationship
- Emotional, e.g. frequent school changes
- Behavioral disorders
- Frequent school absenteeism
- Chronic diseases, e.g. asthma, epilepsy

Assessment: While scholastic performance is objectively reflected in the examination results, school teachers and parents are in best position to identify ***early warning signs*** of scholastic difficulties, e.g.:

a. Avoidance to go to school or *school phobia*,
b. Reluctance to volunteer for reading/writing activities in the class,
c. Tendency to misread/misinterpret information,
d. Difficulties in reading, writing, spelling, mathematical calculations, etc. and
e. Development of behavioral problems, e.g. frustration, aggression, defiance, etc.

A child struggling with scholastic backwardness needs early identification and comprehensive evaluation including: (a) assessment for vision and hearing, (b) general intelligence testing (IQ), (c) formal testing for learning disabilities (Ch 3.7) and (d) search for environmental factors, e.g. socioeconomic and emotional reasons, which are preventing them from achieving their full potential.

Scholastically challenged children with normal IQ scores usually have *learning disabilities*, while those with IQ ranging from 70–89 are considered as *slow-learners*. Those with lower IQ scores (<70) are likely to have intellectual disability.

Management depends on the identified cause, with non-pharmacotherapeutic management being the key. All children and families can be benefitted by a well-planned dynamic program using modalities of remedial education, life-skill training, management of comorbidities and provision of appropriate family/community support. Pharmacotherapy is useful for management of comorbidities. The physician's role as the "*conductor of this orchestra*" of support is vital as part of the journey of each family.

3.11 AUTISTIC SPECTRUM DISORDERS

The term *autistic spectrum disorder* refers to a range of clinically similar disorders with variable severity, all characterized by a *diad* of: (a) impaired social communication and interaction, and (c) rigid, repetitive or obsessive behavior.

Earlier terms of childhood autism, infantile autism, Asperger's disorder, pervasive developmental disorders are now all included under the umbrella of autistic spectrum disorders.

Incidence: While reported incidence of autism in India is in ~1 in 65 children aged 2–9 years, under-diagnosis is common and incidence seems to be rising due to increasing awareness. Autism is 3–4 times more common in males and in high socioeconomic strata, perhaps due to better chances of detection.

Etiology is not well established though ASDs are frequently associated with: (a) family history, (b) chromosomal disorders, e.g. fragile X chromosome, (c) genetic disorders, e.g. phenylketonuria, (d) intrauterine infections, e.g. rubella, (e) congenital brain malformations, e.g. hydrocephalus, and (f) postnatal encephalitis, meningitis and infantile spasms. Familial or genetic predisposition is supported by ~ 80% and 20% concordance rate in monozygotic and dizygotic twins.

Clinical features: Autistic children are often mistaken as "*good babies*" in infancy, as due to poor social interaction, they do not demand much attention. Average age of diagnosis in Indian children is ~3–6 years, though reliable diagnosis can be made as early as 18–24 months of age. Infants who demonstrate echolalia or abnormal hand movements or spinning, etc. should be evaluated for Autism spectrum disorder. Delayed development of verbal and non-verbal communication is usually the initial parental concern in second year of life, with gradual recognition of typical features, as follows:

a. *Impaired social interaction:* These children do not show any interest in their parents and do not make friends. They are withdrawn, spend hours in solitary play, often preoccupied with trivial objects, e.g. buttons or parts of their own body.
b. *Impaired communication with* lack of both, verbal as well as non-verbal communication skills. Even after the development of speech, they are unable to sustain a conversation and have other abnormalities, e.g. echolalia, pronominal reversal, nonsense rhyming, etc.
c. *Stereotype behaviors*, i.e. inordinate desire for *sameness* with rigid interests and repetitive or obsessive activities. These children tend to play for many hours with one object, alone, and do not want to be disturbed.
d. *Associated behavioral problems*, e.g. hyperactivity, short attention span, impulsivity, aggressiveness, temper tantrums are common. Most of them have odd responses to sensory stimuli, e.g. higher pain threshold or over-sensitivity to touch, sound, light, odors, etc.

Intelligence is almost always affected with average IQ of <70 in most cases and many cases have seizures or associated problems, e.g. abnormal gait, toe-walking, etc.

Diagnosis of autism is essentially clinical, based on the DSM V criteria **(Table 3.17)**. However, the assessment of its severity and presence of co-existing abnormalities require: (a) comprehensive assessment of hearing, speech and language, (b) periodic evaluation for cognitive functions (IQ testing), social adjustment, verbal and non-verbal communication, (c) evaluation for secondary behavioral disorders.

Indian Academy of Pediatrics (IAP) recommends that:

a. All children should be screened by a standardized autism screening tool at 18 and 24 months of age, e.g. Modified Checklist for Autism in Toddlers (M-CHAT-R™) **(Table 3.18)**.

TABLE 3.17: Diagnostic criteria for autism (DSM V)*

A. Persistent deficit in social interaction (All four)
- **Deficit in social-emotional reciprocity**
  - Abnormal social approach,
  - Failure of normal back-and-forth conversation
  - Poor sharing of emotions/interests
  - Failure to initiate/respond to social interaction
- **Deficit in normal verbal communication**
  - Poor eye contact or body language
  - Deficit in understanding/use of gestures
- **Deficit to develop/ maintain relationships**
  - Difficulty in adjusting behavior with social context
  - Difficulty in sharing imaginative play
  - Difficulty in making friends

B. Restricted and stereotype behavior (At least two)
- Stereotype, repetitive motor movements/ speech
- Insistence on same, rigid routine
- Restricted, fixed interests (attachment to objects)
- Hyper-/hypo- reactivity to sensory inputs, e.g. indifference to pain, visual fixation with lights

C. Symptoms since early childhood, though masked

D. Symptoms causing significant functional impairment

E. Not explained by intellectual disability or other causes

*Modified for brevity.
Severity for criteria A and B must be described in 3 levels:
Level 3 – requires very substantial support,
Level 2 – requires substantial support, and
Level 1 – requires support.

b. If the screening test is positive, they should be referred for expert and comprehensive evaluation assessment and timely initiation of intervention. Indian Scale for Assessment of Autism (ISAA) or Childhood Autism Rating Scale (CARS) are commonly used tools to confirm the diagnosis.
c. Children <18 months should also be evaluated for social communication skills and must be followed up, till formal screening

M-CHAT-R™ is a simple and freely available screening tool for ASD in toddlers between 16 and 30 months of age **(Table 3.18)**. As a screening tool, M-CHAT-R™ aims to maximize sensitivity and detect as many cases of ASD as possible and hence, has a high false-positive rate. A follow-up test (M-CHAT-R/F™) is also available for borderline cases, though no child should be diagnosed as ASD on the basis of M-CHAT alone (which is only a screening test), but must be referred for further assessment.

D/D of autism includes other cause of inattentiveness and poor communication, e.g. deafness, intellectual disability, developmental language disorder, childhood schizophrenia and attention-deficit hyperactivity disorder.

Rett syndrome is a rare, X-linked disorder, almost exclusively seen in females (lethal in males), characterized by normal development till 6–12 months, followed by regression of motor and linguistic milestones, secondary microcephaly, and stereotyped hand movements, e.g. hand-wringing.

Management of autistic children is a long process and aims to achieve as much functional independence as possible and requires a multi-disciplinary team approach involving pediatrician, developmental pediatrician, psychologist, occupational therapist, speech therapist, special educator, etc.

Intervention should begin as early as possible, even while confirmation of the diagnosis is in progress and should be specific, evidence-based, structured and appropriate to the developmental needs of the child.

Aims of the management have to be realistic and include:
a. Enhancing eye contact, social orientation, nonverbal and verbal communication,
b. Reducing repetitive/restricted behaviors, sensory issues and hyperactivity, and
c. Improving social, motor, and behavioral capabilities. Many good interventional models are in use for these children.

Important components of management include:
a. ***Pharmacotherapy,*** though not curative, is a valuable tool to control certain symptoms. Choice of drug depends on predominant symptoms and includes: (a) Methylphenidate to control hyperactivity (PO 10–40 mg/day in morning), (b) Atomoxetine (PO 1.2 mg/kg/day) , if methylphenidate is not tolerated, (c) Risperidone to control aggressive and self-injurious behavior (PO 0.5–3.5 mg/day), (d) Fluoxetine to control repetitive and rigid behaviors (PO 2.4–20 mg/day), and (e) Melatonin (PO 0.5–1. mg/day) before bed-time for insomnia. Other drugs may be required for co-morbidities, e.g. anxiety, mood disorders, etc.
b. ***Play therapy, language therapy and behavior therapy*** using operant conditioning, have shown promising results in some cases as also psychotherapy in children with at least some communication.
c. ***Educational management:*** While inclusive education is the ideal goal, it needs to be rationalized and based on individual situation. An appropriate individualized educational plan should reflect accurate assessment of the child's strengths and vulnerabilities and their relation to academic skills. Curriculum modification may be required to meet the education needs and capabilities of the child. Individualized planning for education and imparting practical skills should be made.
d. ***Family therapy*** is required for parents to understand the problem and cope with the stress of the illness. Currently, many support groups involving affected parents, health professionals and voluntary organizations are working in India for this purpose.
e. ***Disability support:*** Under the Disability Act 1999, ASD is recognized as a disability, after certification by a designated Autism Certification Medical Board.

TABLE 3.18: M-CHAT- R™

*Please answer these questions about your child. Keep in mind how your child usually behaves. If you have seen your child do the behavior a few times, but he or she does not usually do it, then please answer **no**.*

1.	If you point at something across the room, does your child look at it? *(e.g. if you point at a toy or an animal, does your child look at the toy or animal?)*	Yes/ No
2.	Have you ever wondered if your child might be deaf?	Yes/ No
3.	Does your child play pretend or make-believe? *(e.g. pretend to drink from an empty cup, pretend to talk on a phone, or pretend to feed a doll or stuffed animal?)*	Yes/ No
4.	Does your child like climbing on things? *(e.g. furniture, playground equipment, or stairs)*	Yes/ No
5.	Does your child make unusual finger movements near his or her eyes? *(e.g. does your child wiggle his or her fingers close to his or her eyes?)*	Yes/ No
6.	Does your child point with one finger to ask for something or to get help? *(e.g. pointing to a snack or toy that is out of reach)*	Yes/ No
7.	Does your child point with one finger to show you something interesting? *(e.g. pointing to an airplane in the sky or a big truck in the road)*	Yes/ No
8.	Is your child interested in other children? *(e.g. does your child watch other children, smile at them, or go to them?)*	Yes/ No
9.	Does your child show you things by bringing them to you or holding them up for you to see – not to get help, but just to share? *(e.g. showing you a flower, a stuffed animal, or a toy truck)*	Yes/ No
10.	Does your child respond when you call his or her name? *(e.g. does he or she look up, talk or babble, or stop what he or she is doing when you call his or her name?)*	Yes/ No
11.	When you smile at your child, does he or she smile back at you?	Yes/ No
12.	Does your child get upset by everyday noises? *(e.g. does your child scream or cry to noise such as a vacuum cleaner or loud music?)*	Yes/ No
13.	Does your child walk?	Yes/ No
14.	Does your child look you in the eye when you are talking to him or her, playing with him or her, or dressing him or her?	Yes/ No
15.	Does your child try to copy what you do? *(e.g. wave bye-bye, clap, or make a funny noise when you do)*	Yes/ No
16.	If you turn your head to look at something, does your child look around to see what you are looking at?	Yes/ No
17.	Does your child try to get you to watch him or her? *(e.g. does your child Yes No look at you for praise, or say "look" or "watch me"?)*	Yes/ No
18.	Does your child understand when you tell him or her to do something? *(e.g. if you don't point, can your child understand "put the book on the chair" or "bring me the blanket"?)*	Yes/ No
19.	If something new happens, does your child look at your face to see how you feel about it? *(e.g. if he or she hears a strange or funny noise, or sees a new toy, will he or she look at your face?)*	Yes/ No
20.	Does your child like movement activities? *(e.g. being swung or bounced on your knee)*	Yes/ No

Reproduced with permission:

For all items except 2, 5, and 12, the response "NO" indicates ASD risk; for items 2, 5, and 12, "YES" indicates ASD risk. Following algorithm maximizes psychometric properties of the M-CHAT-R:

- **LOW-RISK (Total Score 0-2)** No further action required unless surveillance indicates risk for ASD. However, rescreen after second birthday, if child is < 24 months old.
- **MEDIUM-RISK (Total Score 3-7)** Administer M-CHAT-R/F (Not included here). If the remains at 2 or higher, child has screened positive and refer for further evaluation. If score on follow-up is 0-1, child has screened negative and no further action required unless surveillance indicates risk for ASD. Child should be rescreened at future visits.
- **HIGH-RISK:** Total Score is 8-20; refer immediately for diagnostic evaluation and eligibility evaluation for early intervention.

Prognosis: Autistic children, reared in a positive environment, show some improvement during early school years. However, symptoms tend to aggravate during adolescence with deterioration in behavioral and cognitive skills, additional psychiatric problems and appearance of epilepsy, especially in girls. As sexual drive increases, they may indulge in embarrassing behaviors.

Absence of communicative speech till 5–6 years of age indicates poor prognosis.

3.12 ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) is a common disorder in children, characterized by three core-groups of age-inappropriate symptoms:

a. Hyperactivity,
b. Impulsivity, and
c. Inattentiveness;

Leading to secondary problems, e.g. poor scholastic performance, conduct disorders, emotional and social maladjustment, etc.

While some children have all three components of ADHD, others manifest with abnormalities in only one or two fields. Accordingly, three major types of ADHD are recognized:

a. ADHD, combined type (~60–70%)
b. ADHD, predominantly inattentive type (~25–30%)
c. ADHD, predominantly hyperactive/impulsive type (~8–10%)

Prevalence: Reported prevalence of ADHD varies according to diagnostic criteria, awareness among health professionals and cultural norms of the community. Frequently under diagnosed, ADHD is estimated to be present in ~10% of Indian children, with striking preponderance in boys (4–6:1). Boys are more likely to be hyperactive/impulsive, while girls are usually inattentive.

Pathology: *Hypoplasia and hypofunctioning of frontostriatal system* is considered as the key pathological defect in ADHD, with altered balance between two important neurotransmitters that modulate attention, mood and movements-neuroinhibitory *dopamine* and neuro-excitatory *norepinephrine*.

Modern investigative techniques have shown significant structural/functional abnormalities in ADHD children including:

a. smaller volumes of frontal lobes and cerebellum,
b. diminished cerebral blood flow,
c. impaired cerebral oxygen/glucose metabolism, and
d. reduced levels or end-receptor sensitivity of dopamine.

Etiology of ADHD is uncertain, currently thought to be a complex interplay of both hereditary and environmental factors. Some important causative factors include:

a. *Hereditary* seems to play a crucial role in ADHD as ~1/3rd of these cases have similar family history and concordance rate in monozygotic twins is ~75–90%. Genetic studies have implicated defect in several genes, modulating dopamine/norepinephrine action, e.g. D2 receptor gene (DRD2), D4 receptor gene (DRD4), and over-expression of dopamine transporter-1 gene (DAT-1), all located on short arm of chromosome 16.
b. *Environmental factors* seem to be more important in cases without family history. Low birth weight and prenatal exposure to maternal smoking, alcohol/drug abuse and environmental toxins, e.g. lead, dioxins and plastic constituents have been frequently implicated. Other adverse factors in family environment, e.g. psychosocial stress, maternal mental disorder, paternal criminality, low socioeconomic status, etc. have also been linked to the increased risk of ADHD.

Clinical presentations: While the diagnosis of ADHD is usually not made till school entry, most cases have abnormal behavioral traits in earlier life, e.g. excessive crying and disturbed sleep in infancy or even unusual intrauterine activity. Some of them may achieve gross motor milestones at an earlier age.

Hyperactivity/impulsivity is often appreciated earlier (at 4–5 years of age) than inattention (8–9 years). Characteristic core-group manifestations of ADHD are as follows, though all children do not have all components:

a. ***Inattentiveness,*** though commonest manifestation is often overlooked in preschool years and rarely noticed before school age. These children have difficulty in focussing their attention in situations that call for sitting *still*, e.g. classrooms or dinner tables. They can only engage themselves in brief activities and change activities frequently. Children with predominantly inattentive type of ADHD often seem to *drift away* into their own thoughts or lose track of what was going on around them.
b. ***Hyperactivity,*** the commonest cause of parental concern is usually noticed in preschool years as excessive movements, restlessness, fidgety, and shortened attention span. As pre-schoolers by nature have shorter attention span that improves with time, persistence of such behavior beyond 3 years of age is a more reliable indicator of ADHD. Even in older children and adolescents, attention span often depends on the level of interest in a particular activity. Most teenagers can listen to music or talk to their friends for hours but may be less focussed during homework. Hyperactivity tends to increase when child is tired, hungry, anxious or facing a new environment.
c. ***Impulsivity*** is closely associated with hyperactivity and often manifests as a dislike or inability for waiting for his/her turn. They interrupt others in their conversations and some of their actions may be extremely irritating or dangerous. When stimulated, they can quickly get out of control and turn aggressive or abusive.

Comorbidities: Apart from core-group manifestations, ~30–50% of these children have co-existing cognitive, learning and language disorders. Further, most of them develop secondary behavioral problems with advancing age, e.g. oppositional defiant behavior, conduct disorders, antisocial behavior and risk-taking behavior like drug abuse, sexual misconduct, teenage pregnancy, etc. Early identification and appropriate intervention for ADHD may prevent these complications in late childhood/adolescence.

Diagnosis: There is no specific diagnostic test for ADHD and diagnosis is exclusively clinical, based on DSM-V criteria **(Table 3.19)**. It should be noted that:

TABLE 3.19: Diagnostic criteria for ADHD (DSM V)*

A. Age-inappropriate behavior (A-1 or A-2)

A-1 Inattention (6 or more)

1. Fails to attend details/make careless mistakes
2. Difficulty in sustained attention during tasks
3. Does not seem to listen, when spoken directly
4. Does not follow instructions. Fails to finish task
5. Troubles in organising the tasks
6. Avoids tasks requiring sustained mental efforts
7. Loses things, e.g. toys, books, etc.
8. Easily distracted
9. Forgetful in daily activities

A-2 Hyperactivity/impulsivity (6 or more)

1. Fidgets with hands or feet
2. Leaves seat in classroom frequently
3. Runs-about/ climbs in inappropriate situations
4. Difficulty in playing quietly
5. "Often on the go" as driven by a motor
6. Talks excessively
7. Blurts-out answers before question completes
8. Difficulty in waiting for their turn
9. Interrupts or intrudes on others

B. Some symptoms evident <12 years of age

C. Symptoms present in >1 situation (home, school)

D. Symptoms interfere in social/school functions

E. Symptoms not accountable to other pervasive developmental or mental disorder

*All 5 criteria (A-E) should be fulfilled.

Note: Classification of ADHD sub-types:
– Combined type: (both A1 and A2 fulfilled)
– Predominantly inattentive type: (only A1 fulfilled)
– Predominantly hyperactivity/impulsivity (only A2 fulfilled)

a. As many of ADHD symptoms are also commonly present in normal preschool children, diagnosis should be reviewed after repeated evaluation and *preferably kept as provisional till 5 years of age*.
b. Some signs/symptoms of ADHD, e.g. verbal impulsivity and restlessness may not be evident in highly-structured situations, e.g. clinics and their absence does not preclude the diagnosis.

Considering the complex nature of disease, a multi-disciplinary assessment is necessary in all cases of ADHD, including:

a. Detailed perinatal and developmental history,
b. Psychometric testing as well as other standardized rating scales-to be completed by the parents and child's school,
c. Thorough physical examination and developmental assessment,
d. Evaluation for abovementioned diagnostic criteria,
e. Evaluation for co-morbidities or secondary behavioral problems, and
f. Psychosocial evaluation of the family and school environment. Laboratory investigations are indicated only to exclude other causes of hyperactivity/inattention.

TABLE 3.20: Guidelines for parents/teachers in ADHD

- Ensure a regular routine and environment
- Divide his/her work into small chunks
- Provide simple and clear instructions
- Make frequent eye contacts with child
- Allow liberal breaks between the tasks
- *Positive reinforcement:* Praise on task completion
- *Non-accusatory feedback* on task completion
- Avoid overstimulation/fatigue to the child
- Avoid exciting TV programs/games at bed time
- Keep dangerous articles beyond the child's reach
- Be loving but consistent and firm with child
- Encourage peer-relations and teach social skills
- Promote his strengths to build self-confidence

D/D: Although features of ADHD are quite characteristic, transient/persistent hyperactivity or inattention may also be due to: (a) allergies, (b) sleep deprivation, (c) chronic physical disability, (d) sensory impairment, e.g. hearing/visual defects, (d) chronic physical disability, (e) intellectual disability, (f) seizure disorders, e.g. absence seizures, and (g) drug toxicity, e.g. anticonvulsants.

Management aims to improve functional outcomes, e.g. decrease hyperactivity and impulsivity levels, improve social and academic functioning, along with treatment of co-morbid conditions. Effective interventions may be broadly divided into two categories: (a) behavioural management, and (b) pharmacotherapy.

Behavioral management should begin as soon as possible, even in pre-school phase before confirmation of diagnosis and should include: (a) *Positive reinforcement,* e.g. rewarding the child after successful completion of given task, (b) *Negative reinforcement,* e.g. withdrawing a reward after an unwanted behavior, (c) Time-outs, e.g. asking the child to stay away for some time after a unwanted behaviour. Some important guidelines for parents/teachers are given in **Table 3.20**.

Pharmacotherapy is largely needed for older children and should not be started before the confirmation of diagnosis at ~6–7 years of age and the family has been counselled about purpose of medications, i.e. *to control the symptom and not to cure the disease*. Parents should be advised that 2–6 weeks of medication may be needed for any therapeutic effect.

Psychostimulants, e.g. *methylphenidate* (MPH), is the cornerstone of pharmacotherapy in ADHD, which boost and balance the level of neurochemicals, e.g. dopamine and norepinephrine, by facilitating their synaptic release and inhibiting their reuptake. About 70–80% cases show positive response to stimulants as reduced hyperactivity, increased attention span, and improved visual/motor skills. However, these agents do not directly address other problems, e.g. academic failure or social maladjustment.

Dosage and frequency requirements of MPH vary in different children. Usually, therapy should begin with a low dose of PO 5 mg/dose 30 minutes after meals and should be increased gradually to maximum of 60 mg (never >2 mg/kg) according to the clinical effect. The action begins with 20–30 minutes with peak effect at 1–2 hours and lasts for 3–5 hours. Side effects, e.g. anorexia, headache, abdominal discomfort, mood instability and insomnia (MPH should not be given after 4 PM) are common at the onset of therapy but rarely require dosage modifications and disappear after a few days. Other side-effects, e.g. tics or persistent hypertension are rare and may require dose reduction.

Long-term use of MPH is known to cause growth suppression and *intermittent drug vacations* are recommended to minimize growth effects. A child with the predominantly inattentive type of ADHD may need medication only on school days, while a child with difficulty in peer relationships may need it every day. A child who participates in afterschool academics or sports activities on certain days of the week may require longer-acting preparations or more frequent dosing on those days.

Atomoxetine hydrochloride, a non-stimulant norepinephrine transport inhibitor, has been recently established as safe and effective alternative. It should be started with a lower dose of PO 0.5 mg/kg/day for at least first 3 days and gradually increased to maximum 1.2 mg/kg/day. Unlike psychostimulants, which are predominantly useful in hyperactive children, atomoxetine has shown effectiveness in both the inattentive and hyperactive symptoms domains.

Dietary interventions, e.g. elimination of foods considered as allergens, e.g. wheat, milk, eggs, etc. or diets incriminated to increase hyperactivity, e.g. sugar, chocolate and caffeine, etc. are of no proven value, as also the *Fein-Gold* diet (free of additives).

Prognosis: ADHD is incurable but can be managed successfully in most cases. Hyperactivity/impulsivity usually lessens with age, often replaced by other problems, e.g. antisocial behavior and learning difficulties. Inattention tends to persist throughout the life. In general, 30% children show near-complete resolution of symptoms by adulthood, 40% persist with some symptoms but overall adequate functioning and the rest continue to have severe dysfunction with secondary complications, e.g. anti-social behavior. Adults with childhood ADHD have a higher likelihood of emotional and social problems, unemployment, and criminality.

Unfortunately, ADHD is not recognized as a disability under the Disability Act 1999, as of now.

CHAPTER

4

Behavioral Disorders

Jane JE David, Mukesh Agrawal

Development of behavior in children is a complex process, influenced by *inherent temperament* as well as *exogenous influences*, e.g. family/social environment and organic brain disorders, e.g. genetic or chromosomal disorders **(Table 4.1)**. Consequently, all children, like all adults, have unique behavioral traits, usually within the acceptable limits of deviance. It is important to differentiate these benign aberrations from more serious behavioral or psychopathic disorders, which require detailed evaluation, expert referral and intensive management.

The term "behavioral disorders" denote a *spectrum of abnormal behavior patterns in children, ranging from transient, minor and essentially benign habit disorders to chronic and debilitating psychiatric illnesses.* While termed as *disorders*, many of these problems in children are mere aberrations in normal behavior, which may disappear with age. Some important and common behavioral problems are discussed in this chapter.

TABLE 4.1: Determinants of child behavior

- **Biologically inherent temperament,** e.g.
  - Easy vs. difficult (fussy) babies
- **Organic causes:**
  - *Chromosomal:* e.g. Klinefelter or Fragile X chromosome
  - *Genetic:* Phenylketonuria
  - Organic brain injury
    - *Prenatal:* CNS anomalies, substance abuse
    - *Perinatal:* Birth asphyxia
    - *Postnatal:* Infections, epilepsy
  - Physical/mental handicaps
- **Environmental causes**
  - *Family factors:*
    - Parental personality, intelligence, education
    - Parent-child bonding (love, rejection, indifference)
    - *Child-caring behavior:* Overprotection/discipline
    - Inconsistent parental behavior (confusion)
  - *Extra-family factors:*
    - Social/economic discrimination
    - Frequent change of schools/ residence
    - Stressful school environment
    - Peer-pressure
    - Effect of mass media, role models
- **Learning and conditioning influences**

4.1 FUSSY INFANT

Fussy infant, while difficult to define, is an *infant who tends to be more demanding or difficult to please*. These babies are often irritable and inconsolable even for minor matters.

Each baby has a different temperament and occasional fussiness is not uncommon, which might be their way to express pain, discomfort or frustration. However, persistent fussiness might be an early sign of more serious underlying problem.

Thomas and *Chess* classified babies in terms of temperament as follows:

- **Easy babies (**40%) who adjust easily to new situations and quickly establish routines. These babies are generally cheerful and easy to calm.
- **Difficult babies (10%),** who are slow to adjust to new experiences and likely to react negatively and intensely to stimuli and events.
- **Slow-to-warm-up babies (15%),** who are somewhat difficult at first but become easier over time.

Temperament of each baby is inherently determined though can be modified to some extent by parents and child rearing practices.

Etiology: All infant may be occasionally fussy due to: (a) *Physical discomfort*, e.g. hunger, wet diapers or diaper rash, lack of sleep, unpleasant hot/cold or noisy environment, (b) *Emotional stress* or frustration, e.g. loneliness, separation from mother, stranger anxiety, or (c) *Feeding difficulties*, e.g. low milk output or nipple confusion often make baby irritable **(Table 4.2)**.

However, persistent fussiness may be a warning signal of more serious underlying health problem and needs to be investigated further before labeling him/her as a fussy infant/child.

Management: Most infants are usually little fussy during early infancy (1–3 months) and no specific intervention is required except: (a) identification and removal of physical discomforts, e.g. hunger, wet diapers, unpleasant environment, etc; (b) exclusion of serious

TABLE 4.2: Causes of fussy infant

- **Physical causes**
  - Hunger/feeding difficulties
  - Wet diapers
  - Unpleasant hot/cold
  - Noisy environment
  - Insect bites
- **Emotional stress**
  - Loneliness, separation from mother
  - stranger anxiety, etc.
  - Overstimulation: Lack of sleep
- **Painful illnesses**
  - Blocked nose
  - Ear infection (Eustachian tube block)
  - Stomach pain, e.g. evening colic
  - Teething/ toothache
  - Gastroesophageal reflex
  - Constipation
  - Undetected injury
  - Headache, CNS infections
- **Developmental issues**
  - Autistic spectrum disorders

or painful underlying illnesses, (c) reassurance to the parents, and (d) training them simple tricks to calm the baby, e.g. cuddling, swaddling, soothing sounds, e.g. humming, gentle rocking or calming motions. However, interventions, e.g. over-feeding or use of pacifiers should be avoided.

Evening colic (*Infantile colic, three-month colic*) is well-recognized entity of unknown etiology, characterized by unexplained crying spells in infants below 3–4 months of age during evenings with flexion of thighs and flushing of face. Each spell lasts for 2–3 hours and recurs with consistent regularity for many evenings (>3 days a week), before gradual cessation by 3–4 months of age.

Incidence: Infantile colic of variable severity is reported in ~5–20% of infants, more common in first-born, active babies of anxious parents.

Etiology is uncertain, probably related to aerophagia and intestinal colic, as evident from gurgling sounds and increased peristaltic movements in some cases. Crying further aggravates aerophagia, to form *colic-cry-colic* cycle.

Diagnosis depends on exclusion of other causes and typical presentation with regular periodicity and timing of spells, in an otherwise healthy and well-fed child.

Management includes—(a) reassurance to parents about benign nature of the problem, (b) training them to comfort the baby by rocking, cuddling and burping during the spell, and (c) counseling the mother about the proper feeding position and burping after feeds, anti-spasmodic drops and probiotics might be useful in some cases, though should preferably be avoided.

4.2 EATING DISORDERS

Minor feeding problems, e.g. refusal to eat, slow-feeding, picky-eating, spitting while feeding, etc. are common in infants and young children, reported by ~25–40% parents. Most of them are transient, self-limiting and are of little consequence, if the child is developing and growing normally. No intervention is required in these cases, except reassurance and guidance to parents.

Some common behavioral feeding problems in early childhood are discussed here, while others like anorexia nervosa and bulimia are largely seen in adolescents and discussed elsewhere (Ch 13.3).

4.2.1 PICKY-EATING

Picky-eating (Fussy, Faddy or Choosy-eating) is a common behavior in early childhood but may cause considerable stress to parents. It is characterized by an *unwillingness to eat familiar foods or to try new foods, as well as strong food preferences*.

Incidence: Estimated prevalence of picky-eaters varies widely from 5–50% of infants, due to lack of consistency in definition or assessment. Incidence gradually starts increasing from 18–24 months of age and peaks at ~5–6 years, before declining. Picky-eating is more common in single children of young-inexperienced parents.

Etiology is uncertain, but factors like delayed or inappropriate introduction of complimentary feeding, forced feeding, choosy dietary habits of the family itself and babies' own personality trait seem to be important among picky-eaters. Maternal eating behavior and food preferences have been also suggested to influence child's food habits.

Consequences: While energy intake in picky-eaters is usually adequate, these children are at-risk for undernutrition due to poor dietary diversity and micronutrient deficiencies. Constipation is common and some may develop serious behavioral problems, e.g. anorexia nervosa, in later life.

Some picky-eaters are also at rare risk to develop *Avoidant/restrictive food intake disorder (ARFID)*, a serious mental health problem in older children or adolescents, characterized by the overall lack of interest in food and/or aversion to eat large number of foods. Aversion may be due to the appearance, smell, taste, etc. or due to fear of adverse consequences based on past experiences, e.g. retching, vomiting or gagging, etc.

Management involves reassurance to parents, avoidance of force-feeding, encouragement or rewards to improve dietary diversity (positive reinforcement) and assessment for underlying behavioral problems in child as well as in family.

4.2.2 PICA

Pica, i.e. *perverted appetite*, is the commonest eating disorder, defined as *"a pattern of eating non-nutritive non-food substances for–(a) at least one month (b) inappropriate to the child's developmental level, and (c) not a part of culturally supported or socially normative practice" (DSM V criteria).*

Substances commonly ingested in pica are clay, dirt and mud (geophagia); paint, pencil-lead (plumbophagia), ice (pagophagia), starch (amylophagia), feces (coprophagia), hair (trichophagia), plaster, ash, wool/cloth, leaves, coal, soap, etc.

Incidence: Pica is a normal developmental behavior till 24 months of age, as infants have a tendency to mouth all objects grasped by their hands. Persistence of pica beyond this age is abnormal, estimated to be present in ~20–30% in toddlers and ~10% in older children. Incidence is relatively higher in low-socioeconomic status, similar family history and institutionalized children.

Etiology: While Pica is largely a behavioral disorder, it has been associated with: (a) mental retardation, (b) emotional neglect, (c) iron and zinc deficiency, and (d) worm infestations (? cause?? effect).

Complications: Children with pica are at risk for: (a) GIT problems, e.g. recurrent abdominal pain, diarrhea or worm infestation, (b) chronic lead poisoning and (c) iron deficiency anemia. Rarely, these cases may develop bezoars, intestinal obstruction or perforation.

Diagnosis is clinical, though investigations, e.g. hemogram (for anemia and infections) and stool examination (for worm infestations) are indicated in all cases. Serum lead estimation may be required in relevant cases.

D/D of pica includes more serious psychological disorders, e.g. autism, schizophrenia, and physical disorders, e.g. Kline-Levine syndrome.

Management of pica includes:

a. *Treatment of predisposing/complicating factors*, e.g. iron deficiency anemia, helminthiasis and lead poisoning;
b. *Parental counseling* regarding –(i) benign and self-limiting nature of problem, (ii) need to provide emotionally stimulating environment to the child and (iii) supervision to keep potentially dangerous substances out of the reach of child;
c. *Behavioral modification* strategies, e.g. positive reinforcement, occasional negative reinforcement or mild aversion therapy.

Rumination is a rare but severe vegetative disorder in infants (3–12 months), characterized by *self-induced or spontaneous regurgitation of food* after feeding (akin to anorexia nervosa/bulimia in adolescents). It is more common in males and emotionally deprived children, often leading to severe failure to thrive and occasionally death.

Severe feeding disorders of infancy or early childhood are defined as *persistent feeding disturbance with: (a) failure to gain weight or significant weight loss for at least one month, (b) no significant medical conditions, mental disorder or lack of available food*, and (c) *age of onset less than 6 years* (DSM-IV criteria).

Incidence: Severe feeding disorders are seen in only ~1–2% of under-five children, more common in those born prematurely or having some developmental handicap.

Types: These disorders are classified in many ways, usually into six sub-types: (a) *feeding disorder of state regulation*-difficulty to maintain a calm state during feeding, e.g. too sleepy or agitated, (b) *feeding disorder of social reciprocity*-no appropriate response to the care-giver while feeding, e.g. smiling or babbling, (c) *infantile anorexia*-lack of interest or refusal to eat adequate amounts of food for at least 1 month below 3 years of age, (d) *sensory food aversions*-refusal to eat foods with specific tastes, textures, or smell, (e) *feeding disorder associated with concurrent medical condition*, e.g. cleft-palate, *and* (f) *feeding disorder associated with previous insults* to the gastrointestinal tract, e.g. choking, severe vomiting, suction, intubation, etc.

Management of these serious feeding disorders requires detailed clinical and behavioral assessment, relevant investigations and a team-approach in management, which is beyond the scope of this book.

4.3 ELIMINATION DISORDERS

An infant is expected to achieve developmentally appropriate bowel control by ~18 months, bladder control by ~24 months during day-time and ~36 months during nights. Elimination disorders include problems related to these vegetative functions, e.g. enuresis and encopresis.

4.3.1 ENURESIS

Enuresis is the commonest elimination disorder, characterized by repeated involuntary passage of urine, beyond the normal age of bladder-control, i.e. ~24 months during day-time and ~36 months during nights. However, occasional bed wetting is not uncommon till 9–10 years.

Depending on the time of occurrence, enuresis is termed as nocturnal (only during sleep) or mixed (nocturnal as well as diurnal). Isolated diurnal enuresis is extremely rare.

As per DSM V criteria, enuresis is defined as "*repeated involuntary or intentional voiding of urine into bed/clothes beyond 5 years of age*, with:

a. Frequency of at least twice a week for at least 3 consecutive months, *or*

b. Presence of significant emotional distress *or* social or academic impairment, and
c. *Without* being the effect of a substance, drug or medical condition, e.g. urinary tract infection.

Incidence of enuresis varies with age, estimated to be ~3–7% at five years and ~2–3% at ten years, being more common in boys.

Etiology: Enuresis may be *primary*, in which the child has never achieved bladder control or *secondary*, in which the enuresis has re-started after a dry period of at least ≥ 6 month. Over 75% cases on enuresis are primary.

Primary enuresis is mostly functional, due to delayed maturation in bladder functions. It is more common in boys (3:1) with similar family history. Various factors attributed in causation of primary enuresis include: (a) premature and/or coercive attempts for toilet-training, (b) abnormal sleep-awake cycle, (c) lack of normal nocturnal surge in ADH secretion, (d) inadequate bladder capacity (e) mental sub-normality, and (f) emotional deprivation. Organic primary enuresis is rare (<5%), seen in cases with neural tube defects or congenital urinary tract malformations.

Secondary enuresis is usually due to *recent emotional stress* in family or school, e.g. birth of a sibling, change in school, etc., or more likely due to an underlying organic pathology. Important organic causes for secondary enuresis include: (a) urinary tract infections, (b) obstructive uropathy, (c) diabetes mellitus or diabetes insipidus, (d) neurogenic bladder, and (e) seizure disorders. Involuntary passage of urine may be the only indicator of unobserved seizure at night.

Diagnostic evaluation of these cases includes:

- *Detailed history*, specially related to age of onset (primary vs. secondary), the time of enuresis (nocturnal, mixed), similar family history, co-existing problems, e.g. dysuria, encopresis, general development and behavioral profile of the child as well as family.
- *Physical examination* to exclude organic etiology, including palpation for enlarged kidneys or full bladder, examination of external genitals and urinary stream, spinal examination for spina-bifida and detailed neurological evaluation.
- *Investigations should* begin with routine urine analysis and culture to exclude urinary tract infection, followed by other relevant tests, e.g. renal function tests, spinal X-rays, urinary tract imaging and urodynamic studies.

Management needs to be individualized in each case, depending on suspected causative or precipitating factor. Organic causes, though rare, should be looked for and treated. Broad recommendations for behavioral management include:

a. *Parental and child counseling*, regarding the nature, probable cause, correct approach towards toilet training and expected results of therapeutic interventions.
b. *Bladder stretching exercises*, e.g. voluntary holding the urine as long as possible in daytime to increase bladder capacity and repeatedly starting/stopping of stream during micturation to increase the sphincter tone.
c. *Habit modifications*, e.g. early dinner (4 hours before sleep), restricted fluid intake after dinner, voiding before retiring, waking the child at night to pass urine, etc.
d. *Behavioral modification* with positive reinforcement, i.e. rewards for dry nights. Negative conditioning, e.g. punishment or humiliation of the child should be strongly discouraged. Psychotherapy, e.g. play-therapy and hypnosis may be used in some cases.
e. *Conditioning devices*, e.g. bed-wetting alarms are useful in refractory cases, with success rate of >70%. In these devices, a sensor attached to the child's underwear or mattress is stimulated as soon as she/he wets the bed, completing an electronic circuit to buzz the alarm and wake the child.
f. *Pharmacotherapy*, should be reserved for selected cases of above 5 years of age and non-responsive to behavioral modification.
   - *Desmopressin acetate* (PO 0.2 mg single dose ~2 hours before bedtime, maximum 0.6 mg/dose) is the drug of choice for enuresis, with success rate of >50%. Treatment should continue for at least 4–6 months (or >4 weeks of consecutive dry nights) to minimize relapse, which may occur in ~70% cases. Desmopressin nasal spray are no longer recommended due to potential but rare risk of hyponatremia and seizures.
   - For resistant enuresis, anticholinergic therapy with PO *Oxybutynin* 5 mg or PO *Tolterodine* 2 mg may be used in combination with desmopressin to reduce uninhibited bladder contractions, specially in children with urge incontinence during daytime. Constipation is a potential side-effect.
   - *Imipramine* (PO 1–2 mg/kg single dose ~2 hours before bedtime), a tricyclic antidepressant to alter arousal-sleep cycle, is rarely used nowadays due to higher relapse rate (90%) and side-effects, e.g. dry mouth, irritability, insomnia and urinary retention.

Giggling incontinence is an uncommon problem in otherwise continent children, characterized by sudden, involuntary, uncontrollable passage of urine during giggling or laughing heartily. It is more common in girls. While most children overgrow this problem, urodynamic studies are warranted in some cases to exclude organic problems.

4.3.2 ENCOPRESIS

Encopresis, i.e. involuntary or intentional passage of feces in inappropriate places beyond the normal age of control, is less common than enuresis.

As per DSM V criteria, encopresis is defined as:

a. frequency of at least once a month for minimum 3 months,
b. persistence beyond 4 years of age, and
c. not due to a substance, drug or medical disorder.

Encopresis may be *Primary*, when toilet training was never achieved or *Secondary* (Regressive) when it reappears in previously continent children for over one year.

Incidence: Encopresis is more common in boys, with an estimated incidence of ~1% at 5 years of age.

Etiology: Encopresis may be classified as retentive or non-retentive.

- *Retentive encopresis* is usually due to chronic constipation with overflow incontinence, e.g. Hirschsprung's disease, anal fissures, hypothyroidism, substance (opiates) abuse and habitual use of laxatives.
- *Non-retentive encopresis* without evidence of fecal retention indicates serious emotional disturbance, often associated with suppressed anger and defiance to coercive toilet training, sexual abuse and negative defecation experiences.

Diagnostic evaluation includes: (a) detailed psychosocial history, (b) per-rectal examination and neurologic evaluation to exclude organic causes, and (c) relevant investigations, e.g. thyroid function tests, anal manometry and barium studies for congenital or acquired megacolon.

Management includes: (a) initial *treatment of constipation* with laxatives, stool-softeners or enema, (b) *prevention of further constipation* by high-fiber diet, (c) *voluntary toilet training to* encourage the child to visit the toilet 10–15 minutes after each meal to induce gastrocolic reflex, (d) *behavioral modification* i.e. positive reinforcement (rewards) for better bowel control, and (e) *psychotherapy* for precipitating and secondary psychological events.

Prognosis: Encopresis is more difficult to control than enuresis and secondary psychological problems are common, e.g. loss of self-esteem, sense of guilt/ depression and frequent school absenteeism.

4.4 HABIT DISORDERS

All children have one or more habits, i.e. repetitive pattern of movements, at some point of time. The term *habit disorder denotes unusual persistence of some habit/s, which interfere in their physical, emotional and social functioning.* Most of these disorders indicate a physical expression of underlying emotional tension (tension-discharge phenomena).

While the list of habit disorders is endless, e.g. head nodding/ banging, body rocking, eye-blinking, throat-clearing, body manipulations, some important ones are discussed here.

Bruxism is one of the commonest habit disorder, characterized by *non-functional repeated grinding of teeth* with a high-pitched sound, usually during sleep. Nocturnal bruxism occurs in ~15% children at some time during childhood.

Etiology: Bruxism is usually considered as a *tension-discharge activity* for the suppressed anger, resentment or anxiety. However, some cases may be associated with: (a) abnormal sleep activity, (b) familial behavior pattern, (c) anal pruritus, e.g. pinworm infestation, and (d) neurological diseases, e.g. mental retardation or cerebral palsy. No relationship with the dream sequence is established.

Management: Bruxism usually subsides spontaneously over time. However, severe cases need: (a) *detailed behavioral evaluation* for underlying psychological conflicts, (b) *behavioral modification* via positive reinforcement (rewards), and (c) *parental counseling* regarding the need for open communication with child. *Psychotherapy, e.g.* hypnosis and pharmacotherapy, e.g. diazepam is very rarely required.

Thumb-sucking is a common habit among infants and toddlers and most children overgrow it by 3–4 years. Persistence of this habit beyond this age is abnormal.

Etiology: Thumb sucking is usually considered as an indicator of *insecurity* and *anxiety*, often associated with (a) emotional neglect, (b) over-disciplined or over-protective rearing, and (c) inherently shy or stubborn behavior.

Clinically, apart from hygiene issues, prolonged thumb-sucking may lead to significant adverse effects, e.g. (a) dental problems, e.g. malocclusion, periodontitis, (b) nail deformities, e.g. chronic paronychia, (c) speech problems, and (d) recurrent diarrhea or worm infestations.

Management: No intervention is required till 4 years of age, except parental counseling. Forcible and over-enthusiastic efforts generate hostility in the child and perpetuation of this habit for a longer time.

In older children, important steps of management include: (a) *psychosocial evaluation and counseling* regarding appropriate parent-child relationship, (b) *behavioral modification* with positive reinforcement, e.g. praising the child's efforts to discard this habit, (c) *distractions,* e.g. engaging him into other activities at the time of habit activity, and (d) *treatment of physical complications*. Application of bitter substances over thumb/fingers or physical restraints, e.g. splinting of hands, may be useful in some cases, though should be avoided.

Nail-biting (Onychophagia) is a common habit in relatively older children, reported in ~30% of school children and even adolescents.

Etiology: Nail-biting too, like thumb-sucking, usually reflects suppressed *anxiety* and is relatively common in children who had thumb-sucking in early childhood. It is also a tension-discharge behavior, which sometimes borders as compulsion or overlapping obsessive-compulsive disorder. Precipitating factors include emotional stress, lack of self-confidence and self-esteem. Co-morbidities, e.g. enuresis, intellectual disability and attention-deficit hyperactivity disorder are common.

Clinically, nail-biting as base-line habit, is often aggravated during the periods of stress. In long-term, it may lead to acute/chronic paronychia, bleeding and permanent damage/deformities to nails. Recurrent diarrhea and worm infestations, e.g. enterobiasis and dental problems are also common.

Management includes: (a) *emotional support during stressful situations* to build the self-confidence of child, (b) *behavioral modification* with positive reinforcement, e.g. praising the child's efforts to discard this habit, (c) *distractions*, e.g. engaging him in other activities at the time of nail-biting, and (d) *treatment of physical complications*.

Tics are characterized by *involuntary, sudden, rapid, recurrent, non-rhythmic or stereotyped motor movements or vocalizations.* Tics are more common in school children, though also seen in children as young as 2 years.

Etiology: Tics are usually benign *tension-discharge* activities, although occasionally seen in psychiatric syndromes, perinatal problems, chorea or encephalitis.

Clinical presentation: Broadly, Tics may be classified as motor or vocal and simple or complex.

- *Simple motor tics* are repetitive, rapid contractions of functionally similar muscle groups, e.g. eye-blinking, lip-smacking, grimacing, body rocking, head banging, etc.
- *Complex motor tics* are less common and involve more purposeful and ritualistic behaviors, e.g. grooming behaviors, smelling/touching of objects, echopraxia (imitation) and copropraxia (obscene gestures), etc.
- *Complex vocal tics* include repeated use of words/phrases out of context, use of obscene words/phrases, Palilalia (repetition of one's own words), and Echolalia (repetition of last words, heard from others).

Generally, tics tend to worsen with emotional stress or parental attention and relieved on distraction or sleep. Multiple tics may be present in the same child or one tick may change to another after some time.

Diagnosis: Tics need to be differentiated from *partial seizures* and d*yskinetic/dystonic extrapyramidal disorders,* on the basis of: (a) changing frequency during stress and sleep, (b) amenability for voluntary control, and (c) normal EEG.

Tics need to be differentiated from ***stereotypies***, which are classically rhythmic, distractable and persist for long time.

Management: Although no specific management is required for benign ticks, socially distressing habits may require: (a) *parental counseling* to ignore the symptom, (b) *behavioral modification* with positive reinforcement, and rarely, (c) *drugs,* e.g. haloperidol in resistant tics.

Gilles *De La* Tourette syndrome is a rare but severe tick disorder, characterized by a *motor component,* e.g. multiple tics and a *vocal component,* e.g. compulsive barking, grunting or shouting obscene words (Coprolalia). It is more common in boys (3–4:1) and first-degree relatives of similar cases.

Etiology: Exact etiology is uncertain, though many factors, e.g.: (a) genetic defect, (b) neurobiological abnormality, (c) emotional and environmental stress, (d) dopaminergic drugs and (e) a pediatric autoimmune neuropsychiatric disorder secondary to streptococcal infection (PANDAS), have been implicated as causative or precipitating events.

Clinical features: Full-blown *Gilles de la Tourette* syndrome is relatively rare in children than in adults. Usually, the motor component appears by ~7 years of age and almost always precedes the vocal component. Early disorder with only motor component is difficult to distinguish from simple tics, though behavioral, emotional and academic problems are more common in this syndrome.

Diagnosis is largely clinical with no specific diagnostic tests. EEG shows non-specific abnormalities in ~80% cases. Verbal scores on psychometric testing are usually low.

Management includes: (a) *parental counseling* regarding the compulsive nature of behavior, (b) *behavior therapy* with positive reinforcement and c) *pharmacotherapy* with a dopamine antagonist, e.g. haloperidol or pimozide, which may reduce the severity of tics by >50%. Other drugs, e.g. clonidine, clonazepam and carbamazepine have been also used.

Prognosis: *Gellis de la Tourette* syndrome persists throughout life, though usually with a considerable reduction in symptoms after 10–15 yrs of initial diagnosis.

Stuttering or stammering is a fluency disorder of speech characterized by difficulty in initiation of some consonants, spasmodic repetition of sounds or syllables or words and pauses or interruptions in speech, known as blocks. Stuttering is common in 2–5 years of age during the phase of rapid language development and resolves spontaneously with advancing age. However, ~1% older children continue to have significant stammering, especially during stress.

Clinically, stuttering denotes unusual hesitancy to speak during the stress or excitement, aggravated when the

child is reminded or corrected while stammering. It is often absent in low-stress settings like playing alone or singing. Many cases develop secondary mannerisms, e.g. blinking of eyes or twitching of facial muscles during speaking, as well as social anxiety and low-self-esteem, avoiding social interactions.

Management includes: (a) reassurance to parents about self-regressing nature of stuttering with age, (b) avoidance of teasing or scolding the young child while stuttering, (c) encouraging loud-reading or speaking in low-stress situations without undue attention, (d) emotional support to anxious child, and (e) *speech therapy* in older children, if the problem persists. Cognitive behavior therapy may be useful in children with major behavioral issues. Drugs like haloperidol or clonidine may be considered in rare cases of socially or functionally debilitating tics.

Masturbation, i.e. stimulation of one's own genitals to derive the pleasure (also termed as gratification disorder), is common even in preschool children. About 30% of boys and 10% of girls are reported to engage in masturbation by 8 years of age, with incidence increasing to >90% by adolescence.

Masturabation is usually a benign habit, sometimes triggered by emotional disturbances, e.g. boredom, agitation or even systemic problems, e.g. abdominal pain or urethral/vaginal irritation. However, compulsive masturbation that interrupts normal activities, engage public displays or lead to development of anxiety or self-guilt, needs intervention.

Management involves reassurance about harmless nature of activity, counseling to avoid such acts in public and maintenance of hygiene, parental education and behavior therapy by experts. Medications are of very limited benefit in these cases.

4.5 SLEEP DISORDERS

Sleep pattern of a child depends on the age, behavioral pattern, frequency/duration of daytime naps and environment during bedtime. A newborn sleeps for >20 hours/day, which is gradually reduced to 8 hours by the end of first year. Circadian rhythm, i.e. day-night pattern of sleep, begins to establish by 3 months and is well established by ~18–24 months.

Biological temperament and emotional stress, e.g. separation anxiety, home/school fears, insecurity, etc. are most important causes of sleep problems in childhood, though *important organic causes* include (a) obstructive sleep apnea syndrome, (b) organic brain disorders, e.g. attention-deficit disorder or autism, (c) other, e.g. Prader-Willi syndrome.

Common sleep disorders include: (a) insomnia or interrupted sleep, (b) hypersomnia or narcolepsy, and (c) parasomnias, e.g. somnambulism (sleep-walking), nightmares or night terrors.

Parasomnia refer to abnormal behavior or motor manifestations during sleep and include:

- Parasomnias during early NREM sleep, presenting with sleep walking (awake and ambulatory), confusional arousals (awake but not ambulatory) and night terrors.
- Parasomnias during late REM sleep include night mares and bizarre movements/behavior.

All these conditions are self-limiting and no specific treatment is required except reassurance.

Night-terrors are commonest sleep problems in pre-school children, characterized by sudden arousal from sleep in disoriented state with screaming and signs of intense autonomic activity, e.g. labored breathing, tachycardia, sweating and dilated pupils. Some children may sleep-walk (somnambulism) for few minutes, before getting oriented or going back to sleep. History of a bad dream (nightmare) is often present. Though occasional attacks are common, recurrent night terrors indicate significant underlying phobia, anxiety or emotional trauma.

Narcolepsy is rare, characterized by excessive daytime sleepiness, cataplexy, sleep paralysis, hypnagogic hallucinations and poor school performance.

It is also considered as a paroxysmal disorder or seizure mimics, with attacks of irrepressible sleep attacks during day time, from which the patient is easily arousable (d/d absence seizures). EEG reveals intermittent attacks of REM sleep. Modafinil acetamide (PO 200 mg OD) is drug of choice in confirmed cases.

4.6 CONDUCT DISORDERS

Children are expected to behave within socially acceptable limits, determined by their age, social norms, training/moral standards and parent-child relationship. *Negativism*, i.e. opposition to parental instructions is a normal phase of development during 18–36 months of age, leading to anger and frustration. By 4–5 years, children learn to control their behavior.

Conduct disorders (disruptive behavioral disorders) denote an anti-social behavior, usually due to parent-child conflict, child's urge for autonomy and expression of underlying anger, defiance or frustration. Emotional neglect and over-disciplined rearing are two important determinants of early disruptive behavior, apart from biological temperament, role models and social circumstances.

While many disruptive behaviors are seen in children, common ones are breath-holding spells and temper tantrums in under-five children and lying, stealing, truancy, etc. in older children. Serious disruptive behavior disorders, e.g. juvenile delinquency, substance abuse, teen pregnancy, etc. are more common in adolescents, discussed in Ch 13.3.

4.6.1 BREATH-HOLDING SPELLS

Breath-holding spells are commonest but benign manifestations of disruptive behavior in infants and toddlers, characterized by *'sudden holding of breath in expiration (apnea), leading to cyanosis or pallor with/without loss of consciousness, hypotonia and seizures'*. Frequency of these spells may vary from occasional attacks to >10–15 spells a day.

Incidence: Breath-holding spells are most common between 6 months to 2 years of age (up to 6 years), during which ~4–5% children experience at least one of these spells. Other high-risk factors include male sex, similar family history and labile temperament.

Etiology: Breath-holding spells are means of expression in a baby for internal frustration, anger and aggression. However, these episodes are essentially involuntary in nature, also termed as non-epileptic paroxysmal disorders.

Clinically: There are two major types of breath-holding spells; the more common *cyanotic spells* and the less common *pallid spells.*

- *Cyanotic breath-holding spells* are usually provoked by anger or frustration (akin to temper tantrum in older children), with a typical sequence of events - a loud shrill cry > forced expiration > breath-holding, i.e. apnea > cyanosis and unresponsiveness. Usually, each spell does not lasts for >10–15 seconds and terminates with a deep gasp > restarted breathing and > gradual disappearance of cyanosis. Baby may remain drowsy for a few minutes after the spell, before complete recovery. However, occasional attack may progress to develop generalized seizures, opisthotonus and bradycardia. *Interictal EEG is normal.*
- *Pallid breath-holding spells*, are less common and differ from cyanotic spells in following features: (a) usually provoked by sudden painful stimulus, e.g. fall, blunt injury or loud noise, (b) pallor and limpness instead of cyanosis, and (c) usually abnormal *interictal EEG.* Pallid spells may be induced by supraorbital pressure to stimulate oculocardiac reflex, though such maneuvers are risky and should be avoided.

Diagnosis depends on typical sequence of events, though should be differentiated from epilepsy, hypercyanotic (Tet) spells in cyanotic heart diseases and cardiac arrhythmias, e.g. long-QT syndrome (d/d pallid spells).

Prognosis: Except a rare prolonged spell with significant hypoxia, breath-holding spells are essentially benign and disappear by 5–6 years of age. However, these children tend to have higher incidence of behavior problems in later life, e.g. temper-tantrums or syncopal attacks.

Management aims towards behavioral modification of the child and for early abortion of the attack, and includes:

a. *Management during the attack:* These spells can be easily aborted by physical stimulation, e.g. pinching, shaking, supra-orbital pressure, blowing air or sprinking water on the face, for which parents must be trained. Other precautions during the spell include avoidance of injury and aspiration by placing the child in lateral position, if looses the consciousness.

b. *Parental counseling:* Parents need to be reassured about benign nature of these spells and the underlying behavioral basis. It is important to emphasize the need for certain discipline and consistency in childcare. The baby's demand, which has provoked the spell, should not be fulfilled immediately on recovery (purposeful neglect). Parents should also try to divert the attention of child from a potential precipitating event.

c. *Pharmacologic therapy*: Iron supplementation may be effective in some cases to reduce the frequency of attacks, even in absence of significant anemia. In children with pallid spells, recurrence of these attacks during a painful procedure may be prevented by previous atropinization.

4.6.2 TEMPER TANTRUMS

Temper tantrum are characterized by *physical aggression*, e.g. *crying, howling, kicking, head banging, throwing objects*, etc. in relatively older children above 2 years of age. Most of them learn to control their behavior by 5 years with gradual reduction in frequency of temper tantrums.

Incidence: Temper tantrums are common in children toddlers and pre-school children (~10%), with risk factors including over-indulgent child-rearing, e.g. in single child or working parents.

Etiologically, Negativism or defiant behavior is a normal phase of behavioral development in pre-school children, aimed to ascertain their autonomy. Temper tantrums are manifestations of excessive defiance and expression of internal anger and frustration. Parental anger and frustration may reinforce this defiance. Fatigue and hunger tend to trigger these attacks.

Management includes parental counseling regarding: *(a) prevention of injury* during the attack, *(b) firm and consistent attitude* towards the child, but with good communication, *(c) purposeful neglect* during attack, i.e. ignoring the child's demand till the behavior is controlled, *(d) positive reinforcement*, i.e. praising or awarding him for periods of controlled anger. Parent should remain calm and firm during these episodes and must try to distract the child from a potential precipitating event.

4.7 ANXIETY DISORDERS

Anxiety/fear is a normal part of development, beginning with stranger's anxiety/fear by 6–8 months of age. The term *anxiety disorders or neurosis* denotes *'disproportionately excessive anxiety to a real event or undue*

anxiety to an imaginary cause'. Common types of anxiety disorders include:

a. *Phobia,* e.g. school phobia (in ~1–2% children) or social phobia, i.e. fear to meet unfamiliar people;
b. *Obsessive-compulsive disorder,* i.e. repetitive thoughts, acts, rituals, e.g. compulsive hand washing, checking of locks, etc.;
c. *Specific anxiety disorders* including separation anxiety, i.e. unrealistic worry towards parents or fear of loneliness and post-traumatic stress disorder;
d. *Generalized anxiety disorders*, more common in adolescents with unrealistic worry for future events, e.g. academic failure.

Post-traumatic stress disorder (PTSD) is an anxiety disorder seen in all age groups including children, in response to any external event, experienced or witnessed by an individual and perceived as dangerous.

Etiology: Life-threatening situations leading to serious injuries or death, e.g. riots, natural disasters, etc. are frequently associated with PTSD. Younger children, females and individuals with high-anxiety personality trait are at an increased risk of PTSD. Physical/sexual abuse is an important cause of PTSD in children.

Incidence of PTSD depends on the severity of precipitating event. Although only ~1% of exposed adults satisfy the DSM criteria for PTSD, over 15% are estimated to suffer with more non-specific stress behavior for a variable period of time. Children are more vulnerable for PTSD than adults.

Clinical features: PTSD may be acute or chronic.

Acute PTSD is characterized by: (a) recurrent recollections and dreams of the traumatic event, (b) intense anxiety, (c) sleep disturbances with startle reactions, and (d) concentration difficulties.

Chronic PTSD is generally seen in children with prolonged physical/sexual abuse, leading to changes in the attitude towards life, people, future, etc., psychologic numbing, i.e. forced amnesia and isolated life-style.

Management: Early identification and management of PTSD is essential to prevent long-term psychotic morbidity and includes:

- *Initial evaluation* to explore the child's understanding, vulnerability and reactions to the traumatic event.
- *Psychotherapy* to provide the child an opportunity to discuss the event and express his/her feelings of helplessness, sadness or anger. She/he should be helped to understand everyday events and distinguish them from past-trauma.
- *Family therapy and parental counseling* to make them understand the basis of child's behavior and encourage their participation in day-to-day management.
- *Pharmacotherapy* with drugs, e.g. *benzodiazepines* to modify the sleep and arousal behavior, in selected cases.

Stranger anxiety is a normal phase of development to appear at ~6 months and lasts till 15–18 months. During this phase, infants tend to avoid interaction with unfamiliar persons and cry or move away from them, towards the parents. No treatment is required except reassurance to parents and emotional support to the child. However, unusually intense discomfort with excessive crying, psychological distress or persistence of this phase beyond second year of life may be an indication of serious behavioral problem, e.g. separation anxiety disorder. Such cases need psychiatric referral for complete evaluation and interventions, e.g. cognitive behavior therapy.

4.8 PSYCHOSOMATIC DISORDERS

Although emotional stress is a known precipitating/exacerbating event for many medical illnesses, e.g. asthma, diarrhea or epilepsy; two specific and important psychosomatic illnesses are conversion disorder and Munchausen syndrome by proxy, discussed here.

Conversion Disorder: The term conversion disorder denotes loss or alteration of physical functioning without a demonstrable illness. This disorder is usually seen in adolescents and older children and more common in females.

Etiologically, it is considered as a physical medium of expression (somatization) of suppressed anger or frustration, especially in over-disciplined children.

Clinically, these cases may present with:

a. Conversion reactions with motor component (hysteria), e.g. mimicked seizures, paralysis, blindness, etc. or rarely,
b. Dissociative reactions, e.g. recurrent abdominal pain, vague body aches and pains, anorexia, etc.

Diagnosis usually rests on exclusion of organic cause, absence or inconsistency of clinical signs, and prolonged observation of behavior. Conversion reactions tend to increase during family/doctor's attention, though frequently, these responses are not within the patient's voluntary control (d/d Factitious illnesses).

Treatment is non-specific during acute phase except exclusion of organic/concomitant illnesses, while psychotherapy is necessary on recovery to prevent recurrence.

Munchausen by proxy syndrome is a form of child abuse; characterized by *illnesses fabricated in children by their parents*, usually mother, in order to get medical attention. These babies are repeated brought for medical consultations with non-existing illnesses, multitude of complaints or problems induced by parents themselves, e.g. bruises, hematuria, fever, vomiting, etc. and some parents even alter the laboratory samples or

temperature measurements of the child to substantiate their complaints.

Important ecological factors include disturbed family, mentally unstable mother or unwanted child.

Clinically, these children present with large spectrum of unexplained symptoms, e.g. fever, vomiting, diarrhea, seizures, hematuria, etc.

Diagnostic indicators include: (a) exotic and wide-spectrum of complaints, (b) discordant physical examination, (c) extremely anxious or unconcerned mothe, (d) history of multiple medical consultations (Doctor shopping), (e) poor response to rational therapy, and (f) absence of symptoms on separation from parents.

4.9 CHILD GUIDANCE CLINIC

Child guidance clinic (CGC) is a specialized health service, based on an *integrated and multidisciplinary approach* to deal with the behavioral and developmental problems of children and adolescents, who are not fully adjusted to their environment. The first child guidance clinic was started in Chicago in 1909.

Objectives: CGCs aim: (a) to identify children with developmental and behavioral problems, (b) to provide comprehensive management for these problems with a teach-approach, (c) to provide appropriate guidance, counseling and support to the parents and family, and (d) to refer children who need specialized services, if required.

Target problems: Individual problems attended in CGC usually include developmental delay, learning disorders, habit disorders, personality disorder, psychosomatic disorders, antisocial behavior and established psychiatric disorders, e.g. autism and attention deficit-hyperactivity disorders (ADHD).

Approach: Child guidance is a team-work comprising of psychiatrist, clinical psychologist, educational psychologist, psychiatric social worker, pediatrician, public health nurses, speech therapist, occupational therapist and a neurologist. The psychiatrist is the most important member of the team who, with others, arrives at a diagnosis and formulates the management plan.

Pediatrician is usually the first contact point for children with behavioral problems and his/her role is crucial in identification of problem, exclusion and treatment of physical causes and timely referral to the child guidance clinic.

Activities: Important functions of CGC include: (a) evaluation of new cases, (b) follow-up of old cases, (c) behavioral interventions including group therapy, play therapy and psychotherapy, (d) parental counseling and support for home management, (e) training and research in the field of behavioral and developmental disorders.

CHAPTER

5

Normal Nutrition

Radha Ghildiyal, Mukesh Agrawal

Nutrition is a dynamic process to supply adequate nourishment for survival, growth and development, repair and creation of future reserves. Weight-wise, nutritional requirements of children are relatively higher than in adults due to higher basal metabolic rate, active growth, building of stores and more pronounced physical activity.

5.1 BASIC CONSIDERATIONS

Diet is the main source of nutrition in children, though some nutrients, i.e. vitamin D and K are also synthesized endogenously in body. An ideal diet should fulfil requirements of all essential nutrients in adequate proportions and composition.

5.1.1 NUTRITIONAL REQUIREMENTS

Often used interchangeably, the term *Nutritional requirements* refers to daily physiological requirements of various nutrients to maintain normal metabolism, while the term *Dietary requirements* denote *need for* daily nutritional intake, essential to fulfil these nutritional requirements after considering absorption and other losses.

Recommended dietary allowances (RDA) is defined as the *'minimum daily dietary requirement of a nutrient in normal healthy person along with some additional allowance for individual variations to cover the needs for >97.5% of healthy (not sick) population, without the risk of over-dosage'*. National Institute of Nutrition under Indian Council of Medical Research (NIN-ICMR) has periodically revised RDA for various nutrients for Indian population, with latest recommendations in 2020 **(Table 5.1)**.

However, there is no specific RDA for energy in 2020 version, instead provided as "Estimated Average Requirement" (EAR), i.e. median daily intake, estimated to meet requirements of half of the healthy individuals in different age/sex groups.

TABLE 5.1 : Recommended dietary allowances* (RDA) for Indian children and adults

Age	*Calories* (Kcal/d)*	*Proteins (g/d)*	*Vit. A (µg/d)*	*Vit. C (mg/d)*	*Vit. D (IU/d)*	*Iron (mg/d)*	*Calcium (mg/d)*	*Iodine (µg/d)*	*Zinc (mg/d)*
0–6 months	530	8.0	350	20	400	-	300	100	-
6–12 months	680	10.5		30		3		130	2.5
1–3 years	1110	12.5	390		600	8	500	90	3.3
4–6 years	1360	16	510	35		11	550		4.5
7–9 years	1700	23	630	45		15	650		5.9
10–12 years	2220 (2060)	32 (33)	770 (790)	55 (50)		16 (28)	850	100	8.5
13–15 years	2860 (2400)	45 (43)	930 (890)	70 (65)		22 (30)	1000	140	14.3 (12.8)
16–17 years	3320 (2500)	55 (46)	1000 (860)	85 (70)		26 (32)	1050	140	17.6 (14.2)
Adults**	2710 (2130)	54 (46)	1000 (840)	80 (65)		19 (29)	1000	140	17.0 (13.2)
Pregnancy	+350	+9.5/+22[1]	900	+15		27	1000	220	14.5
Lactation	+600	+17/+13[2]	950	+50		23	1200	280	14.1

*Denote Estimated Energy requirements for calories instead of RDA, **Moderate worker
[1]In second and third trimester of pregnancy, [2]in first 6 months and during 6–12 months of lactation
Figures in parentheses represent RDA in females, wherever different from males.
Source: Dietary Guidelines for Indians, National Institute of Nutrition, Hyderabad, 2020.

TABLE 5.2: Normal energy requirements (Holiday and Segar formula)

Body weight	*Energy requirements*
<10 kg	100 cal/kg
10–20 kg	1000 cal + 50 cal/kg above 10 kg
>20 kg	1500 cal + 20 cal/kg above 20 kg

Energy is the prime essence of nutrition, required to sustain basal metabolic rate, day-to-day physical activity, normal growth, and to digest and assimilate the nutrients. *Basal metabolic rate* (BMR), e.g. the minimum energy requirement to maintain essential physiological functions of the body at rest, is highest in infancy (55 cal/kg/day) and decreases gradually with advancing age to reach adult values (25–30 cal/kg/day) by late childhood.

A normal child spends ~50% of energy requirements for BMR, 25% for physical activity, 12% for growth, 5% for digestion/assimilation of food and 8% for fecal losses.

Sources: Carbohydrates are the main source of energy in diet. An ideal diet should provide 50–60% of calories as carbohydrates, 20–30% as fats and 10–15% as proteins. *Each gram of proteins, fats and carbohydrates in diet provide 4, 9 and 4 calories, respectively.*

Requirements: Energy requirements in normal children vary according to the age and gender, provided as EAR in **Table 5.1**. For simplicity, these requirements may also be calculated with body weight by *Holiday and Segar formula* **(Table 5.2)**.

It should be noted that these are the requirements for normal and not the malnourished children, who need higher calories for catch-up growth and replacement of stores.

5.1.2 ESSENTIAL NUTRIENTS

Nutrients are the active principles in diet, each with different functions and metabolic patterns. These may be classified as:

- *Macronutrients or proximate principles*, e.g. proteins, fats and carbohydrates.
- *Micronutrients*, e.g. vitamins and minerals.

Proteins, which constitute ~20% of body weight, are important source of energy as well as required for: (a) body building, e.g. growth of muscles and different tissues, (b) repair and maintenance of tissues, (c) synthesis of substances, e.g. antibodies, plasma proteins, enzymes, hormones, hemoglobin, clotting factors, etc. (d) maintenance of osmotic pressure in various tissue compartments.

Biochemistry: Proteins are complex nitrogenous compounds made up of smaller units, e.g. *amino acids*. While some amino acids can be synthesized in body, others cannot and have to be essentially supplied from diet, termed as *essential amino acids*. In general, there are eight essential amino acids—*methionine, threonine, tryptophan, valine, isoleucine, leucine, phenylalanine and lysine* (acronym-MeTTVILPLy). Some other amino acids are essential only in infants (*histidine*) or low birth weight babies (*arginine, cysteine and taurine*).

Requirements: RDA for proteins in different age groups is given in **Table 5.1**. Protein requirements are relatively higher in PEM and during recovery from illnesses/infections, due to endogenous protein breakdown in muscles and liver to provide essential amino acids.

Sources: Dietary proteins are provided from *animal sources*, e.g. milk, meat, egg, fish, etc. as well as *vegetable sources*, e.g. cereals, pulses, beans and nuts. Quality of proteins from different sources differ, depending on the digestibility, biological value (% of absorbed proteins retained in the body) and net protein utilization or NPU (% of ingested proteins, retained in the body).

Animal proteins are nutritionally superior to vegetable proteins. *Egg is considered as a reference protein* due to its high biological value, digestibility and NPU (96%). NPU of other animal proteins is also relatively higher (cow's milk 85%, meat 76%, fish 74%) *vs* of vegetable proteins (rice 77%, wheat 61%). *Soya bean* is the richest source of vegetable protein but with lower NPU (<60%) due to poor digestibility.

Vegetable proteins also lack in certain essential amino acids, termed *'limiting amino acids'*. *Cereal proteins are deficient in lysine and threonine, while pulses are deficient in methionine.* Deficiency of limiting amino acids in vegetarian diet may be corrected by using combination of cereals and pulses in diet, e.g. rice-dal or dal-chapati.

Fats are the major source of stored energy (adipose tissue or brown fat) as well as also required: (a) as a vehicle for fat soluble vitamins, (b) as a source of essential fatty acids (c) for temperature regulation and (d) to increase palatability of food. Being the most concentrated source of energy (9 cal/kg), fats are commonly used to increase the caloric content of food without increasing its bulk.

Biochemistry: Fats are classified as *simple fats*, e.g. triglycerides, *derived lipids*, e.g. cholesterol, and *compound lipids*, e.g. phospholipids. Over 95% of dietary lipids and ~99% of stored lipids in diet are triglycerides.

Fats yield to fatty acids and glycerol on hydrolysis. Fatty acids may be classified as (a) *saturated* fatty acids, e.g. palmitic or stearic acid; *monounsaturated* fatty acids, e.g. oleic acid; and (b) *polyunsaturated* fatty acids (PUFA), e.g. linoleic acid, linolenic acid or arachidonic acid. Of these, PUFA cannot be adequately synthesized in body and have to be derived from ingested food, thus also termed *essential fatty acids* (EFA).

EFA are essential for: (a) normal growth and brain development, (b) structural integrity of cell membrane, and (c) inflammatory response to produce various mediators, e.g. prostaglandins. *EFA deficiency* has been linked with phrynoderma (dry skin), growth failure, developmental retardation, reproductive failure and increased susceptibility for infections.

Circulatory lipids usually exist in bound-form with proteins (lipoproteins), e.g. chylomicrons, high-density lipoproteins (HDL), low-density lipoproteins (LDL) and very low-density lipoproteins (VLDL). HDL has lower fat and higher protein content than LDL/VLDL, hence considered as a *good cholesterol/fat.*

Requirement: Total and saturated fat intake should not exceed 20% and 10% of total caloric intake per day, respectively. In addition, minimum 2–3% of caloric requirements should be derived from EFAs and 0.3% from linolenic acid.

Sources: Dietary fats are derived from either a *visible source*, e.g. animal fats (ghee, vegetable oils) or *invisible sources* (cereals and pulses). In Indian diet, more than half of the fat is consumed as invisible fat.

Animal fats mainly contain saturated fatty acids and are poor source of EFA. Breast milk has enough EFAs to meet the baby's requirements. *All vegetable oils, except palm oil and coconut oil, are rich sources of EFA.*

Coconut oil is a rich source of medium chain triglycerides (MCT)—the only fat that does not require bile for absorption and directly absorbed into the portal vein. Hence, it is often used in malabsorption states, chronic hepatic disease and low birth weight newborns as a human milk fortifier.

Carbohydrates are most important source of ready as well as stored energy, as well as also essential for oxidation of fats and synthesis of certain non-EFAs.

Biochemistry: Carbohydrates are consumed either as free-sugars, e.g. *monosaccharides* (glucose, fructose and galactose) and *disaccharides* (sucrose, maltose, lactose) *or* as complex-sugars, e.g. *polysaccharides,* e.g. starch, cellulose, dextrin, etc. However, all carbohydrates are finally converted to glucose for use as metabolic fuel.

Normal glucose homeostasis is maintained by three important metabolic pathways: (a) *Glycogenesis*, e.g. conversion of free glucose and fat into glycogen for storage in liver and muscles, (b) *Glycogenolysis*, i.e. endogenous breakdown of hepatic/muscle glycogen to provide free glucose in starvation conditions, and (c) *Neoglucogenesis*, i.e. conversion of endogenous or dietary proteins and glycerol into glucose, in starvation states. Unlike hepatic glycogenolysis, glycogenolysis in muscles is an anaerobic process with production of lactic acidosis, responsible for starvation ketoacidosis.

Requirements: Carbohydrates should provide minimum 50–60% of caloric intake, preferably as complex-sugars to minimize post-prandial blood glucose fluctuations.

Sources: Starch is the commonest carbohydrate in diet, present in grains, legumes and tubers. Glycogen is present only in animal sources.

Fibers are complex carbohydrates like cellulose, hemicellulose, gums, pectins, and mucilages, etc., present in plant cell walls. Although of little caloric value due to their non-digestibility (2 calories/gram *vs* 4 calories/gram for other carbohydrates), presence of adequate fibers in diet is essential for colonic water absorption and softening of stools. While vegetarian diet contains adequate fibers, low-fiber non-vegetarian diet has been linked with higher risk of constipation, colonic cancers and hypercholesterolemia.

Vitamins are non-energy-yielding organic compounds, which act as *co-factors in many enzyme systems* to catalyze cellular metabolism. Although required in miniscule amounts, vitamins are essential for normal growth and maintenance of various body functions.

Vitamins may be divided into two groups, i.e. *fat-soluble* vitamins, e.g. vitamins A, D, E, K and *water-soluble* vitamins, e.g. those of B-complex group and vitamin C. Of these, vitamins D and K is also synthesized in body (endogenous source).

Vitamin-related abnormalities may be broadly divided into: (a) *deficiency* disorders, (b) *hypervitaminosis* or *excess* states, and (c) *dependency* states, i.e. inherited errors in metabolic/enzyme activity, dependent on related vitamins. *See* Chapter 6.2–6.7 for normal vitamin biochemistry, functions, sources and deficiency states.

Minerals are non-energy yielding inorganic compounds, which contribute to ~3–4% of body weight and mainly present in bones (~80%), muscles (~10%) and body fluids (~4%). Biologically important minerals are classified as:

- *Macrominerals,* which are present in substantial amounts and their nutritional requirement usually exceeds >100 mg/day. While some of these minerals are concentrated in tissues, e.g. bones and muscles, (e.g. calcium, magnesium, phosphorus, etc.), most of them are major electrolytes in body fluids as cations (Na^+, K^+, Ca^{++}, Mg^{++}) *or* anions (P^-, S^-, Cl^-).
- *Microminerals (trace elements),* constitute <250 µg/gm of tissue matrix, e.g. iron, iodine, zinc, fluorine, etc. Minerals present in still smaller amounts (<100 ng/g of matrix) are termed as *ultra-trace elements*. Despite miniscule requirements, trace elements play significant role in human health and disease (Ch 6.8).

Anti-oxidants are important phytochemicals present mainly in vegetables and fruits. These nutrients, also termed *free oxygen scavengers*, restrict the cellular damage caused by oxygen-free radicals and provide protection

against diseases related to free-radical damage, e.g. atherosclerosis, cancer, inflammatory joint diseases, asthma, diabetes, etc. Raw and fresh vegetables like green leafy vegetables, carrots, fresh fruits including citrus fruits and tomatoes have been identified as good sources of antioxidants (Ch 6.9).

5.2 BREASTFEEDING

Breast milk (BM) is the only food that a baby needs unto first 4–6 months of life and gives the best possible nutritional start to the neonate. *Exclusive breastfeeding (BF)* means that the neonate gets only breast milk and nothing else like honey, water, juices, tonic and medicines (unless prescribed) or any other animal milk.

5.2.1 COMPOSITION OF BREAST MILK

Volume output and composition of BM changes throughout lactation period to meet changing needs of growing infants.

Daily milk output in Indian mothers is ~30–60 ml during first 3 days of life (*colostrum*) that gradually peaks at ~2 months (600–700 ml) followed by gradual decline from 6–7 months onwards to <500 ml by one year and <300 ml by two years.

Colostrum is the thick yellow and sticky milk, produced during first 72 hours of life. Although secreted in small quantities, it is enough to meet the newborn's requirement during this period. Colostrum is not only rich in proteins and anti-infective factors, but also facilitates maturation of gastro-intestinal tract.

Transition milk is secreted between 3rd and 14th day. It has lesser protein and immunoglobulin content than colostrum, but relatively higher fat and sugar content to meet increasing energy requirements.

Mature milk, secreted from 15th day onwards, has further less proteins than the transitional milk, but more volume, fat and caloric content. Composition of mature milk also varies according to maternal diet as well as even during the course of a single breastfeed, as follows:

Fore milk flows at the start of each feed and is *relatively watery to satisfy the baby's thirst*, with lesser fat content, but rich in sugars, vitamins and minerals.

Hind milk, secreted in later part of feeding, is thicker than the fore milk with *higher fat content to satisfy the baby's hunger* and caloric needs.

Preterm milk from mothers of a preterm baby during first few days is qualitatively different from milk of term-mothers, with higher energy density, proteins and sodium content to meet their higher requirements. Preterm milk also contains less lactose and solutes, to adjust for maturational lactase deficiency and relative renal insufficiency in them. It achieves composition of term milk by 4–6 weeks.

5.2.2 ADVANTAGES OF BREASTFEEDING

Breast milk is *species-specific*, i.e. quantitatively and qualitatively most appropriate for human baby. Apart from nutritional superiority, breastfeeding also offers many other advantages to baby, mother, family and even to the community, as follows:

A. Nutritional superiority: BM is easily digestible and contains all essential nutrients in the right quantity and quality, as per baby's requirements **(Table 5.3)**. Major nutritional advantages of BM are as follows:

- *Energy* from BM is mainly derived from easily digestible carbohydrates, e.g. lactose.
- *Protein content* in BM, though less than in cow milk, is qualitatively superior due to:
  - *Better whey-casein ratio*: 75% of human milk proteins are easily digestible *whey proteins* or lactalbumin, unlike casein-rich cow milk, which is difficult to digest due to curd formation.

TABLE 5.3: Composition of human and cow milk

	Contents (100 ml)	*Human milk*	*Cow milk*
a.	**Energy** (cal)	67	70
b.	**Proteins**		
	Content (gm)	1.1	3.3
	Whey: Casein	75:25	22:78
	Essential amino acids	adequate	inadequate
c.	**Fats**		
	Content (gm)	3.8	3.8
	Type	PUFA	saturated
	Essential fatty acids	high	less
	Lipase enzyme	present	absent
d.	**Carbohydrates**		
	Content (gm)	7.8	4.8
	Lactose content	6.5%	4.5%
e.	**Water content**	88%	88%
f.	**Solute load** (gm)	0.2	0.7
	Sodium (mg)	0.2	0.7
	Potassium (mg)	0.5	1.5
g.	**Minerals** (mg)		
	Calcium	34	137
	Phosphorus	15	92
	Ca: P ratio	> 2:1	1.5:1
	Iron (mg/L)	0.5	~ 0.5
h.	**Vitamins**		
	Vitamin A (IU)	~10	>50
	Vitamin C (mg)	~ 6	~ 2
	Vitamin D (IU)	~ 5	~ 2.5
	Vitamin K (µg)	1.5	6.0

PUFA: Polyunsaturated fatty acids

  - *Essential amino acids (EAA):* BM contains all EAAs in appropriate concentrations to facilitate proper cognitive development, (e.g. taurine and cysteine), which are lacking in cow milk.
  - *High protein content* in animal milk increases risk of allergic disorders, due to absorption of macromolecules through immature gut mucosa.
- *Fat content* in BM is quantitatively comparable to cow milk, but with better quality, i.e. higher PUFA and EFA content. Cow milk is richer in saturated fats, which are difficult to digest and increases the risk of hypertension or heart disease in adult life. Human milk also contains *lipase enzyme*, essential for fat absorption.
- *Vitamin contents* in BM is adequate (except vitamin K), while cow milk is deficient in vitamins C and D. While low vitamin K content in BM is responsible for higher risk of hemorrhagic disease of newborn in breast-fed babies, it may be easily prevented by single dose prophylactic vitamin K supplement at birth.
- *Mineral (ash) content* of BM is much lower (1.5%) than in cow milk (>7.0%). High ash content in cow milk poses additional solute burden over developing kidney with limited concentration capability.
  - *Iron* content in BM is comparable to cow milk, but BM iron is better absorbed (~50%) than cow milk iron (10%), due to lesser phosphate load.
  - *Calcium* content is lesser in BM, though BM calcium is better absorbed and utilized due to appropriate Ca: P ratio. Consequently, tetany is less common in breastfed children.
- *Water:* BM contains adequate water (88%) and hence, no additional water is required in exclusively breastfed babies, with less risk of infections.

B. Anti-infective properties: BM is essentially sterile, except in presence of systemic or local (breast) maternal infection. Further, presence of various anti-infective substances in BM is responsible for lower incidence of gut and respiratory infections in breastfed infants. These factors include:

- *Humoral factors,* e.g.
  - Non-specific and specific IgG antibodies
  - Secretory IgA, for local immunity
- *Cellular factors,* e.g.
  - Phagocytic cells, e.g. macrophages
  - Cellular-release factors, e.g. lysozymes
- High complement activity
- *Organism-specific protective factors*, e.g.
  - Para amino benzoic acid (PABA) against malaria
  - Anti-staphylococcal factor
- Others, e.g.
  - *Bifidus factor*, to facilitates the growth of Lactobacillus bifidus in gut and prevents pathogenic colonization,
  - *Lactoferrin*, to binds the iron in gut and inhibit growth of pathogenic bacteria, e.g. *E. coli,* which need iron for their metabolism.
  - Lower pH of BM prevents bacterial overgrowth.

C. Emotional bonding: Breastfeeding creates an emotional bond between baby and mother, necessary for future growth, development, and parent-child adjustment.

D. Advantages to mother include:

- *Enhanced oxytocin secretion* to facilitate placental expulsion and uterine involution with less risk of post-partum hemorrhage.
- *Convenience and less workload*, obviating the need for boiling/mixing the top-milk. She also does not have to worry about the milk supply and spoilage.
- *Natural contraception:* Lactational amenorrhoea due to high prolactin levels is common during first 6 months, with ~98% protection.
- Lower incidence of breast and ovarian cancers.
- *Cosmetic recovery* with faster regaining of figure, due to more caloric consumption.

E. Advantages to family: Breastfeeding is a good economic practice for family as well, due to:

- Negligible cost, except the hidden expenses for additional nutrition to mother.
- Less health care expenses, due to lesser morbidity.
- Natural family spacing.

F. Advantages to the community include:

- *Ecological benefits* due to less consumption of natural resources for animal-milk production (fodder), boiling (fuel) and washing the utensils (water).
- Lesser morbidity in infants with less public health expenses.
- Population control, due lactational amenorrhoea.

5.2.3 PHYSIOLOGY OF LACTATION

Anatomically, the breast is made up of glandular tissue, supporting tissue and fat **(Fig. 5.1)**. There are ~20–25 alveoli in each breast, each lined by epithelial cells and surrounded by myoepithelial cells. Milk is secreted in alveoli by epithelial cells and pushed forward by contraction of myoepithelial cells. Each alveoli drains its output via lactiferous tubules and ducts into ~10–15 lactiferous sinuses, which lie below the areola and open out onto the nipple. The size of the breast depends on the amount of fat and supporting tissue and does not reflect on the milk-producing capacity.

Physiologically, lactation depends on two interdependent processes in mother: (a) production of milk (*prolactin reflex*), (b) secretion or ejection of milk (*oxytocin reflex*), as well as (c) actual sucking by the baby, dependent on neonatal reflexes.

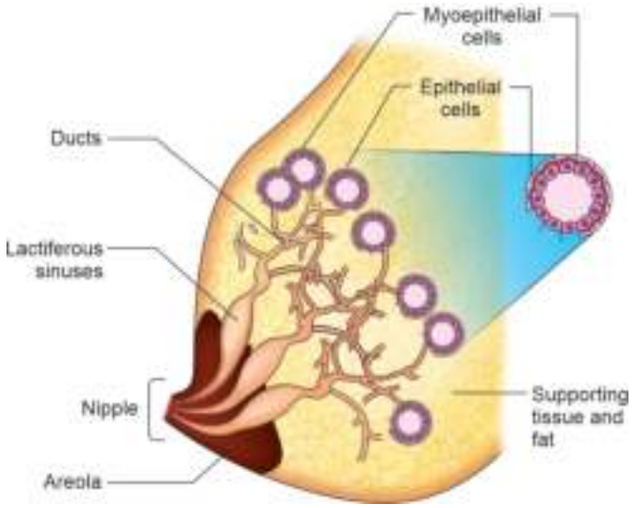

Fig. 5.1: **Normal breast anatomy.**

- **Production of milk (Prolactin reflex):** When a baby sucks, afferent impulses from nipple stimulate *prolactin* secretion from *anterior pituitary*. Prolactin acts on the milk-producing alveolar epithelial cells to stimulate milk secretion. Thus, the prolactin reflex depends on *how early, how often* and *how strongly* the baby sucks.
  - Prolactin activity and milk production is *facilitated* by: (a) adequate emptying of breasts after each feed, (b) early onset of lactation, (c) frequent suckling, (d) expression of breast milk, and (d) night feeds.
  - Prolactin secretion is *inhibited* by: (a) pre-lacteal feeds, (b) incorrect positioning, and (c) painful breast conditions, (d) physical or mental stress to mother.
- **Milk ejection/let down (Oxytocin reflex)** is also initiated during suckling when afferent impulses from nipple reach the *posterior pituitary* to stimulate *oxytocin* production. Oxytocin contracts the myo-epithelial cells surrounding the alveoli and lactiferous sinuses, to push the milk forward towards the nipple. The squeezing sensation in the breast during breastfeeding is a sign of a good "*let-down reflex*". Oxytocin secretion is affected by the physical and mental state of the mother.
  - Oxytocin activity and milk ejection is *enhanced* by: (a) sight and sound of baby, (b) pleasant thoughts of baby, and (c) maternal confidence in her ability to breastfeed.
  - Oxytocin secretion and milk ejection is *reduced* by: (a) mother's anxiety or low-confidence, (b) mental stress or worry, and (c) pain or discomfort during breastfeeding.
- **Actual sucking by baby (Neonatal reflexes):** Three neonatal reflexes, i.e. *sucking, swallowing* and *rooting* reflex, participate in milk extraction during breastfeeding.
  - *Rooting reflex* helps the baby to latch onto the nipple. When the breast or nipple touches the baby's chin, philtrum, upper lip or cheek, the baby opens his/her mouth to search for the nipple.
  - *Suckling reflex* helps the baby to draw milk by converting the nipple and areola into a *teat* pressed between the lower jaw and hard palate. Wave-like movements of tongue facilitate sucking. For successful lactation the baby must be well attached to the breast, with the nipple and most of the areola in his mouth.
  - *Swallowing reflex:* After every 2–3 sucks, collected milk is swallowed by baby, followed by deep breath. Each suck-swallow-breathe cycle lasts for ~2–3 second.

5.2.4 CORRECT BREASTFEEDING TECHNIQUES AND PRACTICES

Although breastfeeding (BF) is a norm in India, many problems during lactation may be avoided by following correct breastfeeding practices, discussed below:

- ***Antenatal preparation*** for successful lactation should begin with each ANC visit including: (a) breast examination to check protractility of nipples, (b) maternal counseling regarding importance and correct practices of breastfeeding, and (c) identification of 'at-risk' mothers, e.g. primipara, multipara, who did not breastfed to earlier babies or those with local nipple problems.
- ***Initiation of breastfeeding:*** *Breastfeeding should begin within the 30 minutes of vaginal delivery and as soon as possible after cesarean delivery*.

  Early feeding (a) stimulates prolactin secretion, (b) stimulates oxytocin secretion and help in placental expulsion with less risk of postpartum hemorrhage, (c) establishes emotional bonding, (d) prevents neonatal hypoglycemia, (e) provides immunoglobulin-rich colostrum, and (f) provides warmth to the baby by skin to skin contact.

  Breast crawl is a very useful practice to achieve early initiation of BF. It involves placing the newborn on mother's abdomen soon after the delivery that allows him/her to find mother's breast on its own and decide when to take the first breastfeed **(Fig. 5.2)**.
- ***No pre-lacteal feeds:*** Any top-feeds, given to the baby before breastfeeding are termed as *pre-lacteal feed*. This includes water, sugar water, honey, gripe water, etc. Pre-lacteal feeds are strongly discouraged due to the risk of: (a) enteral infections, (b) nipple confusion*, and (c) poor sucking efforts by partly satisfied baby with consequent decrease in the BM output.

  When pre-lacteal feeds are given by a syringe, bottle or spoon, easy flow of milk may cause *nipple confusion,* i.e. confuse the baby to properly latch and suck during subsequent breastfeeding.

Fig. 5.2: **Breast crawl.**

Fig. 5.3: **Good attachment (latching) on breast.**

- **Rooming in,** i.e. *keeping the baby with the mother in the same room and on the bed* helps to maintain the baby's temperature, initiate and maintain breastfeeding and develop emotional bonding.
- *Schedule/ frequency of feeding:* Baby should be fed as and when required, i.e. *demand feeding*, rather than to fix-up a *scheduled feeding*. In fact, a normal baby itself develops a flexible schedule by the end of 2 weeks, when she/he demands the feeds ~2–3 hourly.

  If a baby demands more frequently, it is possible that either: (a) the duration of feeding is too short *or* (b) she/he is getting only foremilk.
- *Hygiene:* There is no need to wash breasts before feeding, though general hygiene by daily bath should be maintained.
- *Environment:* Baby should be breastfed in a peaceful and tension-free environment, without hurry and worry of domestic chorus, to avoid forcible interruptions during breastfeeding and consequent problems.
- *Breastfeeding position:* Any BF position is acceptable, provided mother is comfortable and baby is well-attached to the breast. Some commonly used positions are:
  - *Indian position*, i.e. mother sitting cross-legged, with a back support.
  - *Cradle position*, i.e. mother cradling the baby in her arms with the forearm supporting his/her head.
  - *Football-hold position* is useful to feed the twins. In this, the baby is held under the arm of mother with feet pointing backward, abdomen touching mother's chest and body supported by mother's arm.
  - *Side-lying position* is useful for night feeds, BF in immediate post-cesarean period and in sick mother. Mother and baby lie down facing each other with mother's hand supporting baby's back.
  - *Supine position* is helpful in post-cesarean period or when milk-flow from the breast is in excess to the baby's speed of sucking. In this, mother feeds in supine position with baby held onto her abdomen.

  Signs of a good breastfeeding position are:
  1. Baby's whole body is supported, not just the neck or shoulders,
  2. Baby's head, neck and body are in straight line, without any twist or bending. Head can be slightly extended to bring chin closer to the breast,
  3. Baby is held close, with body turned toward mother and abdomens touching each other,
  4. Baby should be facing the breast, with nose at the level of mother's nipple.
- *Proper attachment* of the baby at the breast is essential to prevent painful nipple problems in mother as well as to ensure adequate intake by baby.

  Signs of good attachment include **(Fig. 5.3)**:
  1. Baby's mouth is wide open,
  2. His/her lower lip is everted,
  3. His/her chin is touching the mother's breast,
  4. Most of the mother's nipple and areola is inside his/her mouth, except a small of upper areola. No part of lower areola should be visible.
- *Effective sucking:* Normally baby suckles 2–3 times by pressing the areola with the tongue against the hard palate to squeeze-out the milk, before pausing to swallow the collected milk.

  Signs of effective sucking include:
  1. Baby's cheeks are full and not hollow,
  2. Baby is calm and relaxed,
  3. Mother does not feel any pain.
- *Duration of each feed* should be decided by the baby (some are fast-feeders while others are slow-feeders) and she/he should be allowed to release the breast on its own. As a baby needs both-the *watery foremilk* to satisfy the thirst as well as the *fatty hind-milk* to satisfy the hunger, one breast should be emptied first before the other is offered. In case, baby is unable to empty

Fig. 5.4: **Burping.**

both breasts at one time, other breast should be offered first during subsequent feeding.

- *Burping:* Babies swallow lot of air during BF, especially if not properly attached to the breast. This *aerophagia*, may lead to abdominal discomfort, colic, regurgitation of feeds and rarely, aspiration. *Burping* by placing the baby over shoulders in upright position for 5–10 minutes with gentle stroking of back after feeds, helps to evacuate swallowed air **(Fig. 5.4)**.
- *Expression of breast milk* is advised in cases of: (a) painful breast engorgement, (b) any contraindication for breastfeeding (to discard), or (c) separation of mother and baby due to sickness or other causes. (see Ch 5.4.1)

5.2.5 COMMON BREASTFEEDING PROBLEMS

Common BF problems may be broadly divided into three categories: (I) breast and nipple problems, (II) partial or complete lactation failure, and (III) breastfeeding in special situations, e.g. sick mother, sick baby or working mother.

I. Breast and nipple problems are very common and often used as an excuse to start top-feeding, despite adequate milk output. These problems are more common in primipara mothers and include:

- **Flat or inverted nipples** may prevent proper attachment of baby to the breast. Flat nipples become prominent when pinched at base, while inverted nipples go in. These problems can be easily identified by antenatal breast examination. Flat nipples usually do not pose any feeding problems and can be managed easily by assuring mother and some modification in feeding positions. Persistently flat or inverted nipples may be managed by: (a) nipple-stretching exercises

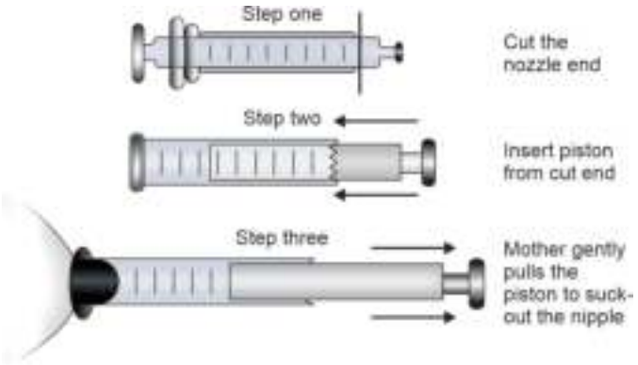

Fig. 5.5: **Syringe method for flat/inverted nipples.**

(pulling the nipple and rolling it between fingers), (b) use of a breast pump to pull the nipple out before every feed, or (c) syringe method.

Syringe method *(Kesri method)* is a simple suction device, prepared by cutting the nozzle end of a syringe and inverting its piston **(Fig. 5.5)**. When the smooth end of syringe is pressed against the nipple and piston is pulled gently, the inverted nipple pulls out of the breast tissue. This should be done before each breastfeed.

- **Sore nipples** are painful, tender nipples with or without cracks or bleed, caused by: (a) wrong positioning/attachment of baby on the breast, (b) forcible separation of baby while sucking, (c) repeated washing of breasts with soap solutions before feeds, (d) local fungal infections (thrush).

  Sore nipples are managed by: (a) correct positioning/attachment of baby, (b) starting each feed on the less affected breast, (c) application of hind-milk on the nipple as *emollient*, and (d) local anti-fungal treatment, if necessary.
- **Breast engorgement** indicates inadequate expression of milk despite adequate production, leading to hard, painful, warm and swollen breasts. It is usually caused by infrequent breastfeeding due to: (a) delayed initiation at birth, (b) maternal/neonatal sickness or (c) painful breast and nipple conditions **(Fig. 5.6)**.

  Most of these cases are self-limiting and can be prevented or managed by: (a) frequent demand feeding, (b) frequent expression of milk, if baby/mother is sick, and (c) local hot-water compresses to relieve pain.
- **Breast abscess (mastitis)** may develop due to infection of engorged breast, with cracked nipple as a portal of entry for infection **(Fig. 5.6)**.

  These cases are treated with: (a) antibiotics and surgical drainage, (b) symptomatic therapy with analgesics and hot compresses (breast massage should be avoided), and (c) frequent expression of milk, which may then be fed to the baby.

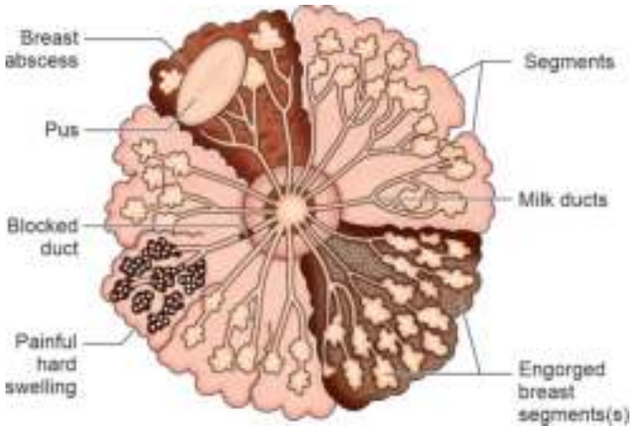

Fig. 5.6: Common painful breast conditions.

TABLE 5.4: Causes of lactation failure

I. Psychological causes ***(↓ oxytocin activity)***
- Lack of self-confidence
  - Primigravidas and teen mothers (inexperience)
  - Unsuccessful breastfeeding in earlier pregnancy
  - Inadequate antenatal counseling
- Physical or mental stress
  - Mental anxiety or worry
  - Physical stress, e.g. working mothers
  - Wrong advice/counseling from family

II. Incorrect breastfeeding practices ***(↓ prolactin activity)***
- Prelacteal feeds and delayed onset of breastfeeding
- Infrequent or less vigorous breastfeeding
  - Painful breast or nipple conditions
  - Weak or preterm baby
  - Schedule feeding
  - Wrong positions or attachment

III. Physical causes ***(true lactation failure)***
- Extreme maternal undernutrition
- Extremely sick mother

II. Lactational failure is defined as *low milk output* in the mother, *inadequate to meet baby's requirements*. It may be *primary* since delivery or *secondary* after successful initiation of breastfeeding at birth; partial *or* complete; transient *or* permanent; and true *or* perceived.

Causes: *True lactation failure is extremely rare.* In most cases, it is a consequence of complex cycle, involving temporary delay in the initiation of BM output due to any cause > maternal anxiety > wrong advice from others > initiation of supplementary feeds > reduced frequency and duration of BF > further decrease in milk-output **(Table 5.4)**.

Management of lactation failure mainly aims to boost mother's confidence in her ability to breastfeeding, eliminate causative factors and advise correct breast-feeding practices. Continuous monitoring is necessary to prevent recurrence of problem. Important steps in lactation management include:

Step I. Assess the BM output, which is probably adequate if: (1) baby is gaining adequate weight, i.e. ~20–30 gm/day after 10th day; (2) baby is passing the adequate urine, i.e. ~6–8 times a day; (3) baby is sleeping comfortably for 1–2 hours after breastfeeding; (4) mother feels a sense of fullness in the breast before next feed time; (5) milk starts dripping from other breast, when the baby is sucking on one breast. *Test weighing*, i.e. weighing the baby before and after feeds, is rarely required.

Step II. Reassure and counsel the mother, if milk output is adequate. Let her understand the indicators of adequate BM output (as above).

Step III. Identify and eliminate causative factors, e.g. local breast/nipple problems, improper attachment, wrong feeding practices, misguidance from others, partial bottle-feeding or maternal illness. Identification of the cause requires detailed history of family environment and breastfeeding practices, observation at the time of BF and physical evaluation of mother/baby.

Step IV. Boost the milk output: Many *galactagogues,* e.g. special foods, herbs, (e.g. satavari), drinks or medications, (e.g. PO metaclopramide 10–15 mg TDS) are claimed to increase milk production by stimulating prolactin secretion. However, most of them have only placebo effect.

The best galactagogue is a nutritious diet to mother and a healthy, exclusively demand-fed baby, vigorously sucking in correct position.

Step V. Re-lactation is possible in some cases of secondary LF, even after many days with following measures:

- ***Non-nutritive sucking:*** Simplest measure to establish re-lactation is to place the baby on the breast at least 8–10 times/day for 10–15 minutes every time, even in the absence of milk output, termed as *non-nutritive sucking.*
- ***Drip and drop method*** may be useful to re-establish lactation in mothers even after many weeks. Lower end of a nasogastric tube connected to milk-filled syringe is fixed with an adhesive tape over mother's nipple and baby is encouraged to suck on nipple while milk is gradually dripped over it. Since baby gets the milk through the tube, she/he is encouraged to suck further, which may help re-lactation.

Step VI. Alternative modes of feeding, e.g. wet-nursing by other lactating mother in family, milk sourced from human milk banking or top-feeding are very rarely indicated, when all efforts to re-establish lactation fail.

III. Breastfeeding in special situations: *There are no absolute contraindications for breastfeeding except* when mother is on certain drugs **(Table 5.5)**, which are unavoidable, excreted in breast milk and can cause serious problems in baby. However, following situations are common in clinical practice, which requires a considered review of BF advisability, sustainability and modifications.

TABLE 5.5: Medications in lactating mothers

Absolutely contraindicated:
(discontinue breastfeeding, if unavoidable)
- Cytotoxic agents
- Radioactive agents
- Lithium

To be avoided:
(use alternatives, if necessary)
- NSAIDs (use paracetamol)
- *Antibiotics:* Sulpha, chloramphenicol, tetracycline
- Estrogen/progesterone preparations
- Thiazide diuretics
- Sulfonylureas
- Oral anticoagulants

To be used with caution:
(continue breastfeeding but monitor toxicity)
- Anti-convulsants, e.g. phenobarb, phenytoin
- Sedatives, e.g. diazepam, phenothiazines
- *Anti-asthma:* Theophylline
- *Others:* Laxatives, quinine, ethambutol

Cesarean delivery: While some mothers may be apprehensive to breastfeed soon after LSCS due to fear of pain and inappropriate advice, they should be motivated to initiate BF as soon as possible, preferably within 1 hour of birth. Mother must be helped to find a comfortable position to breastfeed, e.g. supine position on first day, side-lying position on second day and sitting position subsequently.

Working mothers: Employers must be encouraged to: (a) permit longer maternity/lactation leave for at least 6 months after delivery, (b) permit flexible work-timings for lactating mothers, (c) provide a crèche at workplace. Even in absence of these facilities, employed mothers can successfully continue BF after joining the duty by: (a) breastfeeding the baby while at home, just before leaving for work and immediately on returning home, as well as (b) expressing the milk an hour before leaving the home (which can be stored up to 8 hours at room temperature) and fed to the baby later by caretaker with the help of *Bondla or katori*/spoon.

Maternal infections: Some maternal infections, e.g. HIV, CMV, HBV, etc. may be transmitted to the baby via breast milk, though the risk of transmission is usually less than the disadvantages of top-feeding. HBV positive mothers should continue exclusive BF till 6 months of age, like others. Similarly, BF is default feeding in HIV positive mothers as well in view of universal ART to mother and universal prophylaxis to the exposed baby (Ch 10.28). Top feeding should be considered only if ***AFASS criteria*** (**A**cceptable, **F**easible, **A**ffordable, **S**ustainable and **S**afe) is fulfilled.

Serious physical illness in mother: Most sick mothers can successfully breastfeeding their baby, either directly or through using expressed breast milk. Manual expression should continue even if breastfeeding is not possible, to prevent breast engorgement. Temporary discontinuation of breastfeeding is required if mother is: (a) seriously sick, e.g. shock, coma, etc. or (b) on contraindicated medications.

Serious psychiatric illness in mother, requires discontinuation of breastfeeding if: (a) mother is on lithium therapy, or (b) baby needs to be separated due to violent/unstable behavior in mothers.

Maternal medications: Considerable quantities of certain drugs are excreted in BM, which may produce untoward effects on baby **(Table 5.5)**. In these cases, three options are available: (a) temporary or permanent discontinuation of breastfeeding, (b) switch-over to alternate medications, if possible, and (c) continuation of breastfeeding with closer vigil for adverse events. Only the use of cytotoxic or radioactive drugs or lithium in mother are absolute contraindications for BF.

Preterm babies: Mode of feeding in preterms usually depends on their maturity. Most of the non-sick babies >1500 gm can be safely fed on breast directly or on EBM by katori/spoon/Bondla. Babies between 1200–1500 gm may need nasogastric EBM during early days. Mother's own milk as EBM is the first choice in babies who cannot breastfeed directly, followed by pasteurized donor milk or preterm formula.

Babies with cleft-palate may not generate enough suction to express breast milk. If required, they may be fed directly on breast by using the obturators or may be given expressed breast milk by katori/spoon, etc. Semi-upright position is recommended in these cases to reduce nasal regurgitation and reflux of breast milk into the eustachian tubes.

Serious physical illness in baby: Unless oral feeding is contraindicated, breastfeeding should continue either directly or through expressed breast milk. In cases when oral feeding is not possible, e.g. due to extreme prematurity, critical sickness or surgery in newborn, manual expression of mother's breast should continue to maintain milk output for future use.

Neonatal death: In this unfortunate situation, the lactation reduces spontaneously due to lack of stimulation, though the *drying-up* process may be hastened with some anti-galctogogues, e.g. *bromocriptine*, to prevent breast engorgement and maternal discomfort.

Breastfeeding during travel and social events should continue with minor adjustments in timings and practice.

5.2.6 LACTATION COUNSELING

Breastfeeding plays a crucial role in health growth and development during early infancy. While it is a natural

process, some mothers may need support to successfully establish, maintain and continue BF till desired period.

Objectives: Lactation counseling is a process to encourage and support these mothers for successful lactation and includes:

- Informing mothers about advantages of breastfeeding to baby as well as to mother.
- Demonstrating mothers about correct BF practices.
- Assessing the position and attachment during BF.
- Identify and mange breast and nipple problems, which may hinder BF.
- Provide solutions to mothers for BF in special circumstances and encourage them to continue breastfeeding.

Antenatal lactation counseling: Effort to ensure successful BF must ideally begin from the first antenatal visit to:

- Prime the expectant mother about advantages of BF,
- Prepare her to initiate BF immediately after the delivery,
- Assess the general health to convince her in the ability to breastfeed,
- Examine breasts for local problems, e.g. inverted nipples, and advice for corrective manoeuvres, e.g. manipulative pulling or syringe method,
- Identify potential barriers or contraindications for BF, e.g. HIV positive status or drug therapy.

Antenatal lactation counseling should specially focus on: (a) primpara mothers or (b) mothers who did not BF successfully during previous pregnancy.

Postnatal lactation counseling must begin in the delivery room to initiate BF as early as possible and should continue during each visit in postnatal ward as well as on follow-up after discharge. BF problems are more common in LSCS and low birth weight babies. Postnatal counseling must include:

- History related to timing of first feed, use of prelacteal feeds, frequency and duration of feeding, burping after feeds and any problems during BF. History should also include the state of baby after BF, e.g. cry, sleep and urine frequency to assess the adequate of feeding.
- Observation of mother while breastfeeding, to ensure correct breastfeeding position, proper attachment and signs of effective sucking, discussed earlier.
- Examine the breasts for any local breast and nipple problem, if required.
- Examine the baby for any problem as well as the weight gain after first week of life.
- Offered solutions to her problems or apprehension to encourage continuance of BF.

Mother's privacy should always be respected while observing the BF or examining the breasts, which should always be done with her explicit consent and in presence of other female members/nurse, when done by a male health care worker.

Many online and off-line courses are available at present to train health care workers for better lactation counseling practices.

5.3 BABY FRIENDLY HOSPITAL INITIATIVE

Baby friendly hospital initiative (BFHI) is a worldwide movement, launched in 1992 to *protect, promote and support exclusive breastfeeding*, jointly sponsored by WHO, UNICEF and allied organizations. Revised and expanded version of BFHI has been implemented by UNICEF and WHO in 2009.

Objectives: BFHI aims to:

- Promote correct breastfeeding practices at delivery centers,
- Certify the hospitals following these practices,
- Train and motivate the staff of these hospitals.

Promotion of other baby and mother friendly activities, e.g. antenatal care, essential newborn care, immunization and appropriate management of diarrhea or acute respiratory infections, has been included in further expansion of this program, termed ***BFHI plus.***

Breastfeeding policy: A baby-friendly hospital is expected to follow and promote correct breastfeeding practices, included in a well-defined and written breastfeeding policy.

BFHI certification: A hospital is certified as *baby friendly* after careful evaluation and physical verification of breastfeeding practices by trained and certified assessors.

The certifying criteria for a baby-friendly hospital are: (a) having minimum 250 deliveries/year, (b) following *ten steps for successful breastfeeding* **(Table 5.6)**, and (c) creating baby-friendly community in their locality.

TABLE 5.6: Ten steps to successful lactation

1.	A written breastfeeding policy
2.	Training of health-staff in breastfeeding promotional skills
3.	Antenatal counseling towards breastfeeding
4.	Initiation of breastfeeding, within 30 minutes of delivery
5.	Exclusive breastfeeding and no pre-lacteal feeds
6.	Practicing *rooming-in*
7.	Encourage demand feeding
8.	No artificial teats/pacifiers to breastfeeding infants
9.	Correct breastfeeding practices and continuance of lactation by EBM, even if the baby is separated from mother for medical reasons
10.	Breastfeeding support groups

EBM : Expressed breast milk

A hospital also benefits by BFHI certification as it gets: (a) public recognition and more maternity work input, (b) IEC material for distribution to mothers, and (c) better neonatal survival and lower morbidity.

5.4 ALTERNATIVE INFANT FEEDING

While breastfeeding is the best option for early infant feeding in first 6 months of life, sometimes it may be necessary to explore other options in cases when it is either not possible or contraindicated due to any reason. Three options in these cases include use of: (a) expressed breast milk, (b) milk from human milk banking, and (c) top feeding with animal or formula feeds. Wet nursing by another lactating women is an option, which is rarely feasible in current situation.

5.4.1 EXPRESSED BREAST MILK

Expression of breast milk is advised in cases of: (a) painful breast engorgement, (b) any contraindication for breastfeeding (to discard), or (c) separation of mother and baby due to sickness or other causes.

Milk may be expressed manually *or* with a breast pump, though manual expression is more hygienic, economical and convenient. The mother herself or a relative may express milk in a wide-mouth clean container by applying continuous forward pressure over lactiferous sinuses below the areola.

Manual expression of milk requires following steps:

- Wash the hands and massage the breast gently towards the nipples,
- Place the thumb and index finger opposite each other just outside the areola,
- Press back towards the chest to gently squeeze the milk out of nipple,
- Repeat same steps in different positions around the areola.

This expressed breast milk (EBM) may then either be fed to the baby by a *bondla* or nasogastric tube or discarded. BM can be stored at room temperature for 8 hours, in refrigerator for 24 hours, or in deep freezers, i.e. *breast-milk banks* at –20°C, up to 3 months. Stored EBM should be brought to room temperature before feeding by keeping outside, but it should never be heated or stirred to dissolve the fat globules.

5.4.2 HUMAN MILK BANKING

Human milk banking in India was started in 1989 in Mumbai and is now available at many major centers of the country. It offers a solution to mothers who cannot feed their babies temporarily, especially when they are in hospital or intensive care unit. It involves:

- Collection of milk by voluntary donations from lactating mothers,
- Screening of donor's milk for common infections including cultures to detect bacterial contamination,
- Pasteurization of donor's milk by *Holder method*, before storage in stringent environmental conditions,
- Supply of this stored milk for feeding of sick and small newborns, for whom the mother's milk is no available.

While donor's milk from milk bank is inferior to the mother's own milk due to loss of some immunological and nutritional ingredients during pasteurization and storage, it still retains many advantages of breast milk and is tolerated better than formula milk with lesser risk of (a) infections, e.g. necrotizing enterocolitis (b) feed intolerance as well as risk of (c) metabolic syndromes in later life, with better developmental scores.

5.4.3 TOP FEEDING

Top feeding, i.e. *feeding of milk other than the breast milk in early infancy*, should be strictly discouraged. However, it may be necessary in rare instances of: (a) true lactation failure, (b) maternal death/serious sickness, or (c) any absolute/relative contraindication for breastfeeding.

Top feeding may be loosely classified as: (a) exclusive top feeding, or (b) supplementary top feeding along with breastfeeding, e.g. in partial lactation failure. Important issues in top feeding are as follows:

- **Which milk to use?** Milk sourced from human milk bank is the best option if mother's own milk is not available, though might be difficult to sustain post-discharge. Although many age-appropriate commercial formula feeds are available, prohibitive cost and risk of incorrect dilution by illiterate and poor mothers render them unsuitable for regular use in India. Dried skimmed milk powders or evaporated/condensed milks are also unsuitable for top feeding due to same reasons as well as unbalanced composition. Skimmed milk powders have high protein and solute content (risk of dehydration), while condensed milk has excess carbohydrates (risk of diarrhea).

  Pasteurized or fresh-boiled cow milk remains the most practical, though not the best alternative to breastfeeding in resource-limited population, if top feeding is unavoidable. Composition of the cow's milk is nearest to the breast milk except high protein load, which may be reduced by dilution. It should be diluted with water in 1:1 ratio during first two weeks (longer in preterms) and in 2:1 ratio during next two weeks. Undiluted cow milk may be used after one month of age.

  Commercial formulas are specially prepared to bring their composition nearest to BM after dilution and hence, if used at all, should be diluted strictly according to the manufacturer's instructions.

Fig. 5.7: Bondla feeding.

TABLE 5.7: Complications of top-feeding.

Related to the milk/formula:
- Under nutrition *(over-diluted milk)*
- Dehydration *(concentrated formula feeds)*
- Oral mucosal scalding *(hot feeds)*
- Constipation *(high solute load)*
- Allergic problems *(high protein content)*
- Recurrent respiratory infections *(no immune factors)*

Related to the bottle
- Diarrhea (contaminated bottle)
- Overfeeding or underfeeding
- Aerophagia *due to wrong bottle position*
- Nipple confusion – difficulty in simultaneous breastfeeding
- Weaning problems (refusal to part with bottle)
- Defective dentition/caries (sp. with night feeds)

- **How much to give?** Quantity of top milk depends on baby's age, gestation and weight. As a general rule, top-milk should provide ~110–120 cal/kg/day. And calculated amount should be divided into 8 rations (3 hourly) during first two month and 6–7 ratios (4 hourly) subsequently, to be given during each feed. A term baby normally accepts ~50 ml feeds during first 2 weeks, ~100 ml between 2–8 weeks and ~150–250 ml subsequently.
- **How to give?** Top feeding must be given by *katori* and spoon, or indigenously designed utensils, e.g. *bondla or paladi* **(Fig. 5.7)**. Although convenient, risk of infection and other complications is maximum with bottle-feeding, which should be avoided as far as possible.
- **Which precautions to take?** Important precautions, necessary to prevent complications of top feeding **(Table 5.7)** are:
  - *Proper preparation of feeds*
    - Proper quantity and dilution of feed
    - Use of fresh boiled milk/diluted formula
    - Proper temperature of feed
  - *Proper preparation of feeding equipment*
    - Proper sterilization of feeding utensil/bottle
    - Proper teat-hole size to allow *drop by drop* flow of milk from inverted bottle.
  - *Correct technique of feeding*
    - Semi-upright position to avoid aspiration
    - Burping after feeding.
  - *Early vitamin/mineral supplements*, as vitamin C and iron are deficient in cow milk.
- **How to sterilize feeding bottle/utensils?** While bottle feeding is strongly discouraged, proper sterilization is necessary, if unavoidable. Bottle and nipple may be sterilized by *boiling** or *chemical sterilization* by dipping for 10 minutes in *milton solution* (2% sodium hypochlorite). Other feeding utensils, e.g. *bondla, katori*, spoon, etc. need not be boiled but should be properly cleaned with running or warm water.

  *Before boiling, bottle should be properly cleaned with brush and lukewarm salt-water to remove the stickiness. Subsequently, bottle and nipple should be boiled for 15–20 minutes and 5 minutes respectively and left in container itself, till required, to prevent re-contamination.

Infant Milk Substitutes, Feeding Bottles and Infants Food Act, 1992

Infant Milk Substitutes, Feeding Bottles and Infants Food Act, 1992 (Amended 2003) is a strong legal deterrent against top feeding and includes in brief:
- No person shall advertise or promote of infant milk substitutes to public in any form including inducements, donations or distribution of educational materials.
- No container of infant milk substitute should use words, e.g. humanized, recommended, complete food or images of healthy babies on the label. It should also carry warnings as prescribed in the act.
- No poster or IEC material should be distributed in the hospitals except to registered medical practitioners.
- No inducement of any kind, e.g. money, gifts or sponsorships should be offered to health workers
- No commission on the basis of sales volume should be provided to distributors, sellers and others in supply chain.

Any violation of the act may attract severe fine and punishment, including imprisonment up to 3 years.

5.5 COMPLEMENTARY FEEDING

Complementary feeding (weaning) is defined as *"gradual introduction of semi-solids and solids in baby's diet apart from breast milk, to meet their growing demands, usually at 6 months."*

Note that weaning is a complementary process and *not the discontinuation* of breastfeeding, which should continue as long as possible, preferably till 2 years of age.

Purpose: BM is all that a baby needs till first 4–6 months of life. At this age, introduction of complementary feeds is necessary as:

a. Breast milk output reaches a plateau (600–700 ml/day) by this age,
b. Growing baby's dietary requirements exceed the supply from mother's milk,
c. Baby's stomach is ready to receive and digest food, other than the breast milk.

- *Early* introduction of complementary feeding before 6 months is harmful due to reduction in BM intake and higher risk of infections and allergies as well as obesity in later life.
- *Late* introduction of complementary feeding beyond 6 months affects optimal growth of the baby and may creates difficulties in subsequent weaning due to development of *breast-affinity* in baby.

Characteristics of complementary foods: Common complementary foods used at different ages in infants and young children are shown in **Table 5.8**. Ideal complementary foods should be:

- **Age-appropriate** with consistency appropriate to the developmental readiness of the child in munching, chewing and swallowing. Complementary feeding must begin with soft, homogeneous, thinner and bland feeds, (e.g. Porridge), followed by thicker *mashed* foods and lastly, the *chewable* foods. Gut mucosa is relatively permeable to undigested proteins in early infancy, which may induce allergic mechanisms. Hence, *eggs should not be introduced in diet before 6 months.*
- **Energy-dense** to account for small stomach size of infants. Meals can be made energy-dense by thickening them and adding ghee/butter/oil or jaggery. Energy value may also be enhanced by using fermented, sprouted or toasted grains for preparation of meals.
- **Home-made and less expensive:** Complementary foods must be based on staple diet of the family. Commercial foods must be avoided as due to cost and potential risk of harmful additives or high salt content. Fortified foods with iron, iodized salt, vitamin A, etc. must be encouraged. Junk foods should be avoided.

TABLE 5.8: Common weaning foods* for Indian children

Age 6–8 months (2–3 meals/day; 2–3 tablespoonful/meal)
- Thickened fruit juices and soups
- Mashed fruits, e.g. banana, papaya, cheekoo, etc.
- Boiled-mashed vegetables, e.g. carrot, potatoes, etc.
- Milk-cereal porridge (ragi/nachni/suji), kheer, etc.

Age 9–11 months (3–4 meals/day; ~ ½ cup/meal)
- Cereal-pulse combinations, e.g. khichri, rice-dal
- Chewable foods, softened in dal, e.g. bread, chapati
- Eggs (Not <6 months due to risk of allergy in later life)
- *Non-veg:*, e.g. mashed chicken, fish, by 7–8 months

Age 12–23 months (3–4 meals/day; ~ 1 cup/meal)
- All foods eaten by the family, though less spicy

*Add ghee/oil to increase caloric content

- **Culturally and culinary acceptable:** Non-vegetarian foods are richer in proteins, though vegetarian foods are equally good, if used in combination of cereals and pulses, e.g. khichadi. While some babies may prefer salty or sweet feeds, addition of salt or sugar in complementary feeds is not recommended till 2 years of age.
- **Fresh and hygienic** at all levels of preparation, storage and feeding. Handwashing must be encouraged during preparation/feeding of meals and cooked food must be consumed within 1–2 hours, unless refrigerated.

Principles of complementary feeding: Weaning should be a gradual and pleasant experience to the baby and some important principles include:

- ***Introduction of feeds:*** Start with one food item at a time and continue it for a week or so, till the baby gets used to it before adding next item. Multiple food items should not be started at same time. Increase the quantity, consistency and frequency of each feed gradually, till desired intake is achieved.
- ***Mode of feeding:*** Feed with a *katori* and spoon and never use the bottle. Older children should be encouraged to feed from separate plate, to assess the exact intake. Self-feeding should be encouraged, with fingers/spoon.
- ***Dietary diversity:*** Children should receive complementary foods from at least 4 of the following seven food groups (also termed as *minimum dietary diversity*): (1) grains, roots and tubers, (2) legumes and nuts, (3) dairy products; (4) flesh foods, e.g. meat fish, poultry, (5) eggs, (6) vitamin-A rich fruits and vegetables, (7) other fruits and vegetables.
- ***Frequency of feeding*** *(Minimum meal frequency)**:*** Babies should be fed complementary feeds at least 2–3 times during 6–8 months and 3–4 times during 9–23 months of age. Those, who are not on breast feeds simultaneously must be fed at least 4 times during 6–23 months. Inter-meals snacks of good nutritive value must be encouraged in addition to regular meals. However, junk foods should be strictly avoided as snacks.
- ***Supplements:*** Iron rich/fortified foods or iron supplements should be provided to all infants from 6 months of age.
- ***Target:*** Weaning must be complete by 1 year of age, when baby should be qualitatively eating the regular family diet, albeit in quantities about half of the mother's diet. Breastfeeding should continue as long as possible, as a source of supplementary nutrition.
- ***Responsive feeding.*** Young children should be encouraged to take feed by praising them. Forced feeding with threats and punishment interfere with

development of good feeding habits. Minimize the distractions during feeding.

- ***Breastfeeding*** should be continued till 2 years of age, along with CF.
- ***Feeding during sickness:*** Both, BF and CF should be continued even when the child is sick, if it is tolerated.

Assessment of complementary feeding: All children aged 6 months to 2 years must be assessed for adequacy of CF during each visit with following questions:

- At what age, CF were introduced in diet ?
- Which CFs are being used at present, including the consistency of these feeds ?
- How frequently CF are given in last 24 hours to compare with recommended minimal meal frequency?
- Which CF were given in last 24 hours to compare with recommended minimum meal diversity?
- Whether breastfeeding has been continued and how frequently it is being given ?
- Whether iron supplements are also being given ?
- Whether feeding is/was continued during the sickness of the child.

Mother should be counseled about correct CF practices, as described above under principles of CF. Any deviation from these norms/practices may significantly affect the nutritional status of infant and needs careful monitoring.

5.6 INFANT AND YOUNG CHILD FEEDING GUIDELINES

WHO and UNICEF jointly developed a global strategy for *infant and young child feeding* (IYCF) in 2003, considering the impact of feeding practices and nutritional interventions during critical window period of first 1000 days of life (270 days *in-utero and* first two years after birth) on growth, development, health and survival in children. First national IYCF guidelines were formulated by Government of India in 2004 and revised subsequently.

IYCF guidelines are a *set of recommendations* for appropriate feeding of newborn and children *up to two years of age*. Important components of these guidelines, including those suggested by IAP in 2016 are as follows:

- **Early initiation of breastfeeding** as early as possible after birth, ideally within first hour, including in those born by cesarean section. Colostrum should not be discarded but to be fed to newborn and no pre-lacteal fluid should be given. Antenatal counseling, *rooming-in* and *breast-crawl* are useful strategies to assist early initiation of breastfeeding.
- **Exclusive breastfeeding for the first six months.** No other foods or fluids, even the water, are permitted (except medicines). Useful strategies to promote exclusive breastfeeding include: *demand feeding*, early management of breast/nipple problems and workplace support, e.g. lactation leave/lactation rooms. Brestfeeding should be continued during maternal illnesses unless contraindicated.
- **Timely introduction of complementary feeding** from 6 months of age with introduction of solids and semisolids to complement breast milk, which should continue *ad libitum* till 2 years of age. *Timely* means introducing the complementary feeds when the need for energy and nutrients exceeds that provided through exclusive breastfeeding. The term "complementary feeding" and not "weaning" should be used.
- **Age-appropriate complementary feeding** for children 6–23 months, while continuing breastfeeding in terms of quality and quantity. Children should receive food with:
  - *Minimum food diversity* including 4 or more of following seven food groups: (1) Grains, roots and tubers, (2) legumes and nuts, (3) dairy products, (4) flesh foods (meat fish, poultry). (5) eggs, (6) vitamin A rich fruits and vegetables, and (7) other fruits and vegetables.
  - *Minimum meal frequency*, i.e. 2–3 times for breastfed infants 6–8 months; 3–4 times for breastfed children 9–23 months; 4–5 times for non-breastfed children aged 6–23 months, along with inter-meal snacks.
- **Active feeding for children during and after illness** should be encouraged except in medical contra-indications. In sick or depressed babies, expressed breast milk may be fed via nasogastric tube or cup and spoon. Use of infant feeding formula, even on donation or subsidized supply, should not be encouraged. Even in HIV infected mothers, exclusive breastfeeding is the default option for infant feeding, with opt-out option.
- **Responsive feeding,** i.e.: (a) recognition of early hunger cues given by the baby before crying for feeds, e.g. sucking movements/sounds, lip smacking, restlessness, etc, (b) encouraging the baby to feed himself/herself, (c) avoidance of forced feeding, and (d) psychosocial stimulation during feeding, e.g. playing or caressing the baby while feeding. Feeding should be an enjoyable experience for baby as well as the mother.

5.7 BALANCED DIET

Balanced diet is the *diet containing variety of foods in such quantities and proportions, which fulfils the needs for all essential nutrients, necessary to maintain optimal health, growth and reserves*.

Foods are conventionally grouped as: (a) cereals and millets, (b) pulses, legumes and nuts, (c) vegetables and fruits, (d) animal foods, e.g. milk, milk-products, eggs, fish, meat, etc. and (d) oils/fats and sugar.

Foods are also grouped according to predominant functions as: (a) energy-rich foods, i.e. carbohydrates and fats, (b) body-building foods, i.e. proteins, and (c) protective foods, i.e. vitamins and minerals.

Principles: General characteristics of a balanced diet, based on dietary goals from various sources *(prudent diet; WHO)* are as follows:

- *Quantitatively*, it should fulfil recommended daily allowances **(Table 5.1)** for all nutrients.
- *Qualitatively*, it should provide 15–20% of calories from proteins, 20–30% by fats* and rest 50–60% from carbohydrates, along with all desired micronutrients.

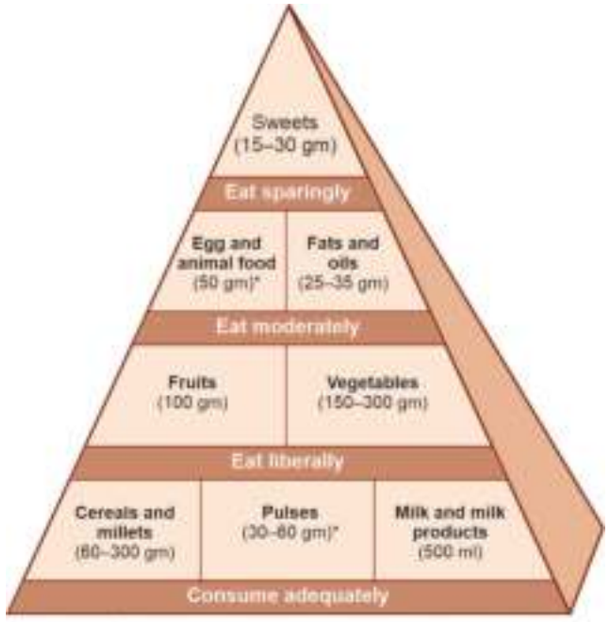
  *However, not more than 10% calories should be from saturated fats.
- It should contain adequate mix of different foodstuffs, e.g. cereals, pulses, vegetables, milk and other animal products, according to local dietary habits, customs and economic capacity.
- Various types of mixed diets include *Double mix* (cereals + pulses), *Triple mix* (cereals + pulses + vegetables) or *Quadri-mix* (cereals + pulses + vegetables+animal food). Cereal-pulse combination (*rice-dal, chapati-dal*) is a very rational dietary practice, as cereal proteins are deficient in lysine and pulse proteins in methionine. Consuming them together complements each other's amino acid deficiency to increase the nutritive value of food.
- Daily salt intake should not exceed >5 gm/day, though higher intake may be necessary in tropical countries, e.g. India.
- A balanced diet should also provide for adequate quality and quantity of other nutrients, e.g. vitamins and minerals, and *non-nutrients*, e.g. fibres, antioxidants and phytochemicals which bestow positive health benefits.
- It should be palatable, digestible and hygienic.
- Junk foods, e.g. colas, wafers, etc. should be restricted.

Food pyramid: Food pyramid is a graphic representation of the balanced diet with grossly recommended frequency and quantity of various food groups. It may vary according to the age, dietary habits and lifestyle **(Fig. 5.8)**.

Healthy plate or my plate concept, designed by the national institute of nutrition, Hyderabad is an easy to understand visual guide to display food from all food groups required in a healthy individuals plate, to ensure consumption of necessary nutrients in right quantity and right proportions, to prevent hidden hunger and protection from diseases.

5.8 NUTRITIONAL PROFILE OF INDIAN FOODS

Due to geographic variations in India, it is important to consider local food preferences, availability and affordability, while offering nutritional counseling. Nutritive values of common cooked ready-to-eat food items in Indian diet are given in **Table 5.9**. Nutritional values of common raw foods items are given in **Table 5.10**, though some important features are discussed here. All protein and caloric values in the following discussion are given as in 100 gm or ml of foodstuff, unless specified otherwise.



Based on: Dietary guidelines of Indians. National Institute of Nutrition 2011.

*Exchange 30 gm pulses with 50 gm of egg/fish/chicken/meat in non-vegetarians.

Figures in brackets denote approximate recommended intake for children 1–12 years (higher of the range for older children).

Fig. 5.8: Indian food pyramid (For children 1–12 years).

Cereals form the bulk of diet and contribute >70% and>50% of daily calories and protein intake, respectively. In general, cereals are rich sources of energy (300–350 cal), proteins (8–10 gm), vitamin B complex and minerals. However, *cereal proteins are deficient in lysine*.

- ***Rice*** is the staple food for over half of the world population. Although it contains less protein (7 gm %) than other cereals, rice protein is of better quality due to higher lysine content. Milling and cooking with excessive water significantly reduces its vitamin B complex content (present in its outer coating) which may be avoided by promoting the use of un-husked or *parboiled* rice. Thiamine deficiency, e.g. beri-beri is more common in rice-staple population.

  Parboiling is a process to preserve the nutritive value of rice by moving its vitamin content from outer coating to inner endosperm. It involves soaking the unhusked rice in hot water (65–70) for 3–4 hours, followed by steaming for 5–10 minutes, before drying and storing/milling.

TABLE 5.9: Nutritive values of ready-to-eat foods

Food items	*Cooked weight*/ number*	*Calories*	*Proteins (grams)*
Chapati (1)	25 gm	80	2.5
Paratha (1)	30 gm	170	2.5
Puri (2)	25 gm	90	2.5
Bread (1 slice)	30 gm	75	2.5
Dal/Sambar (1 katori)	100 gm	100	6
Poha/Upama (1 Katori)	50 gm	170	2
Corn flakes	50 gm	200	6
Idli/Vada (1 piece)	25 gm	100	5
Chicken/Mutton (1 Katori)	100 gm	200	18
Fish (2 pieces)	50 gm	190	2
Rice (1 katori)	25 gm	90	2
Khichri (1 katori)	25 gm	85	3
Daliya /Porridge (1 katori)	25 gm	80	2.5
Green veg (1 katori)	200 gm	50	4
Other Veg (1 katori)	200 gm	120	3
Milk (1 glass)	200 ml	150	6.5
Curd (1 cup)	100 ml	60	3
Biscuit (1)	5 gm	25	0.5
Egg (1)	45 gm	90	6
Banana (1)	Medium	70	0.5
Ghee/Oil (1 tsf)	5 ml	45	–
Sugar (1 tsf)	5 ml	20	–
Tea (1 cup)	150 ml	75	1.5
Coffee (1 cup)	150 ml	110	1

*Approximate values, may vary with cooking practices and size of utensils.
Standard size of utensils: Teaspoon: 5 ml, **Tablespoon:** 15 ml, **Cup/katori:** 200 ml, **Glass:** 250 ml.
Compiled from Dietary guidelines for Indians, National Institute of Nutrition 2011/2017 and other sources.

- ***Wheat,*** the second commonest staple cereal, is deficient in lysine and threonine. Whole grain wheat flour (aata) is more nutritious than white flour (maida), due to loss of vitamin B content during milling.
- ***Maize*** ranks third in world cereal consumption. Apart from lysine it is also deficient in *trytophan* – a niacin precursor, and *Pellagra* is common in maize-staple population. Some strains of maize also contain excess leucine that interferes with conversion of tryptophan to niacin in body.

Millets are smaller grains, e.g. jowar (sorghum), Bajra (pearl millet), ragi, etc., with caloric and protein value equal to cereals (except ragi). However, millet proteins are deficient in lysine and threonine.

Ragi, a low-cost popular millet provides less proteins (7 gm), but is a very rich source of calcium.

Pulses or Legumes include *Grams*, e.g. bengal-gram (Chana), green-gram (Moong), red-gram (Arher) and black-gram (Ural) and *beans*, e.g. soya bean and pea. All grams provide ~350 cal (equal to cereals), apart from proteins, vitamin B complex and minerals. Pulses are very rich sources of proteins (20–25 gm) in vegetarian diet, often termed as *poor man's meat*.

Nutritional value of pulses may be further enhanced by *germination* that increases vitamin B and C content. However, pulse-proteins are deficient in methionine and cysteine. In addition, uncooked pulses also contain some anti-nutrient factors, e.g. phytates and tannins, which inhibit absorption of other nutrients, e.g. iron.

- ***Soyabean*** is a very rich source of protein (42 gm), though deficient in methionine. Soya-milk is also used as infant feed during lactose intolerance.

Vegetables are considered as *protective foods* (along with fruits) due to their high vitamin and mineral content.

- ***Green leafy vegetables*** are essential in diet due to: (a) high vitamin B (except B_{12}), A and C content; (b) high iron and calcium content, (c) high fiber and water content, and (d) low caloric value (25–50 cal) with anti-obesity effect.
- ***Other vegetables***, e.g. potato, carrots, onion, radish, etc. are of limited nutritive value, except to increase palatability of diet. However, some of them are good sources of vitamins, e.g. carrot (vitamin A) or minerals, e.g. iron (radish, drum sticks). Roots and tubers, e.g. potato, sweat-potato and tapioca are rich in carbohydrates.

Fruits are valuable due to: (a) high vitamin content, e.g. vitamin A (papaya and mango), vitamin C (amla), (b) high mineral content, e.g. calcium (custard apple) and potassium (coconut water), (c) high caloric value, e.g. banana (100 cal), custard apple, etc., (d) high cellulose content (anti-constipating effect). *Dry fruits*, e.g. dates, raisins and apricot are rich sources of calories, iron and calcium.

Nuts and oilseeds, e.g. groundnut, coconut, mustard or sunflower seeds are rich sources of fats.

- ***Groundnut*** is a very rich source of calories (~550 cal) and proteins (25–30 gm), also called *poor man's cashewnut*. Even after oil extraction, groundnut flour retains its protein value and has been used to make supplementary foods, e.g. *balahar*.
- ***Dry nuts***, e.g. cashew nut, walnut, almonds, pistachio contain more fat than groundnut (35–65%), but less proteins. These nuts are good but costly source of minerals, e.g. calcium, phosphorus and iron.

Milk is the wholesome food for all ages, being rich and quality source of most nutrients. Breastfeeding is the best source of nutrition in early infancy. Other milks may be divided into two categories: (a) animal milk, (b) modified milk preparations, e.g. skimmed milk, toned milk, evaporated milk, dried milk powders, etc.

Animal milk: Composition of various animal milks differs significantly, as follows:

- *Cow milk* has a composition nearest to human milk with some differences **(Table 5.4)** and hence, commonly used for top feeding in infants, if necessary.

TABLE 5.10: Nutritive values of common Indian foods

Food Item (100 ml/gm)	*Calories (cal)*	*Proteins (gm)*	*Others*	*Food Item (100 ml/gm)*	*Calories (cal)*	*Proteins (gm)*	*Others*
Milk Products				**Non-veg**			
Human milk	65	1.1	F 3.4%	Eggs	168	13.1	–
Cow milk	73	3.3	F 4.4%	Mutton (Goat)	135	20.4	–
Buffalo milk	107	3.7	F 6.6%	Beef	137	22.6	–
Paneer	257	18.9	F ~15%	Pork	236	17.4	–
Curd	62	3.2	F 4.0%	Chicken	382	19.4	–
Cereals				Fish	~100–200	~15–20	–

Coconut (fresh)	407	3.8	F41.4%	Butter	729	–	F 81%
Cashewnut	580	18.8	F 45.2%	**Sugars**			
Walnut	669	14.9	F 64.3%	Cane sugar	398	0.1	–
				Jaggery	352	1.9	–

*Source: Indian food composition tables, National Institute of Nutrition, 2017, **F:** Fat*

- *Buffalo milk* has very high fat and caloric content and hence, should be used only after proper dilution, especially in infancy.
- *Goat milk*, though better digestible than the cow milk (less curd formation), is deficient in folic acid (megaloblastic anemia) and carries additional risk of causing brucellosis, if used without boiling.

As animal milk is regularly contaminated, boiling is essential before consumption. Currently all marketed milks are pasteurized for this purpose.

Pasteurization involves heating of raw milk at 63 for 30 minutes (or 72 for 15 seconds) followed by rapid cooling, to eliminate all pathogenic bacteria and reduce non-pathogenic bacterial count <50,000/ml. Pasteurization also improves digestibility of casein with less curd formation.

Modified milk preparations include:

- *Skimmed milk* is available in liquid and dried form (milk powders), prepared after removing most of the cream from animal milk, with fat content of 0.5% in full-skimmed milk or 1.5% in half-skimmed milk.
- *Toned milk*, cheapest milk, is prepared by mixing natural milk, water and milk powder (1:1:8) followed by pasteurization before packaging. It has composition similar to cow milk.
- *Evaporated milks* are commercial available as concentrated milk in liquid form, with long shelf-life for many months.

Skimmed milk and evaporated milk should not be used for infant feeding due to high protein and mineral content that may cause dehydration. However, these milks are useful as a dietary supplement for older children during fresh milk shortage.

Commercial milk formulas, modified according to the age-related requirements and fortified with various nutrients are available for top feeding, though costly and require careful reconstitution.

Eggs are known for their quality protein content (6 gm/egg), containing all essential amino acids. Egg protein is considered as ideal or *reference protein* (NPU ~96), with whom other proteins are compared. Milk and meat protein has an NPU of 75 and 80 respectively, while vegetable proteins have even lower NPU, i.e. ~ 60–65%.

Boiled egg is better than raw egg as boiling destroys *avidin*—a substance that prevents biotin absorption. Eggs

are also rich sources of energy (70 cal), vitamins (except vitamin C) and minerals.

Sea-foods including fishes, are rich in quality proteins (15–25 gm%), unsaturated fatty acids, fat-soluble vitamins and minerals, e.g. calcium, phosphorus and fluorine. Sea fish/foods also contain iodine, which is deficient in fresh-water fishes. However, fish contains very little carbohydrates.

Meat and animal organs, e.g. liver, are good sources of quality proteins (15–20 gm%), vitamins, e.g. vitamin D and B complex, minerals, e.g. iron, zinc (but deficient in calcium).

Fats and oils are good sources of energy (9 cal/gm) and increase palatability of diet.

- ***Vegetable oils*** are rich in EFA and PUFA (except coconut and palm oil), but contain little vitamins A and D, unless fortified (vanaspati ghee). High PUFA content in vegetable oils limits hypercholesterolemia, obesity and consequent health problems. *Coconut oil* is rich in triglycerides, which is absorbed directly without *micelles* formation (bile-based absorption) and hence, useful source of energy in preterms and chronic liver disease.
- ***Animal fats*** lack EFA and mainly contain saturated fatty acids with obesity-effect. However, animal fats are useful source of energy in malnourished children and contain plenty of fat-soluble vitamins.

Other food products, e.g. sugar, condiments/spices and beverages have very limited dietary value, except to increase its palatability.

5.9 NUTRITIONAL ASSESSMENT

Nutritional assessment is a vital component of child health examination, not only to detect early undernutrition but also to plan appropriate counseling and interventional strategies. While often used interchangeably, term *nutritional assessment* and *dietary assessment* have different connotations.

Dietary assessment denotes assessment of actual dietary intake by the child as compared to recommended dietary allowances for the age and gender to identify the deficit/s, if any.

Nutritional assessment is a broader term to encompass dietary assessment as well as assessment of the nutritional status in terms of anthropometric, clinical and biochemical parameters to identify presence of clinical or subclinical nutritional deficiencies, which may or may not be due to dietary causes.

Nutritional assessment is a comprehensive process, involving:

- *Dietary assessment*, generally based on the 24-hours dietary-recall method. Other methods of dietary assessment, e.g. *diary method* or *replicate diet* are rarely used in clinical practice.
- *Anthropometric assessment* by recording body measurements, e.g. weight, height and mid-upper arm circumference and comparing them with age/gender related norms to identify growth delay, the most common consequence of nutritional deficiencies.
- *Clinical assessment* for signs of macronutrient or micronutrient deficiencies.
- *Biochemical assessment* in selected cases to confirm presence of suspected nutrient deficiencies.

A. Dietary assessment: Dietary history must be relevant to the age, though basic information about early infant feeding (breast/top feeding) and complimentary feeding should be recorded in all cases. Important aspects of dietary history are as follows:

- *In infants < 6 months*, dietary history must concentrate on the type of feeding, e.g. breast/top feeding, appropriateness of breastfeeding practices, problems encountered during breastfeeding, reasons for initiating top-feeding, appropriateness of top feeding, if practiced.
- *In children from 6 months-2 years*, dietary history must focus on complimentary feeding along with a quick review of early infant feeding, with special emphasis on *age* of introducing complementary feeds, *adequacy* of these feeds in terms of quality (minimum dietary diversity) and quantity (minimum meal frequency), and *problems* encountered during complementary feeding. It should also record whether the breast-feeding has been continued.
- *In children > 2 years*, dietary history should concentrate on the current food intake apart from quick review of the early infant feeding and complementary feeding.

In clinical practice, dietary intake is usually calculated by *dietary recall method*, by:

- Asking the mother to recall daily consumption of different food items during last few days before the onset of present illness,
- Calculating the average daily intake of nutrients, mainly energy and proteins using known nutritional value of common Indian feeds **(Tables 5.9 and 5.10)**, and
- Then comparing this calculated intake with reference nutritional requirements for the chronological age, **(Table 5.1)**, to find out the deficit/s, if any.

Other methods to assess dietary intake, e.g. *diary method* or *replicate diet method are used only for research purpose.*

B. Anthropometric assessment: Three anthropometric indices are commonly used for regular nutritional assessment–weight, length/height and mid upper-arm circumference or MUAC (in children < 5 years), which should then be compared with age-related reference values (Ch 2.5).

Age-independent parameters, *e.g.* are useful when the exact chronological age of child is in doubt. These

TABLE 5.11: WHO classification for undernutrition

Underweight	WFA <-2SDS	Severe underweight	WFA <-3SDS
Stunting	HFA <-2SDS	Severe stunting	HFA <-3 SDS
Wasting	WFH <-2SDS	Severe wasting	WFH <-3SDS

WFA: Weight for age; **HFA:** Height for age; **WFH:** Weight for height; **SDS:** Standard deviation score

parameters are derived by comparing the relationship between two age-related parameters—one *early* indicator, e.g. weight and other *late* indicator, e.g. height. *Weight for height is the* commonly used age-independent indicator of undernutrition.

While weight is an early indicator of nutritional faltering (*wasting*), height is not be affected for many months and hence considered as an indicator of long-term nutritional deprivation (*stunting*). Based on anthropometric data, child may be classified as normal, wasted, stunted or wasted and stunted, with different grades of severity as per WHO classification **(Table 5.11)**.

Screening tests are simple, inexpensive tools used in large nutritional surveys of pre-school children, usually based on MUAC, which is fairly consistent between 1–5 years of age. Commonly used screening test include:

- *Shakir's tape*, a special plastic tape with three color zones-green, yellow and red, each representing MUAC of >13.5 cm, 12.5–13.5 cm, and <12.5 cm respectively. When applied on the mid-arm, green zone indicates normal nutrition, yellow zone warns borderline PEM and red zone indicates severe malnutrition.
- *Bangle test* uses a bangle with inner diameter of 4 cm. When slipped over the forearm, if it crosses the elbow, malnutrition is present.

C. Clinical assessment involves thorough physical examination and search for warning signs for nutritional deficiencies, if present. While it is the simplest method to search for nutritional deficiencies, drawbacks include: (a) sub-clinical deficiencies can be missed, (b) quantification of the severity may be difficult, and (c) nutritional deficiencies with common clinical presentations may not be precisely identified, e.g. *xerosis* may be due to vitamin A or essential fatty acid deficiency, or *pallor* may be due to iron or folic acid deficiency.

D. Biochemical assessment is indicated only in selected cases to confirm the presence of selective nutrient deficiency or to identify subclinical deficiencies, if necessary for the purpose of early diagnosis and treatment. Relevant biochemical tests to detect subclinical nutritional deficiencies have been discussed in respective chapters (Ch 6.1–6.7).

CHAPTER

6

Nutritional Disorders

Radha Ghildiyal, Mukesh Agrawal

6.1 CHILDHOOD UNDERNUTRITION

Undernutrition refers to a *range of pathological conditions arising from the coincidental lack in varying proportions of proteins and calories.* Children are more vulnerable to undernutrition due to relatively higher caloric and protein requirements for growth and physical activity.

Prevalence: While rarely a presenting illness by itself, undernutrition is an underlying problem in over half of morbidity and mortality in under-five Indian children.

Epidemiologically, the prevalence of undernutrition is generally assessed and reported in under-five children on the basis of WHO criteria **(Table 5.11)**. Recent NFHS-V data (2020–21) suggests that on all India basis:

- Overall prevalence of *underweight* in under-five children is 32.1%.
- Chronic undernutrition, i.e. *stunting* is more common (35.5%) than acute malnutrition, i.e. *wasting*, (19.3%).
- While the prevalence of underweight, wasting and stunting has marginally declined in recent years, severe wasting continues to be as common, if not more, as in NFHS-IV (2015–16), i.e. 7.7% vs 7.5%.
- Prevalence of undernutrition is much higher in girls, low socioeconomic status, rural children and in underdeveloped BIMARU states, e.g. Bihar, Madhya Pradesh, Rajasthan and Uttar Pradesh.

6.1.1 ETIOPATHOGENESIS

Undernutrition is a result of complex interplay between: (a) *inadequate dietary intake,* due to various dietary, socioeconomic and cultural factors, and (b) *increased nutritional requirements,* due to infections or illnesses. Common etiological factors, associated with undernutrition include:

- ***Child-related factors:***
  - Low birth weight
  - Absence or early cessation of breastfeeding
  - Delayed or inappropriate complementary feeding
  - Incorrect dietary habits, e.g. *food fads and junk foods.*
  - Recurrent infections, e.g. diarrhea, respiratory infections, measles, helminthiasis, etc.
- ***Maternal factors:***
  - Lactation failure
  - Maternal malnutrition/illnesses
  - Ignorance about child-feeding practices
  - Separation, e.g. dead, single or working mother
- ***Socioeconomic factors:***
  - Poverty and unemployment
  - Large family size
  - Unhygienic living conditions
  - Inequitable food distribution in family, with mothers and infants being last priority
  - Disadvantaged children, e.g. girls, orphans, etc.
- ***Cultural factors:***
  - *Wrong beliefs,* e.g. colostrum is harmful, hot/cold foods to be avoided in children, milk aggravates diarrhea, etc.
  - *Wrong customs,* e.g. delayed introduction of complementary feeds, waiting for religious ceremonies (annaprashan).
  - *Wrong cooking practices,* e.g. peeling of vegetables before cooking, use of polished food, draining away the water after cooking, etc.
- ***Community factors:***
  - Natural/man-made disasters with food shortage, e.g. famines, wars, civil unrests.
  - Inappropriate agricultural practices, production and distribution of food grains.
  - Generalized economic depression.
  - Inadequate primary health care.

It is not yet clear, why some malnourished children clinically present differently from others (marasmus *vs* kwashiorkor).Various theories have been suggested to explain different clinical presentations in PEM, of which two are important and deserve mention here

a. **Adaptation theory** suggests that during early stages of nutritional deficiency, human body tries to adapt by: (a) curtailing energy expenditure by reduced physical activity and growth, (b) efficient utilization of available calories by enhanced glucose uptake by

cells, and (c) utilizing endogenous stores, e.g. muscle proteins and subcutaneous fat via neoglucogenesis. However, these adaptive mechanisms require many metabolic and hormonal changes and their success depends on the availability of enough time and endogenous resources.

Children with *gradual nutritional deprivation*, e.g. delayed or inappropriate complementary feeding adapt better and develop marasmus-like illness with growth failure, muscle wasting and loss of subcutaneous tissue. Lack of urgency for endogenous catabolism as well as limited muscle mass and hepatic stores in them prevent development of edema and hepatomegaly.

Conversely children with *sudden nutritional deprivation*, e.g. those with acute illnesses or infections get less time is available to adjust for lower energy intake, necessitating rapid mobilization of endogenous stores (neoglucogenesis), leading to kwashiorkor-like state with edema (due to protein utilization) and fatty hepatomegaly (due to lipolysis).

b. **Role of infections:** Infections and nutrition are closely linked to each other **(Fig. 6.1)** and infections, e.g. diarrhea, acute respiratory infections or measles, are common preceding events to precipitate malnutrition in sub-clinically undernourished children, due to sudden widening of demand–supply gap. Kwashiorkor is relatively more common following infections than marasmus, due to inadequate adaptation.

6.1.2 CLINICAL SPECTRUM

Clinical spectrum of undernutrition is a *continuum*, ranging from borderline growth delay to well-defined syndromes of marasmus or kwashiorkor. Within this spectrum, many other terms are also used to denote clinical variations, e.g. pre-kwashiorkor, marasmic kwashiorkor, nutritional dwarfism, etc.

Kwashiorkor, a term coined by Prof. Cicely Williams, denotes acute PEM due to either sudden nutritional deprivation, e.g. abrupt cessation of breastfeeding (*deposed child*) or sudden increase in nutritional requirements due to infection, diarrhea, etc. *Moderate weight loss (61–80%), edema and mental changes are three cardinal features of kwashiorkor,* usually but not invariably, associated with hepatomegaly, skin/hair changes, vitamin deficiencies, etc.

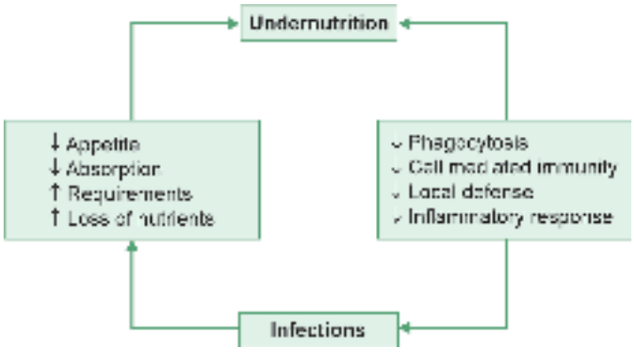

Fig. 6.1: Undernutrition and infection interaction.

Marasmus, a term derived from Greek word *marasmos* (wasting), is a state of chronic and severe undernutrition due to gradual nutritional deprivation, e.g. delayed complementary feeding with widening gap between nutritional requirements and breast milk output. *Severe weight loss (<60%), wasting of muscles and subcutaneous tissue and absence of edema are hallmark of marasmus.*

Some important clinical features of undernutrition with differences between kwashiorkor and marasmus are as follows **(Table 6.1)**:

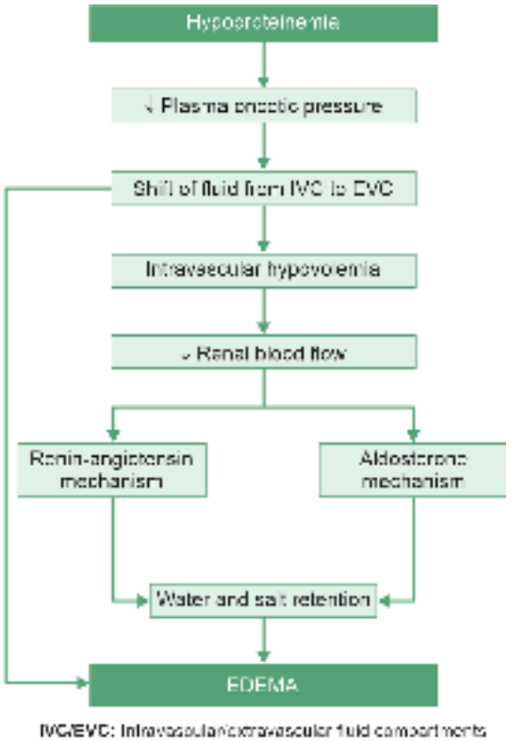
- ***Growth failure:*** Wasting is the essential feature in all malnourished children with/without stunting, more obvious in marasmus due to absence of edema. A marasmic child has typical shriveled (*monkey like*) look with gross emaciation, relatively larger head, staring eyes, prominent ribs, wrinkled skin and loose skin-folds over buttocks, inner thighs, axilla and chest. Buccal pad of fat is usually preserved except in severe marasmus **(Fig. 6.2)**. Bone age and dentition may also be marginally delayed.
- ***Edema*** is the *sine qua non* of kwashiorkor, due to hypoproteinemia and consequent fluid retention **(Fig. 6.3)**, though severity may vary from mild pitting edema over dependent parts, e.g. legs or sacrum, to generalized anasarca **(Fig. 6.4)**. Severe edema may mask underlying wasting, weight loss and dehydration.

TABLE 6.1: D/D kwashiorkor *vs* marasmus

		Kwashiorkor	***Marasmus***
1.	Age	>1 year	Any
2.	Dietary history	Early cessation of breastfeeding	Delayed
3.	Onset	Acute	Gradual
4.	History of infection	Frequent	Uncommon
5.	Edema	Essential	Absent
6.	Growth failure a. Weight b. Height c. Wasting	 60–80% N/↓ +, masked	 <60% ↓↓↓ +++
7.	Mental changes	Apathetic	Alert
8.	Appetite	Poor	Good
9.	Skin/hair changes	Common	Rare
10.	Hepatomegaly	Present	Uncommon
11.	Vitamin deficiencies	Common	Masked
12.	Hypoproteinemia	++/+++	+

Fig. 6.2: Clinical appearance of PEM (Marasmus).

Fig. 6.4: Clinical appearance of PEM (Kwashiorkor).



IVC/EVC: Intravascular/extravascular fluid compartments

Fig. 6.3: Pathogenesis of edema in kwashiorkor.

Fig. 6.5: (A) Crazy pavement dermatosis, (B) Flaky-paint dermatosis.

- ***Mental changes:*** Children are typically apathetic and lethargic in kwashiorkor with little interest in surroundings, probably due to impaired activity of CNS enzymes in an *un-adapted* child. Anorexia is also marked in these cases. In contrast, marasmic children have good appetite and are usually alert with roving eyes as if searching for food.
- ***Skin changes*** are more pronounced in kwashiorkor than marasmus due to combined effect of: edema, multiple vitamin deficiencies, essential fatty acid deficiency and secondary infections. Depending on the severity, these changes include: (a) *phrynoderma*, i.e. generalized dryness of skin, (b) diffuse or patchy areas of hypo/hyper pigmentation, (c) thin, shiny, taut skin over edematous areas, (d) moist ulcerations over flexural areas or pressure points, (e) superadded infections, e.g. pyoderma and scabies. Following lesions are classical but uncommon except in severe kwashiorkor **(Fig. 6.5A and B)**:
  - *Flaky paint dermatosis,* i.e. hyperpigmented and desquamating area (*flakes)* over raw-skin;
  - *Crazy pavement dermatosis,* i.e. hyperkeratotic, fissured skin with alternate areas of hypo-or hyper-pigmentation;
  - *Mosaic dermatosis* with mixed lesions in mosaic form.
- ***Hair changes*** are more common in kwashiorkor with thin, dry, sparse, lusterless, hypopigmented and

easily pluckable hair. Due to intermittent periods of better nutrition, alternate bands of hypo-and normal pigmentation on hair are classically described as *flag sign.* In marasmus, hair are sparse and hypopigmented.

- ***Hepatomegaly*** is common in kwashiorkor due to fatty infiltration of liver, though jaundice is rare and indicates poor prognosis.
- ***Concomitant nutritional deficiencies*** like xerophthalmia, vitamin B complex deficiencies, scurvy and anemia are more obvious in kwashiorkor. Although biochemical vitamin/mineral deficiencies are common in marasmus as well, clinical signs are less prominent in them due to adaptive mechanisms and usually appear in recovery phase.

  Anemia in PEM is usually dimorphic, due to: (a) reduced dietary intake of hemopoietic factors like iron, proteins and folic acid, (b) co-existing infections affecting erythropoiesis, and (c) occult blood losses due to worm infestations.
- ***Concomitant infections*** like intermittent episodes of diarrhea, respiratory infections and skin infections are common in PEM, due to impaired immune mechanisms **(Fig. 6.1)** and mucosal integrity. *Cellular immunity and phagocytic functions are predominantly affected in PEM, while immunoglobulin levels are usually normal or high with good antibody response.*

  Presence of infections may be clinically masked in undernutrition due to poor inflammatory responses, e.g. fever and leukocytosis. Hypothermia is an important indicator of infection in these children. Diarrhea in PEM may also result from malabsorption due to intestinal villous atrophy and consequent lactase deficiency, as well as due to hepatic/pancreatic dysfunction.

6.1.3 DIAGNOSTIC ASSESSMENT

Assessment of a child with undernutrition involves: (I) assessment of dietary intake, (II) assessment of nutritional status, (III) classification of severity, and (IV) identification of complications.

I. Assessment of dietary intake is the first step in screening for undernutrtion, already discussed in chapter on nutritional assessment (Ch 5.9). It includes history of age-related infant and young child feeding (IYCF) practices, e.g. breastfeeding and complementary feeding as well as assessment of the actual dietary intake before the onset of presenting illness, usually by *dietary recall method*.

II. Assessment of nutritional status on the basis of anthropometric, clinical and biochemical parameters, as follows:

- ***Anthropometric parameters*** may be broadly divided into: (i) age-dependent parameters or (ii) age-independent parameters.

  Age-dependent parameters, e.g. weight and height are two most commonly used anthropometric indicators of undernutrition. *Weight* is the first anthropometric parameter to decrease in undernutrition and hence, considered as an indicator of acute malnutrition. Height is affected only after many months of undernutrition and hence, considered as indicator of the chronic undernutrition.

  Age-independent parameters are useful when the exact chronological age of child is in doubt and are derived by comparing the relationship between two age-related parameters-one *early* indicator, e.g. weight and other *late* indicator, e.g. height. Weight for height is the most commonly used age-independent anthropometric parameter in assessment of undernutrition. However, it may be misleading in chronic cases due to proportionate fall in weight as well as height. Other rarely used age-independent indicators include: mid upper arm circumference or MUAC (for children aged 1–5 years only), Kanawati Index (MUAC/head circumference) and skin fold thickness.

  Screening parameters are simple, inexpensive tools for mass nutritional surveillance of preschool children including Shakir's tape or Bangle test (Ch 5.9).
- ***Clinical diagnosis*** depends on the features discussed earlier in Ch 6.1.2, though with following caveats:

  Edema shall be considered as a clinical sign of undernutrition only if it is bilateral and has no other known etiology, e.g. nephrotic syndrome.

  Wasting as an indicator of growth failure is a subjective sign and should be used only if anthropometric parameters are no available or feasible. It may be masked in children with edema (kwashiorkor) or may be more marked in those with associated severe dehydration.
- ***Biochemical parameters*** are rarely used in clinical practice, mainly useful to detect early sub-clinical cases of undernutrition. Earliest biochemical change in undernutrition is the decrease in essential amino acid (EAA) levels—which cannot be synthesized endogenously, leading to altered EAA/non-EAA ratio in plasma. Subsequently, plasma albumin levels fall, though the edema appears only when plasma albumin levels drop < 2.5 gm/dl.

III. Classification of severity: Various classifications systems were in vogue earlier, to denote severity and duration of PEM, as follows:

- *Weight for age (WFA) based classifications*, are simple and commonly used in practice, though do not indicate the duration of malnutrition and include *Indian Academy of Pediatrics classification* **(Table 6.2)**, *Gomez classification, Jellife's classification, etc.*
- *Height/length-for-age (HFA) based classifications* are rarely used in practice and included *Waterlow's classification or McLaren's classification, etc.*

TABLE 6.2: Indian Academy of Pediatrics (IAP) classification

*Weight for age**	*Nutritional status**
>80%	Normal
71%–80%	Grade I PEM
61%–80%	Grade II PEM
51%–60%	Grade III PEM
<50%	Grade IV PEM

*As compared to 50th percentile of normal

TABLE 6.3: Welcome-trust classification

*Weight for age**	*Edema*	*Type of PEM*
80–60%	Absent	Undernutrition
	Present	Kwashiorkor
<60%	Absent	Marasmus
	Present	Marasmic kwashiorkor

*As compared to 50th percentile of normal

- *Composite classifications*, based on anthropometric as well as clinical criteria, are most informative and include *Welcome-trust classification* **(Table 6.3)**, *Waterlow's classification, WHO classification, IMNCI classification, etc.*

  WHO classification, most widely used classification for epidemiological purpose rests on two anthropometric parameters: (a) weight for height (WFH) as a measure of acute malnutrition, and (b) height for age (HFA) as a measure of chronic malnutrition, along with one clinical parameter, i.e. presence of symmetrical *edema*. It classifies all undernourished children in two major categories – moderate malnutrition and severe malnutrition, with each category further sub-divided as wasted and stunted (if WFH and HFA is between 2–3 SD respectively) or severely wasted or severely stunted (if WFA and HFA are < 3SD respectively). All cases with edema are considered as having severe malnutrition **(Table 6.4)**.

  IMNCI classify nutritional status in children from 2 months to 5 years of age as: (a) severe acute malnutrition with complications, (b) severe acute malnutrition without complications, (c) moderate acute malnutrition, and (d) no acute malnutrition **(Table 6.5)**.

IV. Assessment of complications: Malnutrition is rarely a primary cause of hospital visit, often presenting with complications **(Table 6.6)** with significant impact on the morbidity and mortality. Identification of these complications is also important to decide the need of hospitalization and strategies of management.

V. Investigations: Although PEM is a clinical diagnosis, following investigations are required on admission (initial assessment), to exclude or identify complications.

- Complete hemogram including peripheral smear for anemia and infections (malaria).

TABLE 6.4: WHO classification for undernutrition

	Moderate undernutrition	*Severe undernutrition*
Edema	No	Yes Edematous malnutrition
Wt for Ht (Z-score*)	– 2 to – 3 Wasting	< – 3 Severe wasting
Ht for age (Z-score*)	– 2 to – 3 Stunting	< – 3 Severe stunting

*or SD score

TABLE 6.5: IMNCI classification for malnutrition

a.	**Severe acute malnutrition with complications** WFL/H <-3SDS *or* MUAC<11.5 cm *or* bilateral pedal edema **And** medical complications*
b.	**Severe acute malnutrition without complications** WFL/H <-3SDS or MUAC<11.5 cm or bilateral pedal edema **And** No medical complications
c.	**Moderate acute malnutrition** WFL/H <-2 to-3SDS or MUAC<11.5-12.4 cm
D.	**No acute malnutrition** WFL/H >-2 SDS or MUAC<12.5 cm

WFL/H: Weight for length/height, **MUAC**: Mid-upper arm circumference
*Medical complications include (a) any general danger sign, (b) any severe classification, (c) pneumonia, (d) diarrhea with dehydration, (e) poor appetite.

TABLE 6.6: Complications of PEM

Early (presenting) complications		
a.	Infections	
	Common	: ARI, diarrhea, TB, helminthiasis
	Severe	: Gram –ve sepsis, septic shock, DIC
	Opportunistic	: Candidiasis
b.	Hypothermia	
c.	Metabolic	
	Hypoglycemia	
	Hypocalcaemia	
	Hypomagnesemia	
d.	Fluid and electrolyte imbalance	
	Dehydration	
	Hypokalemia	
	Hypernatremia	
e.	Lactose intolerance	
f.	Severe anemia and other nutrient deficiencies	
g.	Congestive cardiac failure	
Late (recovery) complications		
a.	Diarrhea (lactose intolerance)	
b.	CCF (high protein and solute diet)	
c.	Unmasking of subclinical vitamin/mineral deficiencies	
d.	Recovery syndromes (*see* text)	
Long-term effects		
a.	Growth retardation	
b.	Cognitive and learning disabilities	

- Urine examination, specially for pus cells (UTI),
- Stool examination, specially for fat globules (malabsorption),reducing sugars (lactose intolerance) and microscopic ova/cysts,
- Chest skiagram for tuberculosis, respiratory infections,
- Tuberculin test, which may be false negative in severe PEM due to impaired cell mediated immunity.
- Biochemical tests, specially: S. albumin (hypoproteinemia) blood sugar (hypoglycemia) S. electrolytes (Na^+, K^+, Ca^{++} and Mg^{++}) and liver/renal function tests,
- Microbial cultures (blood, urine, others),
- Other relevant investigations.

6.1.4 SEVERE AND MODERATE ACUTE MALNUTRITION (SAM AND MAM)

While chronic malnutrition is more common, children with acute malnutrition are at highest risk of death and serious complications, who need immediate medical attention.

Hence, for the purpose of management, WHO/UNICEF in recent years has categorized acute malnutrition as *severe acute malnutrition* (SAM) and *moderate acute malnutrition* (MAM), to standardize management strategies **(Table 6.7)**.

Severe acute malnutrition *(SAM)* is defined as presence of *any one* of the following criteria in children 6 months to 5 years:

- Weight for length/height < – 3 SDS or z-score,
- Mid-upper arm circumference <11.5 cm,
- Presence of bilateral pedal edema.

In addition, IAP guidelines also include *visible wasting* as an additional criteria for SAM, though it is highly subjective and should be used only if: (a) anthropometric parameters, e.g. Wt, Ht and MUAC are not available; or (b) length is <45 cm, as weight for length charts are not available for children measuring <45 cm.

Moderate acute malnutrition *(MAM)* is defined as presence of *any one* of the following criteria in children 6 months to 5 years:

- Weight for length/height between –2 and –3 SDS or z-score,
- Mid-upper arm circumference between 12.4 cm to 11.5 cm.

TABLE 6.7: Diagnostic criteria for SAM and MAM in children

	6 mo-5 yr	*< 6 mo*	*MAM*
Wt for L/Ht	< 3 SD	< 3 SD	–2 to –3 SD
MUAC	<11.5 cm	NA	12.4–11.5 cm
Bilateral edema	present	Present	Absent
Visible wasting	NA	Present	Absent

MUAC: Mid-upper arm circumference

In children below 6 months, same criteria may be used for diagnosis of SAM and MAM except MUAC and including those with visible wasting as SAM.

6.1.5 MANAGEMENT OF SEVERE ACUTE MALNUTRITION

SAM is a major cause of mortality and morbidity and needs specialized care in a hospital or *nutrition rehabilitation centers (NRC)* – dedicated units in hospitals for nutritional therapy and support. However, some cases of SAM do not need hospital care and may be managed at home under supervised care. Thus, the management of SAM may be broadly divided into: (a) facility-based care, and (b) community-based care, discussed in the following sections.

A. Facility-based Care

Hospitalization is indicated in all cases of SAM (6–59 months) *with* following risk factors:

- Complicated SAM with life-threatening complications, i.e. infections, hypothermia, dehydration, electrolyte/metabolic derangements, severe anemia, etc. **(Table 6.6)**.
- Presence of severe edema
- Presence of danger signs of IMNCI (convulsions, altered sensorium, inability to drink/feed, persistent vomiting)
- Failure to pass appetite test
- Lack of reliable home care/supervision

In addition, *all infants <6 months with SAM and/or those who are too weak or feeble to suckle*, need hospitalization.

Appetite test aims to assess the extent of the loss of appetite. Children with good appetite, even with SAM, can be managed on outdoor basis in absence of other complications. It involves offering the child a measured amount of feed and assessing the unconsumed portion to calculate the intake.

- *For children 7–12 months*: Offer 30–35 ml/kg of catch-up formula diet **(Table 6.11)**. Child is considered to have good appetite, if she/he can consume >25 ml/kg.
- *For children >12 months*: Offer a specially prepared feed from local ingredients (mix *roasted and grinded groundnut 1000 gm, grinded sugar 1120 gm, milk powder 1200 gm and coconut oil 600 gm* and store in air-tight container in refrigerator; to be used within one week).

To pass the appetite test (good appetite), child should be able to consume >15 gm (wt <4 kg), >25 gm (wt 4–7 kg) and >33 gm (7–10 kg) of this feed.

Appetite test should be performed in a separate quiet area after explaining the purpose and procedure to the mother. The child should not have been fed in last two hours and must not be forced to take the feed. The test may take up to one hour and the remaining amount must be measured to assess the intake.

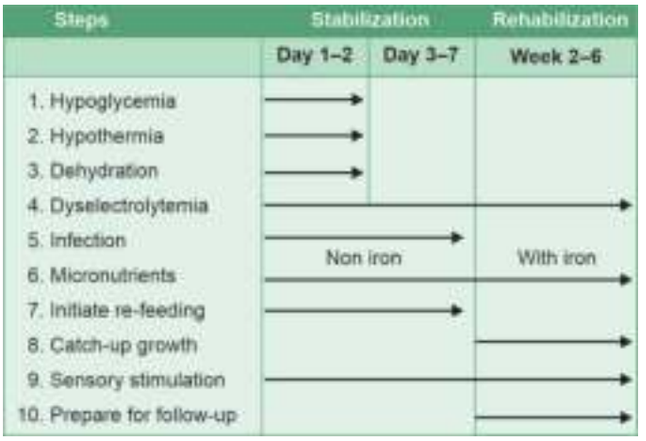


Fig. 6.6: Ten steps in management of SAM (WHO).

Ten steps of SAM management: Management of SAM may be broadly divided into three phases: (a) stabilization phase, (b) transition phase, and (c) rehabilitative phase.

- *Stabilization phase (1–2 days)* involves treatment of major medical complications and initiation of re-feeding with suitable starter feeds to promote normalization of metabolic function and nutrition-electrolytic balance.
- *Transition phase (2–3 days)* after stabilization, aims to ensure that the child is clinically stable before gradual switch-over from starter diet to catch-up diet.
- *Rehabilitation phase (2–6 weeks)* aims to promote rapid weight gain, stimulate emotional and physical development and prepare the child for discharge, after gradual switch-over on home diet.

WHO has proposed 10 essential steps in the management of SAM within a given timeframe **(Fig. 6.6)**, as follows:

Step I. Treat and prevent hypoglycemia: All SAM children are at risk of hypoglycemia (blood glucose <54 mg/dl) and should be checked for blood glucose levels on admission. If it is not possible, hypoglycemia must be assumed to be present.

Asymptomatic hypoglycemia is more common and should be treated promptly by 50 ml of 10% dextrose/sugar solution, fed orally or via nasogastric tube, followed by the first feed of starter F-75 formula (discussed later, **Table 6.9**) every two hours to prevent recurrence. First F-75 feed may be given as small volume ($1/4^{th}$ part of 2-hourly feeds) every 30 minutes, till the stabilization. blood glucose levels should be re-checked 2-hrly, till stabilized.

Symptomatic hypoglycemia with altered sensorium and/or seizures, should be treated promptly with IV dextrose 10% (5 ml/kg) as bolus, followed by oral dextrose/sugar solution or F-75 feed, as discussed earlier for asymptomatic hypoglycemia. Blood glucose levels should be rechecked 2-hourly, till stabilized.

Hypoglycemia can be prevented by frequent regular feeds, including at night along with periodic monitoring.

Step II. Treat and prevent hypothermia: Hypothermia (rectal temperature <35.5°C) is more common in marasmus due to less subcutaneous fat. It may also indicate underlying hypoglycemia or infections. Blood glucose levels should be checked in all cases of hypothermia. Baby should be assumed as hypothermic, if rectal thermometer is not available and temperature is not recordable by skin thermometer.

Treatment of hypothermia involves: (a) gradual re-warming under radiant warmer/blanket or putting him/her on the mother's bare chest for skin-to-skin contact, (b) frequent feeding, and (c) starting antibiotics as per step V. Rectal temperature should be monitored every 30 minutes, till it exceeds 36.5°C.

Prevention of hypothermia involves: (a) frequent 2-hourly feeding even during nights, (b) keeping the baby warm and well covered with mother and dry by changing wet-nappies as needed, and (c) avoiding prolonged cold-exposure for examination or procedures.

Step III. Treat and prevent dehydration: Dehydration is common in malnourished children due to co-existent diarrhea/vomiting, poor oral intake and redistribution of body fluids. Severity of the dehydration is often overestimated in these cases and parenteral fluids should be avoided unless the patient is in shock. Conversely, dehydration may be missed in edematous children. Any SAM child with diarrhea must be presumed as dehydrated.

Mild to moderate dehydration is preferably treated with WHO-ORS, given orally or via nasogastric tube as 5 ml/kg every 30 minutes for first two hours, followed by 5–10 ml/kg/hr for maximum 12 hours, depending on the needs. While IAP recommends use of WHO-ORS for this purpose, WHO recommends use of half-diluted ORS or ***Re**hydration **So**lution for **Mal**nutrition* (ReSoMal) to rehydrate SAM children, except in cases of cholera or profuse watery diarrhea.

ReSoMal, though rarely used, can be prepared by diluting one packet of WHO-ORS in 2 liters of water (instead of 1 liter) and adding 50 gm of sugar and 40 ml of specially prepared electrolyte-mineral solution. It should be used only under medical supervision in in-patient care.

All cases should be monitored for hydration by pulse rate, respiratory rate, urine output and stool/vomit frequency, every 30 minutes in first two hours and then hourly for next 6–12 hours. Oral fluids must be replaced with F-75 feeds in the same volume at 4, 6, 8 and 10 hours, if dehydration continues.

Parenteral fluid therapy is necessary in cases with shock, with a cautious approach due to risk of fluid overload. IV Ringer lactate or N/2 Saline in DW 5% is

preferred, given as 15 ml/kg in first hour and repeated after one hour (in responders), followed by switch-over to oral fluids. All cases should be closely monitored for signs of fluid overload, e.g. tachycardia, tachypnea, edema and puffy eyelids.

If the child fails to improve after the first hour of parenteral fluids, she/he should be assumed to have septic shock and treated with maintenance IV fluids (4 ml/kg/hr) along with fresh whole blood transfusion at 10 ml/kg *slowly* over 3 hours.

Dehydration can be prevented in a SAM child with watery diarrhea by feeding F-75 feeds (step 7) and replacing the stool losses with 50–100 ml of ReSoMal/half-ORS after each watery stool. Breastfeeding should be encouraged in breastfed children.

Step IV. Correct electrolyte imbalance: Dyselectrolytemia is common in malnutrition due to poor intake, losses in diarrhea/vomiting and redistribution of body fluids, even in absence of clinical signs.

All malnourished children have *excess body sodium* due to renal retention, despite low or normal plasma sodium levels and should receive low-salt diet. Hypertonic fluids should be strictly avoided.

Hypokalemia is common due to redistribution of body fluids, which may be asymptomatic or presents with muscular weakness and abdominal distension. Asymptomatic hypokalemia can be treated with oral potassium supplements 3–4 mEq/kg/day for 2 weeks as commercial potassium chloride solution (20 mEq/15 ml),given mixed with feeds. In cases on IV fluids, potassium must be added to IV fluids as 2–3 mEq/kg/day, after the child has passed urine.

Hypomagnesemia is common due to reduced muscle mass and may be corrected by oral magnesium supplementation as 0.8–1.2 mEq/kg. On day one, all malnourished children must receive single dose of IM magnesium sulfate (0.3 ml/kg, max 2 ml).

Hypocalcemia may be present due to low albumin-bound fraction, but rarely needs to be treated as ionic calcium is usually normal.

Step V. Treat and prevent infections: Infections are common but may be difficult to recognize due to poor inflammatory response and absence of constitutional signs, e.g. fever. All cases of SAM on admission must be presumed to have infection and treated with empirical antibiotics. Presence of hypothermia, hypoglycemia, shock and bleeding tendencies indicates potentially serious underlying infection.

Choice of empirical antibiotics and duration of therapy varies with severity of sepsis and presence of complications **(Table 6.8)**, which should be modified after culture reports. Some workers also suggest metronidazole (PO 30 mg/kg/d q8h 7 days) to cover anaerobic infections. Antimalarial therapy is indicated only if smear is positive.

TABLE 6.8: Antibiotic therapy in SAM

No complications:
PO Amoxicillin 60 mg/kg/d q8h × 5 days
Complications: (excluding shock, meningitis or dysentery)
IV Ampicillin 200 mg/kg/d q6h × 7 days ***with***
IV Gentamycin 7.5 mg/kg/d q24h × 7 days
Add:
IV Cloxacillin 100 mg/kg/d q6h
(In suspected staphylococcal infections)
Septic shock or no improvement in initial hours:
IV Cefotaxime 150 mg/kg/d q8h ***or***
IV Ceftriaxone 100 mg/kg/d q12hr ***with***
IV Gentamycin 7.5 mg/kg/d q24h
(No second dose of gentamycin, till urine is passed)
Meningitis: (14–21 days)
IV Cefotaxime 200 mg/kg/d q6h ***or***
IV Ceftriaxone 100 mg/kg/d q12h ***with***
IV Amikacin 15 mg/kg/d q8h
Dysentery:
IV/PO Ciprofloxacin 30 mg/kg/d q12h × 3 days ***or***
IV Ceftriaxone 100 mg/kg/d q12-24h × 5 days

Step VI. Correct micronutrient deficiencies, *which* are common but often asymptomatic due to adaptive mechanisms.

Vitamin A supplementation is indicated in age dependent single oral dose (2, 00,000 IU <1 yr, 1, 00,000 IV in 0.5–1 yr and 50,000 IU <6 mo) on admission. However, in cases with clinical signs of deficiency, three doses on day 1, 2, 14 are required. Intramuscular administration is needed (half of the oral dose) in cases with severe anorexia, edematous malnutrition or septic shock. WHO recommends daily vitamin A supplements (5000 IU/day) and not the single dose therapy as above, except when feeds not fortified with vitamin A.

Vitamin K (IM 2.5 mg) is also recommended as singledose on the day of admission.

Other vitamin-mineral supplements, except iron, must be given from the day of admission for at least 2 weeks **(Table 6.9)**, either separately or as combined preparation. Multivitamin preparation should also contain vitamin A, C, D, E and B_{12} along with other minerals, in doses twice of the recommended dietary allowance.

Iron supplements should be delayed till the baby starts gaining weight and is on catch-up diet for at least 2 days, as it may be utilized by organisms for their metabolism and deteriorate the underlying infection. It should be continued for at least 2 months to replenish stores. Transfusion should be avoided due to potential risk of CCF, indicated only in cases with hemoglobin <4 gm or

TABLE 6.9: Micronutrient supplements in SAM

On day 1
• PO/IM Vitamin A: Single age-dependent dose*
• IM Vitamin K 2.5 mg single dose
From day 1–14 (all orally)
• PO Multi-vitamins (in twice RDA dose)**
• PO Folic acid 1 mg/d (5 mg on day 1)
• PO Zinc 2 mg/kg/d
• PO Copper 0.3 mg/kg/d
From the time weight gain starts
• PO Iron 3 mg/kg/d q12h

*see Table 6.14
**see Table 5.1

Energy (kcal/100 ml)	100	100
Proteins (gm/110 ml)	2.9	2.9
Lactose (gm/100 ml)	3.8	3.0

*Cook for 4 minutes

4–6 gm with respiratory distress. In them, whole blood may be transfused (10 ml/kg over 3 hour), along with IV furosemide (1 mg/kg) at the beginning of transfusion. Packed cells transfusion (5–7 ml/kg) should be used instead of whole blood in presence of CCF. All cases should be monitored or fluid overload. Blood transfusion should not repeated in next 4 days, if avoidable.

Step VII. Initiate re-feeding: Feeding should begin as soon as possible, though cautiously due to fragile physiological state and limited homeostatic capacity. Early feeding at this stage aims to provide sufficient energy and proteins for basic metabolic processes, without expectation of weight gain. However, these children have poor appetite and limited capacity to handle proteins, fats and solutes. Important considerations to initiate re-feeding are as follows:

- Recommended dietary intake during this phase is~*100 kcal/kg/d of energy, 1–1.5 gm/kg/d of proteins and 130 ml/kg/d of fluids of actual weight* (100 ml/kg/d fluid, if the child has severe oedema).
- Starter feeds must provide ~ 75 kcal and ~ 0.9 gm protein per 100 ml **(F-75),** which may milk-based or cereal-based, preparedly locally **(Table 6.10)**.
- Frequency and volume of feeds depend on the acceptance. Usually, small and frequent (8–12/day) feeds are required in the beginning, given throughout the day, including in night. Volume of each feed may be increased gradually as the appetite improves.
- Oral feeds are preferable, though nasogastric feeding is indicated if the baby is unable to consume at least 80% of offered feeds.
- Breastfeeding should be encouraged *ad libitum* in breastfed cases, along with starter feeds.
- All cases should be monitored daily for body weight, losses in stools/vomiting and 24-hr intake, carefully assessing the feeds offered and leftovers.

Step VIII. Feeding for Catch-up growth: Once the appetite returns and child is stabilized, usually after a week, rehabilitation phase begins to rebuild wasted tissues and ensure weight gain. Important considerations for catch-up diet during this phase are as follows:

- Catch-up diet **(F-100)** must be relatively more energy-dense, containing ~100 kcal and 2.9 gm protein per 100 ml, which may milk-based or cereal-based, preparedly locally **(Table 6.11)**.
- To being with, starter-formula feeds (F-75) must be replaced with the same amount of catch-up formula (F-100) for first two days, followed by gradually increasing the each feed by 10 ml, until some feed remains uneaten. Usual intake at this stage is expected to be ~30 ml/kg/feed or ~200 ml/kg/day.
- To begin with, child should receive at least 8 feeds/day of catch-up formula. Gradually, some of these feeds may be replaced by ready-to-use therapeutic foods (RUTF, discussed later) or locally prepared therapeutic foods or modified family foods with comparable energy and protein concentration, e.g. *khichri or halwa*, to prepare the child for discharge on home diet. Breastfeeding should be continued *ad libitum*, in breastfed children.
- Child should be encouraged to eat as much as possible and offered more feeds next time, if finished everything. Frequency may be reduced gradually to 6 feeds/day, as the volume per feed improves. *At the end of this phase, target is to give 200 calories ml/kg/day and 4–6 gm/kg/day of proteins, of actual weight.*

- All cases should be monitored for daily weight gain, expected to be ~10 gm/kg/day. Child should be reassessed for underlying infection or psychosocial problems, if weight gain is inadequate. All cases should also be monitored for signs of heart failure.
- Infants <6 months should not given undiluted F-100 due to risk of solute overload and must be managed with breastfeeding and/or F-75.

Failure to respond during rehabilitation phase is defined as *weight gain <5 gm/kg/day*, while those with gain between 5 and 10 gm/kg/day are considered to have moderate response. Poor weight gain may be due to: (a) inadequate feeding, (b) specific nutrient deficiencies, (c) underlying infection or systemic disease, and (d) emotional deprivation.

Failure to respond is further classified as *primary failure* when child fails to: (a) regain appetite by 4th day, (b) start loosing edema by 4th days, (c) loose edema by 10th day, and (d) gain weight by at least 5 gm/kg by 10th day. *Secondary failure* denotes weight gain of <5 gm/kg/day for three consecutive days in rehabilitation phase.

Step IX. Provide sensory stimulation and emotional support: Developmental delay and behavioral changes are common in SAM children. Emotional and physical stimulation is an integral part of management in these cases and includes: (a) tender and loving care, (b) cheerful and stimulating environment, (c) encouragement of physical activity, (d) maternal involvement in child care, and (e) structured play-sessions including language and motor activities with the help of toys, etc.

Step X. Prepare for follow-up after recovery: Most cases need ~10–15 days of hospitalization, while remaining part of rehabilitation phase may be completed at home, followed by periodic follow-up for 4–6 month to prevent recurrence. While preparing for the discharge:

- Child should be gradually switch-over from catch-up diet to regular family meals, in adequate quantity and appropriate quality.
- Mother must be trained to follow correct feeding practices, including need for breastfeeding, preparation of nutritious feeds and feeding frequently.
- Immunization must be completed for age.
- De-worming must be done with single oral dose of Albendazole 200 mg (400 mg for >2 yr).
- Follow-up plan must be shared with mother, who should also be trained to recognize signs which need immediate medical attention.

Criteria for discharge: WHO recommends that SAM cases should be discharged only after achieving: (a) Wt for Ht >-2 SDS/z-score, (b) no edema for at least 2 weeks, and (c) MUAC > 12.5 cm. WHO does not recommend use of *percentage weight gain* as criteria for discharge. However, considering the patient-load, Government of India guidelines recommend that a SAM case can be discharged from the hospital if:

- has gained >15% of pre-admission weight with satisfactory gain for 3 consecutive days (>5 gm/kg/day),
- accepting adequately the nutritious foods that the mother can prepare at home,
- all infections and other medical complications have been treated,
- has been provided with micronutrients,
- has been fully immunized, and
- mother has been trained for good feeding practices and sensory stimulation at home. She must also be able recognize the signs which need immediate medical assistance.

On discharge, these cases should be transferred to the outpatient therapeutic program (OTP), discussed later, and must be followed up every 2 weeks in first month and then monthly thereafter until weight for height reaches >-1 Z/SD-score.

Re-feeding (Recovery) syndromes: While rarely seen at present due to the use of standard guideline-based management, children recovering from SAM are prone to develop many complications due to unmasking of subclinical nutrient deficiencies and should be carefully monitored for:

- *Diarrhea* due to relative lactase deficiency and other malabsorption states, precipitated by increased nutritional intake,
- *Congestive cardiac failure* due to shift of edema fluid in intravascular compartment, following high solute and protein diet,
- *Un-masking of sub-clinical vitamin and mineral deficiencies*, e.g. scurvy, zinc deficiency, due to disturbed adaptation.

Two well-defined clinical syndromes seen during the recovery phase are *Kahn and Gomez recovery syndromes*, probably caused by unmasking of subclinical nutrient deficiencies.

- ***Kahn's recovery syndrome*** is characterized by sudden onset of tremors and encephalopathy, probably due to unmasked deficiency of gamma aminobutyric acid (GABA)–a major neuroinhibitors.
- ***Gomez recovery syndrome*** is characterized by progressive abdominal distension, ascites, hepatomegaly and diarrhea, due to secondary malabsorption and dyselectrolytemia, e.g. hypokalemia.

B. Community-based Care

Generally, SAM is managed in hospitalization set-up while MAM is managed on outpatient basis. However, it is neither possible nor desirable to provide facility-based care to all SAM children in resource-limited settings. Community-based care or home-based care is a more feasible concept for the management of malnutrition in resource-limited settings and includes:

- ***Outpatient therapeutic program*** (OTP) for children with SAM but good appetite and no medical complications or those who have been prematurely discharged from the facility-based care.

  OTP should aim to provide ~150 calories and 4 gm/proteins per day till complete recovery, using frequent energy/protein dense meals either as read to use therapeutic food (RUTF) or home-based modified diet along with micronutrient supplementation. Children are followed-up weekly at an OTP site in a community setting, for periodic check-ups and replenishment of RUTF.
- ***Supplementary feeding program*** (SFP) for children with MAM or those who have been graduated from OTP. SFP provides for dry take-home rations and routine basic treatment.

However, *facility-based care is a must for* children with SAM and poor appetite (failed appetite test) or associated medical complications.

Ready-to-use therapeutic food (RUTF) is an energy-dense mineral/vitamin-enriched food, specifically designed to treat SAM cases under OTP care. Although similar to F-100 in formulation, RUTFs have been shown to promote faster rate of recovery.

An ideal RUTF should be: (a) caloric dense with adequate proteins, vitamins and minerals, (b) palatable and acceptable, (c) affordable cost, (d) stable with long-shelf life, and (e) easy to administer, and (f) available in suitable packs to avoid wastage.

RUTF is an oil-based preparation that contains a little water to make it microbiologically safe for storage. Since it is eaten uncooked, RUTF is also time-saving with no loss of micronutrients during cooking.

While commercial RUTFs are available in some countries, low-cost RUTF can be prepared locally using simple and easily available ingredients, e.g. whole milk powder (30 gm), peanut butter (25 gm), sugar (28 gm) and vegetable oil (15 gm), fortified with micronutrients. Each 100 gm of this RUTF provides 520–550 calories, including 45–60% from fats and 10–12% from proteins. It can be stored for 3–4 months without refrigeration and should be fed directly with plenty of water.

However, RUTF should not be confused with ready to-use foods (RTUF), e.g. maggi noodles, and should be used only for therapeutic purpose and not as supplementary food, for limited time period (4–8 weeks) until the child recovers from SAM.

RUTF *vs* Modified home diet: Government of India does not approve use of RUTF and favours the use of modified home diet or locally prepared therapeutic diets for these children, along with supplementary nutrition. Several locally prepared therapeutic diets have been developed and being used for community-based management of acute malnutrition programs of different states, e.g. Telangana. Some states provide for take-home ration program at community centers to provide 150–180 cal/kg and 3.5–5.5 gm/kg of proteins.

Amylase rich foods (ARF) are easily digestible and enriched sources of proteins and vitamins, prepared by *soaking* common cereals or pulses in water for 12 hours > *sprouting* by wrapping in a moist cloth for 48 hours, > *drying* > *roasting* > *grueling* to make porridge grinding, before storage. One teaspoonful (5 gm) of this powder may be added in each infant food after cooking. On soaking, the amylase breaks down grain-starch into easily-digestible maltodextrins, reducing the viscosity and bulk of diet. Germination also enhances vitamin content.

6.1.6 SEVERE ACUTE MALNUTRITION IN INFANTS < 6 MONTHS

Severe acute malnutrition infant below 6 months is less likely in children with exclusive breastfeeding, usually seen in top-fed infants and diagnosis rests on following criteria:

- Weight/height < 3 SDS or z-score, or
- Bilateral symmetrical edema or visible wasting

MUAC cannot be used for diagnosis of SAM in infants <6 months and use of wasting for diagnosis of SAM should be made with utmost caution.

Management of SAM in infants <6 months is similar to management in older children with following considerations:

- All these infants should preferably be hospitalized irrespective clinical status, unless there are overriding barriers.
- In view of the high-risk of underlying sepsis, all these infants should receive parenteral antibiotics in initial days of hospitalization or a course of oral antibiotics, e.g. Amoxicillin, if cannot be hospitalized.
- Breastfed children should continue breastfeeding with assessment of local breast/nipple problems, position, attachment and adequate intake. Mother should be encouraged for frequent breastfeeding after proper lactation counseling.
- In non-breast infants (in order of preference).
  - Attempt should be made re-initiate lactation, using supplementary sucking techniques (discussed below), or
  - Provide expressed breast milk or milk from human milk banking or
  - Use a generic infant milk formula or started F-75 diet or diluted catch-up F-100 diet (by adding 30% water), either alone or in addition to the breast milk. Undiluted catch-up diet should not be used due to high solute load.
- Assess the physical and mental status of mother, with appropriate counseling and support.

Supplementary sucking techniques (SST) aim to re-establish breast milk output in mothers who have stopped BF due to some reason before consultation and includes:

- ***Non-nutritive sucking,*** i.e. to place the baby on the breast at least 8–10 times/day for 10–15 minutes every time, even in the absence of milk output.
- ***Drip and drop method,*** in which a nasogastric tube connected to milk/formula filled cup (~100–130 ml) is fixed with an adhesive tape over the nipple and baby is encouraged to suck on nipple while milk is gradually dripped over it. Cup is kept 5–10 cm below the nipple level so the milk does not flow too quickly. Sucking efforts by the baby stimulate prolactin reflex to re-establish BM output. Gradually the cup should be lowered further to encourage stronger sucking efforts.

SST should initially be done on both breasts 4–6 times a day along with intermittent *katori*/spoon feeding and the frequency should be reduced gradually over next 7–14 days. If the baby does not finish supplementary feed after few days but is gaining weight, it means that breast milk output is increasing.

Discharge: Infant <6 months with SAM should be discharged only if weight for height has reached >–2 z-score, though early discharge may be considered in cases with: (a) continuous weight gain (> 5 gm/kg/day) for > 2 weeks, (b) good appetite (c) absence of medical complications, (d) availability of effective alternative supervision.

6.1.7 MODERATE ACUTE MALNUTRITION

AS stated earlier, moderate acute malnutrition is defined as: (a) weight for height between – 2 to – 3 z-score, (b) MUAC between 11.5–12.4 cm, and (c) absence of edema or visible wasting.

Children with MAM are best managed at home, unless have some other co-morbidity or medical complications. Some cases can be managed in nutritional rehabilitation centers (NRCs) in early stages. Important considerations in the management of MAM include:

- Initial assessment for complications and appropriate management, including de-worming.
- Ensure minimum daily caloric intake of 150 calories/kg and 2–3 grams proteins/kg from all sources including regular and supplementary feeds.
- Supplementary foods must be energy-dense providing 1.5–2 cal/gm (instead of usual 0.8 cal/gm) along with-35–45% calories from fats with minimum 5% from n-6 PUFA, 0.5% from n-3 PUFA, linolenic acid:alpha-linoleic acid ratio of 5–15% and protein digestibility corrected amino acid score (PDCAAS) of >70% (*WHO 2014 recommendations*). A cereal/legume mix diet with milk and animal protein sources may be used in appropriate quantity and frequency. Supplementary foods through various sources, e.g. RUTF or home-made items may be used for this purpose.
- Micronutrient supplementation or fortification of foods.
- Nutritional counseling for appropriate volume, frequency and diversity of home diet, cooking practices, food hygiene, etc.

6.1.8 PREVENTION OF UNDERNUTRITION

Undernutrition is more of a socio-economic problem, rather than the medical disease. A comprehensive approach is required, especially in developing countries to overcome it. Important preventive steps against PEM include:

I. Promotion of general health and nutrition:

- ***Actions at family level*** to promote:
  - Correct breastfeeding and weaning practices
  - Consumption of cheap, local, nutritive foods
  - Correct cooking practices
  - Avoidance of wrong food taboos and habits
  - Equitable food distribution in the family
  - Setting of kitchen gardens/poultry keeping
  - Correct feeding practices during illnesses
  - Nutrition in pregnant/lactating mothers
  - General child health/hygiene
  - Family planning practices
- ***Action at community level:***
  - Nutritional surveillance
  - Nutritional education
  - Development of local low-cost foods
  - General measures to improve child health, e.g.
    - Improved water supply and sanitation
    - Widespread immunization services
    - Preventive/curative healthcare facilities
  - Creation of local job opportunities
- ***Action at national level*** to promote:
  - Agricultural production
  - Food-storage facilities and public distribution
  - General rural/urban-slum development
  - Poverty-alleviation measures,
  - Food subsidies to high-risk population
  - Targeted health and nutritional programs
- ***Action at international level:***
  - International aids for socioeconomic development.
  - World Food Program (1963) to meet food requirements in needy countries.
  - International cooperation during emergencies, e.g. natural disasters and wars.

II. Specific protection to high-risk children:

- Nutritional surveillance in preschool children
- Nutritional supplementation/food fortification
- Periodic deworming and iron supplements, etc.
- Immunization to control infections

III. Early diagnosis and management:

- Growth monitoring of under-5 children
- Nutritional assessment at all contact points
- Early diagnosis and management of PEM
- Early diagnosis and treatment of infections

IV. Follow-up and rehabilitation:

- Nutritional rehabilitation centers/services
- Follow-up of recovered cases

National Nutrition Policy, (1993) to tackle problem of undernutrition, has four major components:

a. Nutritional intervention for vulnerable groups, e.g. children, pregnant mothers and adolescent girls,
b. Fortification of essential foods,
c. Popularization of low-cost nutritious food,
d. Control of micronutrient deficiencies among vulnerable groups.

Many supplementary nutrition programs are operational in India to achieve these objectives, some as follows:

Mid-day Meal Programme was first launched in 1925 for disadvantaged children in Madras Municipal Corporation. In 1995, it was converted to a centrally-sponsored scheme for children in classes I–V of the government, government-aided and local body schools. Coverage was later extended to alternative educations institutions and then to children in upper primary classes (VI–VIII) in 2004.

Objectives: Mid-day meal program aims to provide ~1/3rd of the calories and ½ of the protein requirements, using low-cost, locally available and acceptable food items, to: (a) improve the nutritional status of children, and (b) to encourage them to attend school regularly and prevent drop-outs.

Beneficiaries include all children up to 8th standard, studying in government or government-aided schools, including alternative education centers, e.g. madarsa.

Activities: Under this scheme, only cooked lunch with minimum 300 calories and 8–12 grams of protein is provided to primary school children (classes I–V); and 700 calories and 20 grams of protein to those in higher classes. Mid-day meal should be considered only as a *supplement* and not the replacement of regular meals.

Organization: Central government provides free food grains @ 100 grams per child per school day, along with transport and cooking costs. However, the program is carried out by local authorities. Non-government organizations or self-help groups are used for cooking, under supervision of local committees or parent-teacher associations.

Integrated child development scheme (ICDS) provides supplementary nutrition is to children <6 years and pregnant mothers, along with other services for children 6 months –6 years, it provides 500 cal and 12–15 gm proteins/day (800 cal and 20–25 gm proteins/day to children with SAM) (for details See Ch 28.4).

Poshan Abhiyaan (***P**rime Minister's **O**verarching **S**cheme for **H**olistic **N**utrition*), previously termed as *National Nutrition Mission*, was launched in 2018 to:

- To reduce prevalence of undernutrition, stunting, anemia and low birth weight by 2% annually,
- To enhance nutritional status of children, adolescents, pregnant women and lactating mothers.

Implemented by *Ministry of Women and Child Development* under policy directions from *National Council for Nutrition*, Poshan Abhiyaan involves:

- Mapping of various schemes related to malnutrition and develop a robust convergence between them,
- Real-time monitoring of data and encouraging Anganwadi workers to use IT-based tools for this purpose,
- Measurement of height of children at Anganwadi centers,
- Scaling up of the interventions under World Bank assisted ICDS.
- Setting-up Nutrition Resource Centres, social audits and involving masses for participation in nutritional activities.

6.2 VITAMIN A DEFICIENCY

Vitamin A deficiency, till recently, was the commonest cause of preventable blindness in Indian children. While the prevalence of severe disease has substantially declined in recent years due to preventive programs, subclinical deficiency continues to be common with a prevalence of ~1–3% in preschool children.

Physiology: Vitamin A is a fat-soluble vitamin **(Table 6.12)**, existing in two forms:

a. *Pre-formed vitamin*, e.g. *retinol,* present in animal sources; and
b. *Pro-vitamin*, e.g. β-*carotene*, present in plant sources, which is converted to retinol in the gut.

Retinol is actively accumulated in liver (as retinyl palmitate) during last trimester of pregnancy and breastfeeding. Postnatally, retinol is better absorbed than β-carotene and transported in blood, bound to a retinol-binding protein.

RDA for vitamin A in children is ~350–600 µg/day increasing with age to ~800–1000 µg/day in adolescents, all values in terms of retinal equivalent (1 RE = 3.3 IU)

Dietary sources: Important source of vitamin A include yellow fruits, milk and animal products and fortified foods and at least half of the RDA should be derived from animal sources.

TABLE 6.12: Vitamin A at a glance

RDA: 350–1000 µg RE (1200–3000 IU)
Dietary sources
• ***Plant foods:***
Yellow fruits: Mango (1000 IU), papaya (400 IU)
Vegetables: Carrot (4000 IU), spinach, amaranth
• ***Animal foods:***
Milk products: Butter, margarine, cheese
Non-veg: Eggs, liver, fish, cod liver oil (54,000 IU)
• ***Fortified foods:*** Vansapati ghee
Functions
– Production of *rhodpsin*—night-vision pigment
– Maintenance of epithelial integrity
– Anti-oxidant (free-radical scavanger)
– *Others* - in bone metabolism, spermatogenesis, etc.
Deficiency states
• Xerophthalmia
• Phyrnoderma (follicular hyperkeratosis)
• Susceptibility to infections
Toxic effects (hypervitaminosis)
• *Acute:* Pseudotumor cerebri
• *Chronic:* Dry skin, alopecia, hyperostosis (limb-pains)
• *Carotenemia:* Yellow discoloration of skin

RE: Retinol equivalents (1 µg = 3.3 IU)

Functions: Vitamin A is essential for retinal functions, maintenance of epithelial integrity to resist infections and removal of toxic free-radicals from body.

Vitamin A Deficiency (VAD)

Etiology: VAD is most common in toddlers and preschool children from low socioeconomic status. Common causes of VAD include:

a. Dietary deficiency
b. Malabsorptive states, e.g. chronic diarrhea, worm infestations, etc.
c. Impaired metabolism, e.g. in chronic liver disease
d. Reduced transport proteins, e.g. in malnutrition, nephrotic syndrome, etc.
e. Higher requirements in infections, e.g. measles.
f. Less intrauterine stores, e.g. in preterms
g. *Darrier disease*—a genetic defect (*vitamin Adependency*).

Clinical manifestations of VAD may be divided into two broad groups—ophthalmic (xerophthalmia) and extra-ophthalmic manifestations.

A. Xerophthalmia denotes a spectrum of ocular signs in VAD **(Table 6.13)** including:

- *Night blindness*, i.e. inability to see clearly in dim-light or slower dark-adaptation.
- *Conjunktival xerosis*, i.e. dry, wrinkled, lusterless, muddy conjunktiva due to cornified epithelium and *Bitot' spots*—chalky gray triangular plaques, generally near the temporal limbus, due to heaped-up dry epithelium **(Fig. 6.7A)**.
- *Corneal lesions* of variable severity: (i) *xerosis*, i.e. dull, dry and cloudy cornea, (ii) *ulcers*, limited to a few layers of cornea, or (iii) *keratomalacia*, i.e. liquefaction and rupture of full-depth cornea, leading to loss of vision **(Fig. 6.7B)**. Even mild cases may lead to corneal scarring on recovery.
- *Fundal changes*, e.g. retinal xerosis and detachment.

TABLE 6.13: WHO classification of xerophthalmia

Primary signs	*Secondary signs*
X_{1A}: Conjunctival xerosis	X_N: Night blindness
X_{1B}: Bitot's spot	X_S: Corneal scarring
X_2: Corneal xerosis	X_F: Fundal changes
X_{3A}: Corneal ulceration	
X_{3B}: Keratomalacia	

Fig. 6.7: (A) Bitot's spot; (B) Keratomalacia.

B. Extra-ocular manifestations include:

- *Phrynoderma (follicular hyperkeratosis),* presenting as dry and scaly skin with *toad-like* texture, specially over extensor aspects of extremities, e.g. dorsum of tibia, knees and elbows. Phrynoderma is also associated with essential fatty acid deficiency.
- Recurrent respiratory infections, due to squamous metaplasia of respiratory mucosa.
- Recurrent urinary tract infections, pancreatitis or parotitis due to epithelial metaplasia of urinary or exocrine tracts.
- Rarely, atrophy of genital epithelium may lead to reproductive dysfunction in adults.

Diagnosis of VAD is largely clinical, though subclinical deficiency may be identified by:

a. *Conjunctival impression cytology* (CIC), to detect loss of mucus-secreting goblet cells and epithelial metaplasia on special staining,
b. Dark-adaptation test, and
c. Low plasma carotene levels (<20 µg/L).

Treatment: As per WHO recommendation, standard treatment of VAD includes 3 age-dependent doses of

TABLE 6.14: Treatment of vitamin A deficiency (WHO)

	< 6 months	*6–12 months*	*> 12 months*
Day 1	50,000 IU	1,00,000 IU	2,00,000 IU
Day 2	50,000 IU	1,00,000 IU	2,00,000 IU
Day 14	50,000 IU	1,00,000 IU	2,00,000 IU

concentrated, preferably fat-soluble vitamin A (1,00,000 IU/ml), given orally, on day 1, 2 and 14 **(Table 6.14)**.

In cases with malabsorption or persistent vomiting, IM therapy with water soluble vitamin A (50,000 IU/ml) may be used, given as *half of the oral dose* with same schedule. Local ophthalmic treatment of corneal lesions with antibiotics, mydriatics and eye-padding is equally important.

All cases treated for VAD should receive dietary counseling and vitamin A prophylaxis till 6–8 years of age (2,00,0000 IU every 6 month) to prevent the recurrence.

Prevention of VAD includes nutritional counseling, vitamin A supplementation, fortification of dietary feeds (*see* national program below) and prevention of precipitating illnesses, e.g. measles.

National Control Programme Against Nutritional Blindness Due to Vitamin A Deficiency

Launched in 1970, currently this program is a component of National Health Mission, aimed to decrease the incidence of VAD and consequently preventable blindness. Prevalence of night blindness in pre-school children is considered as the best indicator of VAD, classified as *severe* (>5%), *moderate* (1–5%) and *mild* (<1%).

Beneficiary: Children from 9 months to 5 years.

Components of this program include:

- ***Universal prophylaxis*** with 6-monthly administration of oral vitamin A 1,00,000 IU (<1 year) and 2,00,000 IU in older children, from 6 months to 5 years of age. This protocol was first developed by National Institute of Nutrition, Hyderabad and later adopted by WHO as global strategy. Presently, first two doses are given during immunization visit at 9 months (with MR vaccine) and 15–18 months (with first booster dose). Subsequent doses at 24, 30, 36, 42, 48, 54 and 60 months of age are given in some states. IAP recommends this vitamin A administration to all children only till 3 years of age.
- ***Additional doses*** of vitamin A, after illnesses, e.g. measles, severe PEM, chronic diarrhea and long febrile illnesses.
- ***Dietary counseling,*** to encourage consumption of cheap and locally available vitamin A rich foods.
- ***Prevention of precipitating illnesses,*** e.g. measles by vaccination coverage and breastfeeding promotion.
- ***Periodic monitoring*** and evaluation.

Note: In national program, oral vitamin A is supplied as multi-dose liquid preparation (1 lac IU/ml), with a special 2 ml spoon. Only this spoon should be used and *not* the regular 5 ml spoon to avoid over-dosage.

Hypervitaminosis A

Being fat-soluble, excess vitamin A is not readily excreted in urine and accumulates in tissues with following presentations:

- **Acute hypervitaminosis**, due to acute preventive or therapeutic overdose (>3,00,000 IU), presents as *pseudotumor cerebri*, i.e. transient, self-limiting, benign intracranial hypertension with headache, vomiting, drowsiness, bulging fontanels and/or papilledema (Ch 18.4). Exact mechanism is unknown, probably relates to massive rupture of lysosomal membranes.
- **Chronic hypervitaminosis** due to prolonged vitamin A therapy, e.g. for acne, presents with anorexia, weight loss, dry pruritic skin, alopecia, tender extremities (hyperostosis on X-ray), hepatosplenomegaly and pseudotumor cerebri.
- **Hypercarotenemia,** asymptomatic, transient yellowish discoloration of skin/body fluids, due to excess consumption of β-carotene containing fruits.

Massive vitamin A administration in first trimester may also have severe teratogenic effects on fetus.

6.3 VITAMIN B COMPLEX DISORDERS

Vitamin B complex is a heterogeneous but closely linked group of water-soluble vitamins, all being important constituents of various enzyme systems. As many vitamins of this group share common source and inter-related metabolism, multiple vitamin B complex deficiencies are more common than isolated disorders.

Table 6.15 presents a synopsis of important functions, dietary requirements, sources and deficiency states for different members of this group, though the exact role of some of them is not yet well established.

Thiamine (B1) deficiency is an essential coenzyme for acetylcholine synthesis and oxidative utilization of glucose in *Krebs* cycle, also involves in synthesis of nucleic acids and fatty acids.

Thiamine deficiency in India is predominantly seen among rice-eating population of *costal Andhra Pradesh,* though the incidence has substantially markedly declined in recent years.

Etiology: RDA for thiamine is 0.2–2.2 mg/day. Although widely distributed in dietary sources, thiamine is a water-soluble and heat-labile vitamin, mainly present in outer-coating of grains. Consequently, its deficiency is endemic areas is predominantly associated with: (a) use of milled and polished rice as staple cereal, and (b) vigorous washing and prolonged boiling with excessive water during cooking.

TABLE 6.15: Vitamin B complex at a glance

Vitamins (RDA)	*Sources*	*Functions*	*Deficiency states*	*Causes of deficiency*
Thiamine (B_1) *(0.2–2.2 mg)*	Whole grain cereals Milk Non-veg foods	CHO metabolism Acetylcholine synthesis	• Beriberi • Wernicke's encephalopathy • ***Dependency states –*** Leigh disease, B, responsive anemia, Maple syrup urine disease (MSUD)	BF by B_1 deficient mothers Wrong cooking/ processing Malabsorption states Increased requirements
Riboflavin (B_2) *(0.4–3.1 mg)*	Milk and eggs Cereals, pulses, meat, *Fish are poor sources*	Cellular oxidation B_6 & folate metabolism Light adaptation?	• *Oral*: Stomatitis, cheilosis, glossitis • *Ocular*: Keratitis, photophobia • ***Dependency states –*** Pyruvate kinase deficiency	Dietary Malabsorption states Chronic diarrhea *Drugs:* Phenothiazines
Pyridoxine (B_6) *(0.1–3.0 mg/day)*	Widely distributed	CHO, P, Fat metabolism Normal CNS function	• Peripheral neuritis & Seizures • ***Dependency states –*** B_6 responsive anemia/seizures,	Dietary deficiency rare, *Drugs:* INH, Penicillamine Malabsorption states
Niacin (PP factor) *(2–22 mg)*	Direct: Non-veg diet Tryptophan rich foods: Milk and eggs	DNA synthesis	• Pellagra • ***Dependency states –*** Hartnup disease, Schizophrenia ?	Dietary (maize/jowar eaters)
Pentothenic acid *(10 mg)*	Widely distributed	Steroid synthesis	Not well established • Burning feet syndrome • Asthenia, depression, • Hyperemesis	? Dietary (rare) TPN Total parenteral nutrition
Folic acid Or folates *(25–340 µg)*	Widely distributed Deficient in goat milk Destroyed by Over-cooking	Nucleic acid synthesis Hb synthesis	• Megaloblastic anemia • Diarrhea, glossitis, cheliosis • Neural tube defects* • ***Dependency states –*** Folate metabolism defects	Dietary (rare) Increased requirements *Drugs*: Folate-antagonists e.g. methotrexate
Cynacobolamin (B_{12}) *(1.2–2.5)*	Non-veg foods Endogenous synthesis	Nucleic acid synthesis Myelination	• Megaloblastic anemia • Demyelinating diseases • Infertility • ***Dependency states –*** Methyl malonic acidemia	Dietary deficiency (rare) Intrinsic factor deficiency Malabsorptive states Increased requirements
Biotin *(Not established)*	Widely distributed	Not well-established	*Skin:* Dermatitis, alopecia *CNS:* Hypotonia, parasthesia ***Dependency state –*** Rett syndrome	Rare except— eating of raw egg white Formula feeding, Total Parenteral nutrition
Choline *(Not established)*	Widely distributed	Not well-established	? ↓ immunity, Liver/Renal injury ? therapeutically used in chorea, amnesia, ataxia	Experimental information only
Carnitine **(NE)** *(Not established)*	Widely distributed	Not well-established	?Myopathy, organic aciduria	Not known, hereditary

RDA: Recommended dietary allowance; **BF:** Breastfeeding; **TPN:** Total parenteral nutrition; **CHO:** Carbohydrate; **P:** Protein

Other causes include: (a) breastfeeding by thiamine-deficient mothers, and (b) total parenteral nutrition.

Clinical spectrum of thiamine deficiency is extremely wide, ranging from non-specific manifestations to well-defined syndromes, e.g. *beriberi* and *Wernicke's encephalopathy.*

- ***Beriberi***, may be classified as: (i) dry beriberi, (ii) wet or cardiac beriberi, and (iii) infantile beriberi. These cases present with:
  - *General features*, e.g. mental changes (irritability, apathy) failure to thrive and gastrointestinal upsets like anorexia, nausea and vomiting.
  - *Dry beriberi* with predominant neurological manifestations, e.g. peripheral neuritis (paresthesia, hyporeflexia, calf pains), ocular signs (ptosis/optic atrophy) and hoarseness/aphonia due to laryngeal nerve paralysis (characteristic).

  - *Wet or cardiac beriberi* with predominant cardiac manifestations, e.g. CCF with edema, cardiomegaly and pericardial effusion.
  - *Infantile beriberi* presents at 2–4 months of age with vomiting, peripheral neuropathy and puffiness, in breastfed infants of thiamine-deficient mothers.
- ***Wernicke's encephalopathy*** is a rare manifestation of thiamine deficiency in severe undernutrition or unsupplemented parenteral nutrition, presenting with irritability, ataxia, ophthalmoplegia and altered sensorium.
- ***Non-specific manifestations*** are more common in endemic as well as non-endemic regions than well-defined beriberi, presenting with anorexia, mild calf tenderness and absence of ankle/knee jerk.

Diagnosis is best established by clinical response to thiamine administration, though biochemical tests, e.g. *low RBC transketolase levels* or *elevated urinary glyoxalate excretion* indicate subclinical deficiency.

Management includes oral or parenteral thiamine administration (5–10 mg/day) for at least 6 week, followed by low-dose oral supplements (0.5–1.5 mg/day) and proper diet. Mothers of infantile beriberi, even if asymptomatic, should be treated with oral thiamine (50 mg/day).

Riboflavin (B_2) deficiency is a cofactor for various enzymes involved in cellular oxidation, energy metabolism and erythropoiesis. Riboflavin deficiency is rarely isolated, usually a part of multivitamin deficiency in sick children.

Etiology: RDA for Riboflavin is 0.5–3.0 mg/day. Deficient dietary intake or malabsorptive disorders, e.g. chronic diarrhea are most important causes of riboflavin deficiency, though sub-clinical deficiency may occur in newborns on phototherapy (destroys riboflavin) or during drug therapy, e.g. phenothiazines (interfere with its metabolism).

Clinically these cases present with:

- *Oral signs:* For example, angular stomatitis, cheilosis, glossitis
- *Ocular signs:* For example, keratitis, conjunktivitis.
- *Others:* For example, neuromotor dysfunction, poor wound healing or normocytic normochromic anemia.

Diagnosis is clinical, though subclinical deficiency may be detected by decreased urinary riboflavin excretion (<30 mg/day) or low *glutathione reductase* content in RBCs.

Treatment includes PO riboflavin (3–10 mg/day) till disappearance of signs, followed by adequate dietary intake and treatment of primary cause. Severe or non-responsive cases may need intramuscular riboflavin (2 mg TDS) in early stages.

Niacin (B_3) deficiency (Pellagra) is a component of two important glycolytic enzymes—nicotinamide adenine dinucleotide (NAD) and NAD phosphate, as well as a regulator of DNA synthesis and repair. Nutritionally, it is available as:

- *Preformed niacin* or nicotinic acid, mainly in non-vegetarian foods, e.g. meat and fish; or
- Synthesized from its precursor—*tryptophan,* mainly present in milk and eggs (60 mg tryptophan yields ~ 1 mg of niacin).

Cereals and vegetarian diet are poor sources of free niacin as well as tryptophan.

Etiology: RDA for niacin is 2–22 mg/day. Niacin deficiency is prevalent in *maize-eating* populations, dueto high leucine content in maize that interferes with endogenous conversion of typtophan into niacin (aminoacid imbalance). However in India, it is mainly seen in *jowar-eating* population of Telangana, due to same reason.

Clinically, *Pellagra, the* prototype manifestation of niacin deficiency, presents with a triad of *3 D's*, as follows:

- ***D**ermatitis*, i.e. photosensitive rashes on exposed parts of body, often described as *pellagrous glove* (hands), *boot* (legs), *necklace* (neck), etc. Chronic cases may develop vesicobullous, weeping, desquamating or hyperpigmented lesions.
- *Chronic **D**iarrhea* with/without vomiting.
- ***D**ementia* with depression, dizziness, disorientation, delirium and burning sensation/numbness (paresthesia).

Diagnosis rests on clinical triad, dietary history and response to niacin therapy. Reduced urinary excretion of *N-methyl nicotinamide* (a metabolite) has been used as an indicator of subclinical deficiency.

Treatment includes oral niacin supplementation (50–300 mg/day). IV niacin (100 mg) may be given in severe cases, though it lead to an unpleasant sensation of local heat and flushing, and rarely the cholestatic jaundice. Avoidance of sun-exposure, soothing topical agents over skin lesions and treatment of co-existing vitamin deficiencies is also necessary.

Vitamin (B_6) deficiency includes three compounds—pyridoxal, pyridoxine and pyridoxamine, each convertible to *pyridoxal phosphate*—a co-factor for many neuroenzymes, e.g. GABA, apart from other functions. Consequently, seizures and peripheral neuropathies are most common manifestations of pyridoxine deficiency.

Etiology: RDA for pyridoxine is 0.1–3.0 mg/day. Pyridoxine deficiency is rarely dietary, due to adequate vitamin content in milk and cereals. It is mainly caused by: (a) chronic diarrhea and malabsorptive states, (b) treatment with pyridoxine-antagonists, e.g. INH, penicillamine, etc. and (c) dependency states, due to

genetically abnormal structure/function of vitamin B_6 dependent enzymes.

Important *dependency states* include pyridoxine-dependent seizures, anemia and homocystinuria.

Clinically, these cases present with one or more of following four features: (a) peripheral neuritis, (b) seizures, (c) microcytic hypochromic anemia, and (d) dermatitis with cheilosis, glossitis and seborrhea around eyes, nose and mouth.

Pyridoxine-related seizures include:

- ***Deficiency seizures*** due to dietary deficiency in formula-fed children. These seizures are typically generalized and present in infancy, beyond neonatal period.
- ***Dependency seizures*** due to: (i) genetic defects in pyridoxine-dependent enzymes, or (ii) mega pyridoxine therapy in pregnant mothers for hyperemesis gravidarum. These seizures are typically intractable myoclonic seizures, beginning in first week of life (termed 5th day fits). A *hypsarrhythmic pattern* on EEG is diagnostic, which rapidly responds to pyridoxine administration.

Diagnosis must be suspected after exclusion of other causes for seizures and anemia. In a suspected case, 100 mg pyridoxine is given intramuscularly, preferably with concomitant EEG recording. Immediate control of seizures and EEG abnormality suggests pyridoxine deficiency/dependency.

Tryptophan loading test, a biochemical test, to differentiate between pyridoxine deficiency and dependency states, involves loading with 100 mg/kg of tryptophan that leads to increased *urinary excretion of xanthurenic acid* in deficiency states. This test is normal in dependency states.

Treatment: Pyridoxine-deficiency seizures are treated with IM pyridoxine (100 mg), followed by adequate dietary intake and treatment of primary cause. Pyridoxine-dependent seizures need long-term daily therapy (PO 10–100 mg or IM 2–5 mg).

Folic acid deficiency (pteroylglutamic acid) is essential for normal DNA synthesis and hence, folic acid deficiency mainly affects rapidly dividing cells, e.g. bone marrow (megaloblastic anemia) or in fetus (neuronal tube defects). In natural diet, folic acid exists as folates.

Etiology: Folic acid deficiency is rarely dietary due to miniscule daily requirements (25–350 µg/day), usually caused by: (a) malabsorption states, e.g. fish tapeworm infestations, (b) increased requirements, e.g. in pregnancy and hemolytic anemia, and (c) anti-folate drugs, e.g. methotrexate, pyrimethamine. *Goat and camel milk are poor sources of folic acid.*

Clinically, these cases present with four important manifestations: (a) megaloblastic anemia, (b) chronic diarrhea, (c) neurological manifestations, e.g. tremors and developmental regression, and (d) skin hyperpigmentation, specially on knuckles and thigh. Severe deficiency may also be associated with thrombotic episodes and atherosclerosis, due to altered homocysteine metabolism.

Diagnosis depends on peripheral smear (megaloblastic anemia), supported by low RBC/serum folate levels (normal: 5–20 ng/ml). *FIGLU test*, i.e. urinary excretion of formiminoglutamic acid after loading dose of histidine, may detect subclinical deficiency.

Treatment: Folic acid deficiency is treated with PO or parenteral folic acid (1–5 mg/day) for 3–4 weeks, along with concomitant vitamin B_{12} supplementation and elimination of offending drug, if applicable.

Folic acid deficiency in pregnancy is an important cause of neural tube defects in fetus, which can be easily prevented by Routine folic acid supplementation with 400 µg/day to all pregnant mothers or 5 mg/day to all mothers with previously affected child (recurrence) from 1 month before to 3 months after the conception (Ch 18.10.1).

Also *see* Chapter 19.4.2 for folic acid deficiency anemia.

Cobalamin (B_{12}) Deficiency is a cobalt-containing vitamin, essential for nucleic acid metabolism and myelin formation (*Cyanocobalamin* is the therapeutic preparation, used to treat vitamin B_{12} deficiency).

Widely present in animal sources, vitamin B_{12} is absent in plant foods, but may be endogenously synthesized by colonic bacteria. Vitamin B_{12} absorption requires hydrolysis by gastric acid and combination with a specific protein in stomach—*intrinsic factor of castle (IFc)*. This B_{12}–IFc complex attaches to specific receptor sites in terminal ileum, where B_{12} component is absorbed, transported in bound form with a plasma protein-*transcobalamin* and stored in tissues, bound to another protein-*transcobalamin I*.

Etiology: RDA for vitamin B_{12} is 1.0–2.5 µg/day. Vitamin B_{12} deficiency is rarely dietary, due to extremely low requirements, usually caused by congenital or acquired defects in its absorption, e.g. (a) congenital IFc deficiency or *juvenile pernicious anemia*, (b) malabsorption disorders, (c) *imerslund syndrome*, i.e. IFc-B_{12} receptor deficiency, and (d) congenital transcobalamin deficiency.

Clinically, vitamin B_{12} deficiency presents with a triad of: (a) megaloblastic anemia, (b) glossitis, and (c) signs of demyelination, e.g. ataxia, paresthesia, hypo/hyperreflexia (*subacute combined degeneration of cord*).

Diagnosis is usually based on:

- Megaloblastic anemia on smear that does not respond to folic acid therapy, *supported by*
- Low serum vitamin B_{12} levels (<100 pg/ml)
- Methylmalonic aciduria (>3.5 mg/day).

Schilling test is used to confirm vitamin B_{12} deficiency as well as to differentiate between IFc deficiency and malabsorption defects (Ch 19.4.2).

Treatment: Oral vitamin B_{12} therapy is unreliable due to defective absorption, though may be given as 500–1000 µg/day for 3 months, in cases without neurological signs.

Cases with neurological signs should be treated with parenteral Vitamin B_{12} (IV/IM) 250–1000 µg/day for 2 weeks, then weekly for next 2–3 months, and then monthly doses till correction of anemia. Lower range of dose (0.2 mg) may be used in infants and young children. Life-long therapy is required if cause is untreatable, e.g. juvenile pernicious anemia or malabsorption disorders.

Prevention with prophylactic Vitamin B_{12} is advised in cases with malabsorptive states.

Biotin deficiency: Role of biotin as an important co-factor of various carboxylase enzymes in carbohydrate/fat metabolism is being increasingly recognized in recent years.

Etiology: Biotin deficiency is rarely dietary, as it is also synthesized by intestinal bacteria. Important causes include: (a) excessive consumption of raw egg-white, which is rich in *Avidin*—a biotin-binding protein, (b) unsupplemented formula or parenteral feeding, and (c) genetic *biotinidase* deficiency an enzyme required to recycle biotin (*dependency state*).

Clinically, it presents with: (a) skin lesions, e.g. exfoliative dermatitis and alopecia, (b) GIT manifestations, e.g. anorexia and glossitis, and (c) neurological manifestations, e.g. extreme lassitude and muscle pains. Genetic defects may also present with *Rett syndrome*.

Diagnosis depends on dietary history, clinical features, organic aciduria and response to biotin therapy. A *filter-paper spot test* is available to screen newborns for biotinidase deficiency, testing increased excretion of 3-hydroxyisovaleric acid in urine.

Treatment includes PO or IM Biotin therapy with 2–5 mg/day for 3 weeks, though higher doses (10 mg/day) are required for dependency states.

6.4 VITAMIN C DEFICIENCY (SCURVY)

Scurvy is well-defined acute manifestation of vitamin C deficiency, though mild or subclinical deficiency states may present with impaired wound healing, bleeding gums, mild anemia and susceptibility for infections.

Physiology: Vitamin C or ascorbic acid **(Table 6.16)** is a water-soluble vitamin and hence not stored in the body and rapidly excreted in urine.

RDA of vitamin C is ~20–45 mg/day in children and 50–85 mg in adolescents, higher during infections and fever as it is not stored in body.

TABLE 6.16: Vitamin C at a glance

RDA: 20–85 mg/day
(Higher in infections *e.g.* fever, diarrhea)

Sources:
- *Richest source:* Amla (600 mg)
- *Citrus Fruits:* Guava (212 mg), orange, lemon, pineapple
- *Vegetables:* Cabbage (124 mg), tomato, green vegetables.
- *Germinated pulses*
- *Non-veg foods, e.g.* liver and kidneys (not in meat)

Functions:
- Essential for collagen formation
- Wound healing and epithelial integrity
- Facilitate iron absorption and folate metabolism
- Antioxidant effect

Deficiency states:
- *Typical:* Scurvy
- *Others:* Poor wound healing, anemia, recurrent infections

Dietary sources: Breastfeeding is an adequate source of vitamin C in early infancy. Citrus fruits, leafy vegetables and germinated seeds are rich sources of vitamin C. However, it is extremely heat-labile, rapidly inactivated on cooking and extrudes in cooking-water. Milk products and lean meat are poor sources of vitamin C.

Functions: Vitamin C essential for synthesis of: (a) normal collagen by incorporating proline and hydroxyproline, and (b) chondroitin sulphate – a component of inter-cellular matrix required for epithelial integrity and wound healing. It also facilitates, (c) iron absorption, (d) folate metabolism (conversion of folic acid into folinic acid), and (e) elimination of toxic-free radicals (antioxidant).

Vitamin C Deficiency (Scurvy)

Etiology: Scurvy is usually precipitated by sudden increase in vitamin C requirements due to infections, acute febrile illnesses, diarrhea, etc. in children with subclinical dietary deficiency, e.g. in undernutrition or top feeding. Wrong cooking practices, e.g. over-boiling of vegetables in excess water or throwing the excess cooking-water are important causes of dietary deficiency.

Clinical manifestations: Scurvy usually presents in late infancy or in toddlers, following an infective episode, e.g. diarrhea or viral infection in malnourished children. A typical case present with:

- *Skeletal signs:*
  - *Pseudoparalysis*—severe tenderness and restricted limb movements with *pithed-frog posture*
  - *Scorbutic rosary*—tender, sharp, nodular beading at costochondral junktions, due to subluxation rib epiphyses at sternal joints.
- *Skin/mucosal signs:*
  - Swollen, purple, *bleeding gums,*

- Petechial/ecchymotic perifollicular hemorrhages over skin and mucus membranes. Severe gastrointestinal or intracranial bleeds are rare.

- *Mental changes:*
  - Apprehensive facial appearance
  - Extreme irritability *or* apathy
- *Signs of subclinical deficiency:*
  - Poor wound healing
  - Moderate dimorphic anemia
  - Increased susceptibility for infections

Diagnosis of scurvy depends on:

- ***Suggestive clinical features*** with history of precipitating event, e.g. fever or diarrhea;
- ***Characteristic radiological finding***, best seen at the end of long bones at knee joint **(Fig. 6.8)** and include:
  - *Ground-glass appearance* of the shaft and epiphysis due to loss of trabecular pattern,
  - *Thinning* or *penciling of cortex* with sharply outlined epiphyseal ends,
  - *Wimberger's ring sign*-ground-glass appearance of epiphyseal centers, surrounded by a white ring of compressed collagen,
  - *White line of Frankel*—a thick, irregular, transverse, white line at epiphyseal ends due to thickened provisional zones of calcification.
  - *Trummerfeld zone of rarefaction*—a narrow zone of metaphyseal rarefaction proximal to Frankel's line, due to atrophy of subepiphyseal cortex.
  - *Angle sign*—a triangular, rarefied, lateral defect proximal to Frankel's line, representing early stage of the zone of rarefaction.
  - *Corner sign* or *Pelkan spur*—a lateral spur-like growth of *Frankel's* line, due to compression of soft shaft.
  - *Lifting or separation of periosteum* from the cortex due to sub-periosteal hematoma. Actual hematomas are visible only after 1–2 weeks of illness as *enveloping-shell appearance*, due to calcification.
- ***Biochemical diagnosis*** is required only in sub-clinical cases, based on *low ascorbic acid levels in a buffy coat* (WBCs) sample of oxalate blood (Normal: 25–40 mg/dl). A level of zero in this layer indicates scurvy, even without clinical signs. Plasma ascorbic acid levels are unreliable, though fasting levels >0.6 mg/dl exclude scurvy. Urinary excretion of >80% of dose after 3–5 hours of a loading dose of 100 mg/kg vitamin C, indicates no vitamin C deficiency.

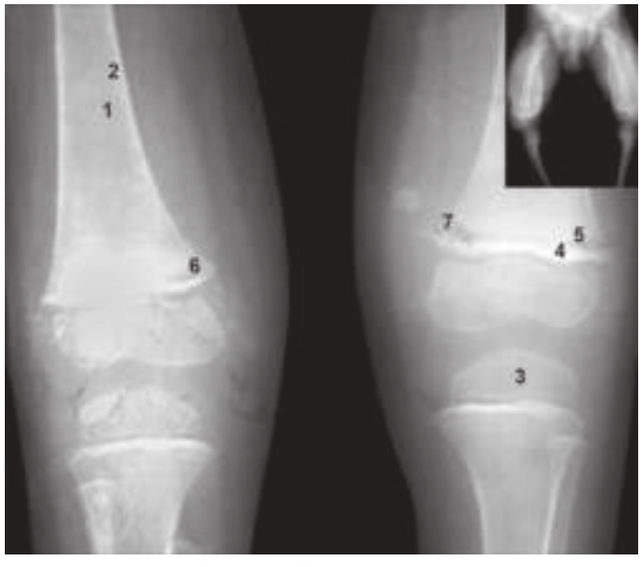

Fig. 6.8: Scurvy: X-ray

X-ray knee showing: 1. Ground glass matrix, 2. Pencil-thin cortex, 3. Ring sign, 4. Frankel's line, 5. Zone of rarefaction, 6. Angle sign, 7. Pelkan spar. ***Inset:*** Subperiosteal hematoma

D/D: Scorbutic bony lesions need to be differentiated from other cases of *pseudoparalysis*, e.g. (a) osteomyelitis/septic arthritis, (b) transient synovitis, (c) trauma, (d) congenital syphilis, and (e) leukemic bone involvement.

Scorbutic rosary is different from rachitic rosary as it is: (a) tender, and (b) has sharper margins *vs.* rounded contour of the rachitic beading.

Treatment: Vitamin C therapy (PO 200–500 mg/day for a week) is highly effective with dramatic clinical recovery within 24–48 hours, though radiological improvement may take many weeks. Recurrence must be prevented by adequate diet and therapeutic supplementation (100 mg/day) for many weeks.

Prevention includes nutritional counseling, correct cooking practices and vitamin C supplementation in lactating mothers, top-fed infants and during acute infective illnesses.

Vitamin C excess: Being a water soluble vitamin with free urinary excretion, large doses of vitamin C are well tolerated though some studies have shown higher risk of renal stones and iron load after excess vitamin C intake for long periods.

6.5 VITAMIN D DEFICIENCY (RICKETS)

Rather than a vitamin, vitamin D is now considered as a prohormone to the active form *1,25-dihydroxycholecalciferol*, which is synthesized endogenously, secreted under the control of another endocrinal product—*parathormone (PTH)* and plays a vital role in mineral metabolism.

Physiology: Vitamin D is a fat-soluble vitamin, essential for normal mineralization of growing bones **(Table 6.17)**.

RDA for vitamin D varies from 400 IU in infants and 600 IU in older children and adolescents.

Sources: *Cholecalciferol* (vitamin D_3) is the natural form of vitamin D, present as a *preformed vitamin* in animal

TABLE 6.17: Vitamin D at a glance

RDA: 400–600 IU/day
Sources:
- Endogenous synthesis under sunlight (see text)
- *Animal sources:* Animal fats and fish liver oils
- Fortified foods

Functions:
- Gut absorption of calcium and phosphorus
- Bone mineralization
- Renal reabsorption of phosphates and ? calcium

Deficiency states:
- Rickets (in children)
- Osteomalacia (in adults)

Hypervitaminosis D (develops after 1–3 months)
- *Renal:* Polyuria, polydipsia, renal failure
- *GIT:* Anorexia, vomiting
- *CNS:* Irritability, hypotonia
- *Metastatic:* Soft-tissue calcifications, osteopetrosis

sources, e.g. fats and fish liver oils. However <10% of the daily requirement is fulfilled by the diet.

Major bulk of the vitamin D is synthesized endogenously on exposure to ultraviolet rays in sunlight, from a natural pro-vitamin (*7-dehydrocholesterol*), present under the human skin. Plants do not contain vitamin D_3, though another variant (calciferol or vitamin D_2) may be derived by irradiation of a plant sterol – ergosterol.

Cholecalciferol, itself an inactive substance, needs to be sequentially hydroxylated in the liver and kidneys, to convert into either an active metabolite 1,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$) or relatively inactive metabolite 24,25-dihydroxycholecalciferol ($25(OH)D_3$), depending on the needs **(Fig. 6.9)**. Active metabolite promotes calcium and phosphorus absorption from gut and kidneys as well as bone mineralization.

Functions: Vitamin D plays an important role in mineralization of bones and absorption of calcium and phosphates from gut and reabsorption from renal tubules.

6.5.1 VITAMIN D DEFICIENCY RICKETS

Vitamin D deficiency is estimated to be present in ~22–90% of infants and ~14–24% on older children and adolescents, though many cases are subclinical. Rickets is the commonest manifestation of vitamin D deficiency in children, characterized by *failure of mineralization of the growing bones*, which should not be confused with *osteomalacia*, i.e. defective mineralization of mature bones, or *osteoporosis*, i.e. demineralization of premineralized bones.

Rickets may be broadly divided into two categories: (a) Vitamin D deficiency or nutritional rickets, and (b) Vitamin D-resistant or dependent rickets **(Table 6.18)**. Nutritional rickets accounts for over 90% cases in childhood, discussed in this section.

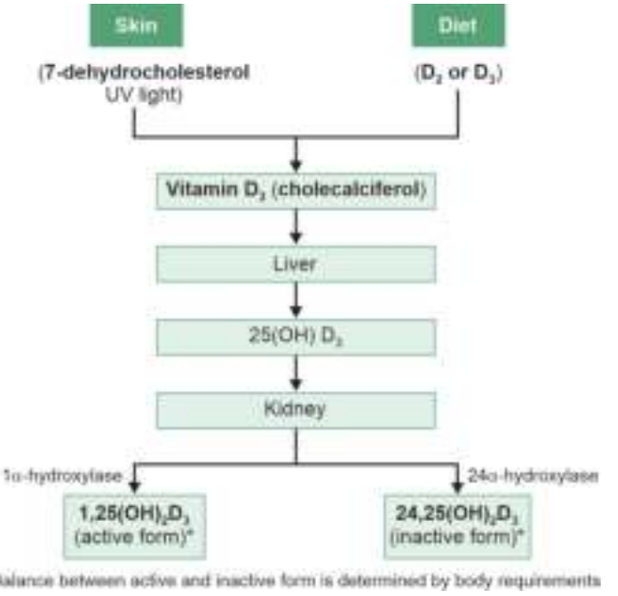

Fig. 6.9: Vitamin D metabolism.

TABLE 6.18: Etiological classification of rickets

A. Vitamin D deficiency (nutritional) rickets:
- Higher requirements in growing child
- Inadequate dietary intake
- Lack of exposure to sunlight
- Poor stores at birth—preterms, IUGR
- Malabsorption states
- Anticonvulsant therapy

B. Vitamin D resistant (refractory) rickets:
- Chronic hepatic disease
- Chronic renal disease (renal osteodystrophy)
- Hypophosphatemic rickets
  - Familial hypophosphatemia
  - Renal tubular acidosis or Fanconi syndrome

C. Vitamin D dependent rickets
- *Type 1:* Autosomal 1-hydroxylase deficiency
- *Type 2:* End-organ resistance to vitamin D

Etiologically, Vitamin D deficiency is rarely dietary, mainly seen in *rapidly-growing* children due to relatively higher requirements.

Inadequate endogenous synthesis due to limited sun-exposure in dark-skinned population, high altitudes or veil-wearing communities, e.g. muslins, is another contributory factor for rickets in India, as also poor maternal stores in vitamin D deficient mothers.

Malabsorption states, chronic liver disease and chronic renal diseases also impair vitamin D metabolism, leading to vitamin D deficiency.

Pathophysiology: Vitamin D deficiency leads to reduced calcium and phosphorus absorption from gut and reabsorption from kidneys with consequent rise in PTH levels to maintain normocalcemia. High PTH activity stimulates calcium mobilization from bones leading to:

- *Deficient mineralization* of growing osteoid tissue with typical clinico-radiological changes in rickets;
- *Increased osteoblastic activity* with elevated serum alkaline phosphate levels-*first biochemical change* in rickets.

Increased renal reabsorption of calcium leads to compensatory phosphorus excretion and low serum phosphorus levels-second biochemical change. *Normocalcemia is usually maintained in rickets by elevated PTH levels, except in severe cases*.

Clinical manifestations: Rickets commonly present at 6 months-2 years of age with bony deformities and hypotonia of supporting ligaments/muscles. Important clinical features of rickets include **(Fig. 6.10)**:

- *Craniofacial changes:*
  - *Craniotabes*—softening and thinning of skull bones with *ping-pong ball* like resilience on pressure over parietal bones, which is normal up to 3 months of age;
  - *Frontal bossing*—prominence of frontal bones;
  - *Caput quadratum*—box-head or hot cross-bun appearance due to fronto-parietal bossing;
  - Delayed closure of anterior fontanel;
  - Delayed dentition.
- *Thoracic changes:*
  - *Rachitic rosary*—round, non-tender beading due to widening of costochondral junktions;
  - *Harrison sulcus*—a groove/depression along the lower costal margins
  - Sternal deformities like *pectus excavatum*, i.e. depression of sternum, *pectus carinatum*, i.e. forward projection of sternum, or *pigeon-chest deformity;*
- *Limb deformities:*
  - Widening of wrist/ankles *(double malleolus)* due to widened epiphysis and metaphysic;
  - Gait abnormalities, e.g. knock-knee (*genu recurvatum*), bow-legs and coxa-vara;
  - Green-stick pathological fractures of long bones.
- *Spinal deformities:*
  - Kyphosis or scoliosis due to lax ligaments;
  - Short stature due to deformed spinal curvature;
- *Generalized hypotonia with:*
  - Pot-belly, due to abdominal muscle hypotonia;
  - Visceroptosis due to ligamental laxity;
  - Hyper-extensible joints (*acrobatic rickets*).
- ***Other manifestations***, e.g. excessive sweating over forehead, recurrent respiratory infections, etc.

Craniotabes

Widening of wrists

Rachitic rosary

Pectus excavatum

Knock knee

Bow legs

Fig. 6.10: Rickets: Clinical signs.

Rickets in severely malnourished children may present without clinical signs despite extensive radiological changes *(**atrophic rickets**)*.

Diagnosis of rickets depends on:

- ***Typical clinical defomities***, discussed above,
- ***Characteristic radiological changes***, best demonstrated at wrist joint **(Fig. 6.11)**, showing:
  - *Widening* of epiphyseal ends with increased space between diaphysis and epiphysis, due to poor visibility of thickened but uncalcified metaphysis.
  - *Fraying* at the visible end of long bones, (*raveled sleeve appearance)*, due to irregular mineralization of metaphysis.
  - *Cupping*, i.e. concavity at the visible end of long bones, due to poor mineralization of relatively less vascular center and pressure changes.
  - *Splaying* of the ends of long bones, due to pressure changes on poorly mineralized bones.

Other late changes include delayed bone age, costochondral widening with spatulate ribs, tri-radiate pelvis and spinal deformities.

After vitamin D administration, radiological recovery is visible in 7–10 days with appearance of *provisional zone of preparatory calcification*—a transverse

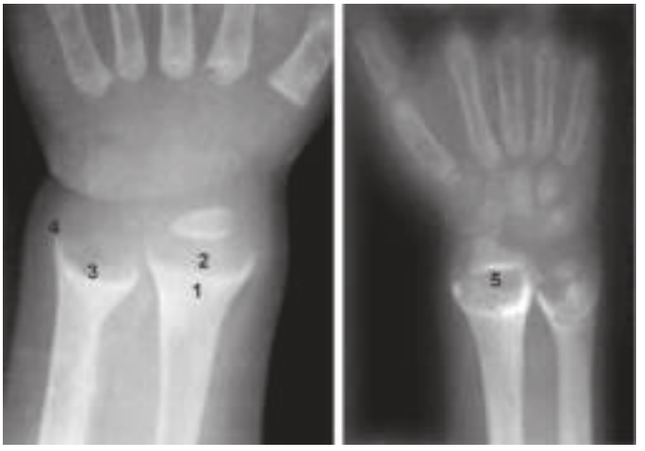

Fig. 6.11: Rickets: X-ray.

X-ray wrist showing: 1. Widening, 2. Cupping, 3. Fraying, 4. Splaying, 5. Line of preparatory calcification.

line beyond the visible end of shaft, suggestive of *healing rickets*. Absence of this zone after 3 weeks indicates possibility of refractory rickets. Complete X-ray clearance takes 2–3 months, though deformities may persist for many years.

- ***Biochemical changes*** depend on severity of disease and differentiate active disease from old deformities. Important changes in order of appearance are:
  - Elevated S. alkaline phosphatase (>20 KA units)
  - Low S. phosphorus levels (<4 mg/dl)
  - Low Ca × P index (<30)
  - Low S. calcium levels (<9–11 mg/dl)
- ***Serum vitamin D levels [25(OH)D_3]*** of < 12 ng/ml are interpreted as *deficient* while levels > 20 ng/ml are considered as *sufficient* (IAP guidelines 2021) in children to provide a buffer for periods of stress, exigency, and seasonal patterns.

D/D: Nutritional rickets need to be differentiated from vitamin D resistant/refractory rickets, discussed later. Some important indicators of non-nutritional rickets are given in **Table 6.19**.

Treatment: Conventional *Stoss regimen* was once the most widely used method to treat nutritional rickets and to differentiate them from resistant rickets. It involved administration of a single mega dose of vitamin D_3 orally or parenterally (3,00,000–6,00,000 IU) on diagnosis along with oral calcium supplements and repeating the X-ray wrist after 2–3 weeks to see for line of preparatory calcification **(Fig. 6.11)**. While appearance of this line indicates vitamin D deficiency rickets, absence of the line of preparatory calcification even after 3 weeks strongly indicates possibility of vitamin D resistant rickets and need for detailed investigations. However considering the potential risk of vitamin toxicity, stoss regimen is rarely used at present.

IAP guidelines 2021 recommend treatment of vitamin D deficiency with daily oral therapy with 2000 IU of vitamin D_3 in infants (or 3000 IU > 12 months age) for minimum 12 weeks along with daily calcium intake of 50–75 mg/kg/day (max 500 mg), followed by 400–600 IU/day as maintenance dose.

However in children with poor compliance for daily therapy, infant may be given equivalent of 2000 IU/day doses on weekly/monthly basis, while children >12 months may be given 60,000 IU every two weeks for total 5 doses (not to exceed cumulative dose of 3,00,000 IU).

Prevention of rickets as per ***IAP Guidelines 2021*** includes:

- Daily oral vitamin D supplementation (400 IU) in all infants < 1 year of age.
- No routine vitamin D supplementation is recommended beyond infancy, though adequate dietary calcium intake (500–600 mg/day; 800 mg in adolescents) and sufficient sun-exposure must be ensured. Daily sunlight exposure of 17–30 min in infants and 30–45 min in older children over 15–40% body surface area is recommended at least five times a week during noon (11AM-3PM) for preventing vitamin D deficiency across different regions and seasons.
- Routine vitamin D supplementation (400 IU/day) in children with high-risk conditions, e.g. chronic liver/renal disease, malabsorption states, chronic neuromuscular disorders and long-term therapy with anticonvulsants or steroids.
- While studies have shown lower vitamin D levels in pneumonia, tuberculosis, HIV, asthma, and ADHD/autism, causative association is not consistent and no vitamin D supplements are recommended in these cases.
- Universal maternal vitamin D supplementation is not recommended.

TABLE 6.19: Indicators of non-nutritional rickets

- Strong family history
- Rickets within first 6 months of life
- Failure to thrive, gross muscle wasting
- Signs of renal or hepatic disease
- History of mental retardation or anticonvulsant therapy
- No response to vitamin D therapy (Stoss regimen)
- *Urine:* low pH, aminoaciduria, phosphaturia

6.5.2 VITAMIN D RESISTANT RICKETS

Table 6.19 enlists some important indicators of non-nutritional rickets, the most important being no response to vitamin D therapy. Some important causes of resistant rickets are as follows:

Familial or primary hypophosphatemia, an *X-linked dominant* disease, is a leading cause of non-nutritional rickets due to defects in: (a) renal reabsorption

of phosphates, with consequent phosphaturia and hypophosphatemia, (b) conversion of 25(OH)D_3 into 1,25$(OH)_2D_3$.

Clinically, these cases usually present as toddlers with severe bow-legs and waddling gait, typically more severe in males.

Diagnosis rests on: (a) no response to vitamin D therapy, (b) similar family history, (c) heavy phosphaturia despite hypophosphatemia, and (d) absence of glucosuria, aminoaciduria and bicarbonaturia (d/d renal tubular acidosis).

Treatment includes daily phosphate supplements as *Joulie solution* (PO 0.5–1.0 gm/day q4hr), along with vitamin D_2 (2000 IU/kg/day) or preferably, 1,25 $(OH)_2D_3$ (30–60 ng/kg/day). Mega vitamin D therapy, as used in nutritional rickets, should be avoided due to the risk of hypercalcemia and nephrocalcinosis.

*(*Joulie solution: 30.4 mg phosphates/ml)*

Vitamin D-dependent rickets manifest at 3–6 months of age and are of two types:

- ***Type I***, due to 25(OH)D3–1 -hydroxylase deficiency that prevents renal conversion of vitamin D into active form, and
- ***Type II,*** due to inherited end-organ resistance.

While type I may be treated with massive doses of vitamin D_2 (2–10 lac IU/day), type II needs to be treated with 1,25$(OH)_2D_3$ (15–30 µg/kg/day).

6.5.3 HYPERVITAMINOSIS D

Hypervitaminosis D is almost always iatrogenic, due to erroneous ingestion of large doses of vitamin D during treatment of rickets. Rare cases may be related to prolonged formula feeding in preterms.

Serum vitamin D levels >100 ng/mL are considered as toxic, though levels between 50–100 ng/ml should also alert the physician to avoid further vitamin D supplementation.

Clinical manifestations develop after 1–3 months of overdose, with:

- *Hypercalcemia,* leading to:
  - Irritability, anorexia, vomiting, and constipation,
  - Cloudy cornea, retinopathy and aortic stenosis.
- *Hypercalciuria,* leading to:
  - Impaired urinary concentration with polyuria, polydipsia, dehydration and failure to thrive,
  - Nephrocalcinosis with pallor, hypertension and progressive renal failure.

Diagnosis depends on history, hypercalcemia, hypercalciuria and radiological abnormalities, e.g. generalized osteoporosis and metastatic calcifications in soft tissues. X-ray knee shows deposits of dense bone, producing the typical *spectacle sign*. ECG may suggest myocardial damage with ST elevation.

D/D includes other causes of hypercalcemia, e.g. chronic renal failure, hyperparathyroidism and idiopathic hypercalcemia (*William's syndrome*).

Treatment includes:

- Discontinue vitamin D and reduce calcium intake,
- Calcium chelators, e.g. oral $Al(OH)_3$ *or* sodium versenate for 2–3 weeks to reduce absorption,
- Cortisone 100 mg/day for 4 weeks in severe cases.

6.6 VITAMIN E DEFICIENCY

Vitamin E is a group of natural fat-soluble compounds-α-tocoferols.

Physiology: Vitamin E is an important antioxidant (free-radical scavenger), consequently considered as protective against severe inflammatory and neoplastic pathologies. It is involved in nucleic acid metabolism and stabilization of cellular membranes.

RDA of Vitamin E is ~5–10 mg of -tocoferol equivalent/day (1 mg = 1.5 IU), higher in preterms and adolescents (10–15 mg/day).

Dietary sources: Vitamin E is widely distributed in vegetable oils, fats and nuts, specially those rich in polyunsaturated fatty acids. Whole wheat, egg yolk and milk products are also rich sources of Vitamin E.

Vitamin E Deficiency

Etiology: Vitamin E deficiency is mainly seen in: (a) preterms due to poor stores, (b) chronic liver disease, (c) Malabsorption syndrome, and (d) high iron states, e.g. in hemolytic anemia.

Clinically vitamin E deficiency has been implicated in:

- Hemolytic anemia in preterms (at 6–10 weeks)
- Edema in kwashiorkor
- Degenerative neuropathy in biliary atresia or chronic liver disease, presenting as ataxia, peripheral neuropathy and posterior-column abnormalities
- Retinopathy of prematurity

Treatment: Though exact role and dose of vitamin E is not established, daily oral supplementation of 5–25 IU in high-risk children, e.g. preterms or those with chronic liver disease may prevent or reverse clinical abnormalities.

6.7 VITAMIN K DEFICIENCY

Vitamin K is a fat-soluble vitamin with very important role in hemostasis (coagulation) and to some extent, in bone metabolism.

Physiology: Vitamin K is essential for normal coagulation, via: (a) hepatic synthesis of FII, VII, IX and X, (b) activity of anticoagulant protein C and S, platelet stimulating factors, and (c) activity of osteocalcin—a calcium-binding protein.

Sources: Vitamin K available in 3 forms: natural fat-soluble vitamin K_1 in dietary sources, endogenously synthesized vitamin K_2 in gut by normal bacterial flora, and water-soluble synthetic preparations (vitamin K_3 or menadione).

Vitamin K_1 is present in animal foods, beans, green vegetables and milk, though major requirement is fulfilled by endogenous intestinal synthesis. Cow milk contains more vitamin K than human milk.

RDA of vitamin K is ~2–3 µg/day in infants, 30–60 µg/day in children and 60–120 µg/day in adolescents.

Vitamin K deficiency is seen in:

- Breastfed newborns due to low vitamin K content in breast milk.
- Altered gut flora after chronic diarrhea or prolonged antibiotic therapy, due to reduced gut synthesis.
- Defective utilization in chronic liver disease or during drug therapy, e.g. dicoumarol and aspirin.

Clinically vitamin K deficiency commonly manifests as *hemorrhagic disease of newborn* (Ch 12.17.1), though in older children, it may present as bleeding from multiple sites.

Diagnosis depends on clinical suspicion, increased prothrombin time and elevated PIVKA-II levels (***p**roteins **i**nduced in **v**itamin **K** **a**bsence*), with normal range of 17–50 mAU/ml.

Treatment: Therapeutic vitamin K preparations are available as fat-soluble vitamin K1 or aqueous synthetic analogues (menadione). Hemorrhagic manifestations may be rapidly controlled with 5 mg of any of these preparations (preferably aqueous), given parenterally. However, large doses of synthetic analogues may precipitate hemolysis in G6PD deficiency and in preterms. Blood/plasma transfusions is necessary in severe bleeding.

Prevention: Single oral *or intramuscular* vitamin K administration (1.0 mg) at birth is enough to prevent hemorrhagic disease in newborn, while periodic supplementation is necessary in chronic liver diseases and other deficiency states.

6.8 MINERAL DISORDERS AND TRACE ELEMENTS

Minerals are non-energy yielding micronutrients, which despite contributing <5% of body weight, play a vital role in human metabolism, health and disease. Minerals, along with other micronutrients, e.g. vitamins, are considered as responsible for *hidden hunger,* i.e. nutrient deficiencies without apparent manifestations in early stages.

Biologically important minerals may be broadly classified into:

- ***Macrominerals,*** which are present in substantial amounts with nutritional requirement usually exceeding >100 mg/day. Most of them are distributed in tissues as well as function as major electrolytes in body fluids, e.g. sodium, potassium, calcium, magnesium, etc. Important macrominerals have been discussed in Ch 7.
- ***Microminerals (trace elements),*** which constitute <250 µg/gm of body tissue matrix. Minerals present in still smaller amounts (<100 ng/gm) are termed as *ultra-trace elements*.

Role of trace elements in health and disease is being increasing recognized in recent years, which can be broadly divided into three categories, based on current knowledge:

1. *Essential trace elements with known biological functions*, e.g. iron, iodine, zinc, fluorine, selenium, copper, molybdenum and chromium.
2. *Essential trace elements with hitherto ill-identified functions*, e.g. manganese, silicon, nickel, boron, cobalt and vanadium.
3. *Potentially toxic trace elements with unknown biological functions,* e.g. lead, aluminum, tin, cadmium, arsenic, mercury, etc.

Table 6.20 presents an overview of important trace elements in human health and disease. While some of them have been discussed elsewhere, e.g. iron (Ch 19.4.1) and iodine (Ch 22.3.3), other important trace elements are discussed as follows:

Zinc is a component of many enzymes, e.g. carbonic anhydrase, carboxypeptidase, alkaline phosphatase, etc. Although widely distributed in tissues, average adult body contains <2–3 gm of zinc. Zinc deficiency is widely prevalent (~40–45%) in Indian children.

Physiology: Zinc is essential trace element for: (a) normal growth, (b) normal chemotaxis and T-cell immunity, (c) normal wound healing, and (d) synthesis of some hormones, e.g. insulin and nucleic acids. Zinc is not well conserved in body as there are no conventional tissue reserves.

RDA for zinc varies from 2.5 mg/day in infancy to ~15 mg/day in adolescents and adults.

Sources: Important sources of zinc include animal foods, e.g. meat, milk and fish, as well as plant foods, e.g. grains, legumes and nuts, though the bioavailability of zinc from plant sources in relatively poor.

Etiologically, zinc deficiency is rarely dietary, usually caused by:

- Increased requirements in early infancy, adolescents and pregnancy
- Decreased intake, e.g. in maternal zinc deficiency, total parenteral nutrition, etc.

TABLE 6.20: Essential trace elements at a glance

*Minerals (RDA)**	*Important functions*	*Deficiency states*	*Toxicity*
Iron (3–30 mg)	Heme synthesis (Hb, myoglobin) *Enzymes:* MAO, cytochrome oxidase	Anemia, growth failure Learning disabilities	Hemosiderosis Hemochromatosis
Iodine (90–140 mg)	Constituent of thyroid hormones	Goiter, Endemic cretinism	Goiter
Zinc (5–15 mg)	Constituent of metalloenzymes Wound healing	Acrodermatitis enteropathica Acquired deficiency	*Acute:* GIT upsets, seizures *Chr.:* Anemia, CNS signs
Fluorine (0.7–10 mg)	Bone mineralization Formation of dental enamel	Dental caries	Fluorosis
Selenium (10–50 µg)	Antioxidant *Enzyme:* Glutathione peroxidase	Keshan cardiomyopathy Arthritis, myositis	*Selenosis:* Loss of hair and nails Dental caries, garlic breath
Copper (30–80 µg/kg)	*Hematopoisis:* Iron utilization *Enzymes:* Tyrosinase, uriase Antioxidant	Anemia/neutropenia, Scurvy-like bone changes Recurrent diarrhea	Wilson's disease, ICC Menkey's disease Hemolytic anemia
Chromium (Not established)	Facilitates insulin action (co-factor)	? Hyperglycemia	Renal failure, dermatitis
Molybdenum (1.0–1.5 µg/kg)	*Enzyme: Xanthine oxidase*	Oral/esophageal cancers Seizures, mental retardation	Bony deformities Hyperuricemia
Cobalt (Not established)	Component of vit B_{12} & erythropoietin ? Iodine metabolism	? Hypothyroidism Anemia	Cardiomyopathy Goiter
Manganese (Not established)	Enzyme: Superoxidase dismutase	Failure to thrive, Skeletal abnormalities Reddening of hair	Encephalopathy
Nickel (Not established)	Membrane stabilizing effect *Enzyme: Urease*	Not known Nasal and lung cancers	Dermatitis, liver necrosis
Silicon (Not established)	Normal collagen formation	Not known, ? related to aging	Granuloma/fibrosis of lung
Boron (Not established)	Co-factor in steroid metabolism	Hypocalcemia, osteoporosis	Not known
Vanadium (Not established)	Sodium-potassium exchange	Not known	Not known

RDA: Recommended dietary allowance; **ICC:** Indian childhood cirrhosis

- Decreased absorption in:
  - Acrodermatitis enteropathica
  - Chronic diarrhea and malabsorptive states
- Increased urinary excretion in:
  - Chronic renal or liver disease
  - Hypoalbuminic states, e.g. kwashiorkor
  - Massive tissue injury, e.g. burns
  - Iron chelation therapy, e.g. in hemolytic anemia

Clinical features of zinc deficiency include:

- Failure to thrive, IUGR and hypogonadism
- Chronic diarrhea and anorexia
- Eczematous skin lesions and alopecia
- Increased infections and delayed wound healing.

Acrodermatitis enteropathica is an autosomal recessive defect in zinc absorption due to defective zinc transporter protein (ZIP4), which usually manifests during or after weaning with: (a) growth failure, (b) chronic diarrhea, (c) eczematous skin lesions, mainly on acral (hands/feet), inguinal and/or flexural parts of body, and (d) alopecia.

Diagnosis is confirmed on serum zinc estimation (N:6.6–19.4 µg/ml) and response to therapy.

Treatment: Oral or parenteral supplementation with 5 mg/kg/day (20–40 mg/kg/d in acrodermatitis enteropathica) usually leads to dramatic clinical response within a few days, which should be followed by adequate dietary modification to prevent recurrence. Long-term zinc supplementation is indicated in children with severe growth failure and acrodermatitis enteropathica.

Zinc supplementation is also indicated for 2 weeks in all children with – severe acute malnutrition (2 mg/kg/day) and diarrheal disorders (20 mg/day or 10 mg/day in infants < 6 months). It is also recommended as adjunct therapy in preterms (2 mg/kg/d for 3 months) and haemolytic anemia, e.g. sickle cell disease or thalassemia.

Fluorine is the most abundant element in nature, though never found in free elemental gaseous form. About 96% of body fluorine is present in bones and teeth.

Physiologically, fluorine is required for formation of *apatite*—a mineral complex essential for bone mineralization and dental enamel.

Sources: Drinking water is the principle source of fluorine to man apart from sea-food and cheese as other rich sources.

Fluorine deficiency is relatively uncommon, considered to be associated with higher incidence of dental caries and can be prevented by use of fluorinated toothpastes.

Fluorine excess (fluorosis) is more important public health problem in India, endemic in areas with high fluoride content in drinking water (>0.5–0.8 mg/L or >2 ppm).

Prolonged ingestion of high-fluoride water presents with: (a) mottling of teeth, (b) brittle bones with osteosclerosis, (c) calcification of muscles/tendons, and (d) failure to thrive, anemia and asthenia. As excess fluorine interferes with calcium metabolism, co-existing calcium deficiency is common and contributes to skeletal changes with osteoporosis/osteomalacia.

Controlling the fluoride content of drinking water is the only method to prevent fluorosis in children.

Copper: Nearly 60% of copper is present within erythrocytes, rest being in plasma (bound to ceruloplasmin) or tissues (bound to metallothionein).

Physiologically, copper is a constituent of many metabolic enzymes, involved in connective tissue formation, iron metabolism, neuronal myelination, melanin synthesis and cellular energy/oxygen utilization.

Copper deficiency is rarely dietary, presenting as neutropenia, microcytic hypochromic anemia, hypopigmented hair, osteoporosis and defective immune function.

Copper toxicity, usually due to use of copper cooking utensils and has been implicated in Indian childhood cirrhosis and hematological malignancies.

Inborn errors of copper metabolism are most important cause of altered copper status in body and include:

- *Wilson disease*—an autosomal recessive defect in mobilization of hepatic copper, presenting with a triad of chronic liver disease, extra-pyramidal signs and Kayser-Fleischer ring over cornea (Chapter 15.7).
- *Menkes-kinky-hair syndrome*—a rare X-linked recessive disorder, characterized by fine, brittle and light colored hair, progressive psychomotor retardation and hypopigmented skin.

Selenium is mainly required for: (a) synthesis of *glutathione peroxidase*, an important anti-oxidant enzyme, and (b) conversion of T4 into T3.

Selenium deficiency is definitely associated in two endemic diseases in China— *Keshan cardiomyopathy* and *Kaschin-Beck osteoarthritis*. It has been also implicated in higher risk for malignancies and atherosclerosis. Selenium deficiency may affect growth and development due to poor conversion of T4 into T3.

Selenium excess (selenosis) is associated with alopecia and nail deformities.

Molybdenum is a constituent of many enzymes, specially xanthine oxidase and xanthine dehydrogenase-essential for xanthine metabolism.

Molybdenum deficiency is mainly seen in children on prolonged total parenteral nutrition, presenting with renal calculi (due to xanthinuria) and myopathy. It has been also implicated in higher risk of dental caries an esophageal cancers.

Chromium: Major biological role of chromium is to potentiate the action of insulin in carbohydrate, lipid and protein metabolism, probably by acting as a glucose tolerance factor.

Chromium deficiency has been reported only in children on prolonged total parenteral nutrition, leading to impaired glucose tolerance and hyperglycemia. Dietary chromium supplementation may improve glucose tolerance in malnutrition.

6.9 FREE RADICALS IN HEALTH AND DISEASE

Free radicals, i.e. *atoms or molecules with one or more unpaired electrons in their outermost orbits*, are regularly formed in body during normal metabolic activity and eliminated by various antioxidant mechanisms. Excess production *or* inadequate elimination of these radicals has been recently identified as an important contributor in cellular aging, disease and death.

Three most important free radicals in human context are: *singlet oxygen* (O^-), *superoxide* and *peroxide* anions and *hydroxyl* radicals.

Sources: Free radical excess is implicated to:

- *Exogenous or environmental sources*, e.g. smoke, air pollutants, radiation, ultraviolet rays, etc. or
- *Endogenous or metabolic sources*, e.g. infections, cellular ischemia/hypoxia, toxic tissue injury.

Antioxidants: Important antioxidant substances in body may be broadly divided into three categories:

a. *Metabolic enzymes*, e.g. superoxidase mutase, catalase, glutathione peroxidase, etc.
b. *Metal ion chelators*, e.g. plasma proteins, transferrin, ceruloplasmin, etc.
c. *Oxygen scavengers*, e.g. vitamins (A, E, C) and minerals (selenium, zinc).

Pathology: Free radical tissue injury is considered as an important cause of *altered cellular permeability and metabolism*, leading to early cell death in innumerable disease processes, including:

- Hyperoximia-related problems in preterms, e.g. retinopathy of prematurity or bronchopulmonary dysplasia,
- Hypoxic-ischemic injuries, e.g. neonatal enterocolitis, hypoxic-ischemic encephalopathy,
- Sepsis/septic shock,

- Metabolic disorders, e.g. kwashiorkor, Wilson disease, hemochromatosis, etc.,
- Hemolytic anemia or malignancies, and
- Premature atherosclerosis or aging in adults, etc.

Prevention of free radical injury depends on avoidance of environmental risk factors, early treatment of primary disease and adequate consumption of natural antioxidants, i.e. vitamins and minerals. Consumption of fruits and vegetables (400 gm/day) is considered as adequate to minimize free radical injury.

Treatment: Recently, many synthetic antioxidants have been used in selected cases of suspected free radical injury, e.g. *xanthine oxidase inhibitors*, e.g. allopurinol, *N-acetylcysteine*, *recombinant enzymes*, e.g. glutathione peroxidase analogues, superoxide dismutase, coenzyme Q derivatives, etc. or *natural antioxidants* (as above), with equivocal results.

CHAPTER

7

Fluid and Electrolyte Balance

Milind S Tullu, Mukesh Agrawal

Fluid and electrolyte composition of body is in a state of dynamic balance, regulated by various inter-related mechanisms. Understanding of these mechanisms and their abnormalities is essential for rational fluid and electrolyte therapy in sick children.

7.1 WATER HOMEOSTASIS

Total body water (TBW) contributes to ~78% of body weight at birth, but declines rapidly due to physiological diuresis in newborns and growth of adipose tissue in late infancy, to reach the adult level of ~55–60% by *one year* of age. Post-pubertal females and obese persons have relatively less body water due to excess fat accumulation. In non-obese children, TBW may be calculated as:

TBW (Liters) = 0.61 Body weight in kg + 0.251.

TBW is distributed into four body compartments:

a. *Extracellular compartment* or ECF (20–25%) as plasma (5%) and interstitial fluid (15%).
b. *Intracellular compartment* or ICF (30–40%).
c. *Transcellular water* (2%) as urine, gut secretions, CSF and body cavity fluids.
d. *Slowly exchangeable fluid compartment* in bones, cartilages and connective tissue.

At birth, ECF is more than ICF, but this ratio is reversed by the end of infancy due to postnatal diuresis and cellular growth. Transcellular water and water in slowly exchangeable fluid compartments, though important metabolically, does not play significant role in water homeostasis.

7.1.1 PHYSIOLOGY OF WATER BALANCE

Physiology of water balance may be broadly divided into: (a) overall quantitative regulation of TBW, and (b) its inter-compartmental distribution, as follows:

A. TBW homeostasis revolves around the maintenance of normal plasma volume and osmolality. *Volume* of the TBW depends on the equilibrium between external intake and small amount produced endogenously on oxidation of nutrients on one side; and excretion via urine (65%), skin (40%), lungs (15%) and stools (5%) on other side.

Osmolality of the plasma depends on the pressure exerted by its two components: (a) *colloids*, e.g. albumin, and (b) *crystalloids* or electrolytes, e.g. Na^+ and Cl^-. Though colloidal (oncotic) pressure contributes only to a small fraction of total plasma osmotic pressure, it is more important determinant of osmotic gradient across the cell membranes than crystalloid pressure, as colloids do not pass through cell membranes.

The terms *molality* and *molarity* refers to number of solute molecules in 1 kg and 1 liter of solvent, respectively. Accordingly, *osmolality* refers to the 'pressure exerted by number of molecules in 1 kg of solvent', while *osmolarity* denotes 'molecular pressure in 1 liter of solvent'. Normal plasma osmolality (285–295 mOsm/kg H_2O) roughly equals to the twice of plasma sodium concentration in mEq/L, though may be precisely calculated by following formula:

$$\text{Osmolality} = 2\,(Na^+ + K^+) + \frac{\text{Glucose}}{18} + \frac{\text{BUN}}{2.8}$$

Osmolality in mOsm/kg; Na/K in mEq/L; glucose/BUN in mg/dl.

Important regulatory mechanisms for TBW balance in human body **(Fig. 7.1)** are as follows:

a. Water intake depends on *thirst*, i.e. conscious desire to drink water, which is regulated by a center in mid-hypothalamus with two important afferents: *Osmoreceptors* in hypothalamus to detect changes in plasma osmolality and *baroreceptors* in atria and vascular bed to sense changes in plasma volume. Probably, elevated angiotensin II levels in hypovolemic states also stimulate thirst.

Primary disorders of thirst, i.e. *polydipsia* or *adipsia* are usually psychogenic in origin, though altered thirst may also indicate hypothalamic disorders, hypokalemia, malnutrition and disorders of renin-angiotensin system.

b. Urinary excretion is the most important determinant of TBW regulation. A part of urinary water excretion is *obligatory*, necessary to excrete the solute load. However beyond this, urinary volume is regulated by: (a) plasma

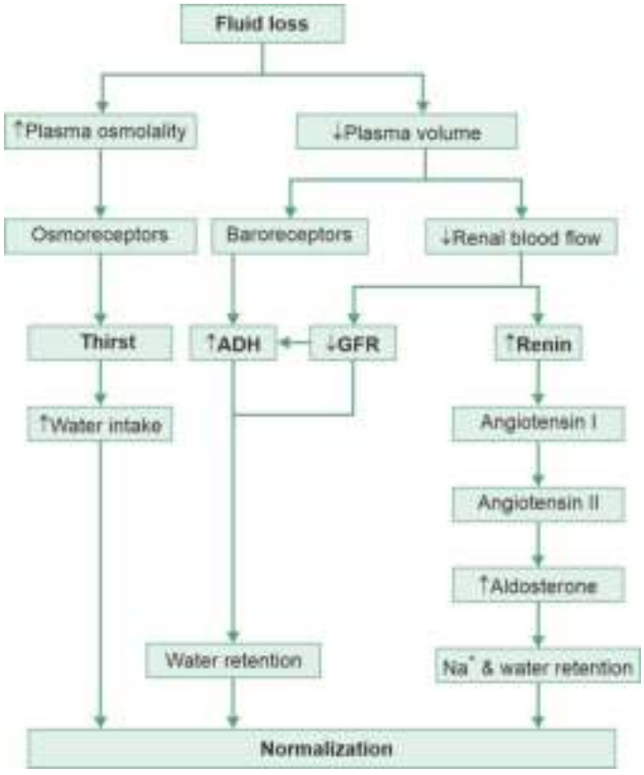

Fig. 7.1: Physiology of total body water balance.

volume and osmolality, (b) dietary solute load, (c) renal functions, and (d) hormonal control. Three important hormonal regulators of urinary water excretion are antidiuretic hormone (ADH), aldosterone and atrial natriuretic hormone peptide.

- *Antidiuretic hormone* of hypothalamic-hypophyseal axis, is a direct regulator of urinary water excretion. ADH secretion is regulated by osmotic pressure of ECF and it acts by increasing the cell-permeability of collecting ducts to enhance water absorption.

  Important ADH disorders include: (a) excess secretion in neurological disorders, i.e. syndrome of inappropriate secretion *or* SIADH, (b) ADH deficiency in central diabetes insipidus, and (c) tubular non-responsiveness to ADH in nephrogenic diabetes insipidus (Ch 22.2.4).
- *Aldosterone, a*n adrenal hormone, is an indirect regulator of urinary water excretion, by manipulating sodium excretion. It is mainly secreted in response to reduced plasma volume via renin-angiotensin mechanism and increases tubular sodium reabsorption with *passive* water absorption.
- *Atrial natriuretic hormone peptide* is produced and stored in atrial myocytes and released in response to ECF overload leading to atrial stretching. It prevents the sodium/water reabsorption by antagonizing the renin-angiotensin mechanism.

TABLE 7.1: Major ions in body fluids

	Plasma	*Interstitial fluid*	*ICF*
Cations			
Sodium	**142**	**144**	6
Potassium	5	5	**154**
Magnesium	3	5	40
Anions			
Bicarbonates	24	27	13
Chlorides	**105**	**118**	–
Proteins	15	–	60
Phosphates	5	5	**106**

Figures in bold indicate major cation/anion in respective fluid compartments

c. Non-urinary losses in stools or insensible losses via skin/lungs are fairly constant in normal children with a little influence on overall water balance. However, these are important exits in pathological states, e.g. diarrhea (stools), fever (skin), respiratory distress (lungs). Insensible losses are also influenced by environmental temperature, humidity and body surface area, which should be considered during calculation of fluid requirements in sick children.

B. Inter-compartmental distribution: Water in ECF and ICF compartments is freely exchangeable and exists in a state of dynamic equilibrium. Within ECF too, water continuously moves between plasma to interstitial fluids. Important determinants of these inter-compartmental water distributions are as follows:

Extracellular *vs* intracellular fluid: Water movement between these two compartments depends on the relative osmotic gradient and active movement of ions. While *sodium is the principle cation in ECF, potassium is principle cation in ICF* **(Table 7.1)**. Since cell membranes are free permeable to water, osmotic force across them is maintained by active transport of Na^+ out of the cell and K^+ into the cell-an energy-consuming process. Any change in Na^+ content of ECF alters its osmolality with secondary effects in ICF. For example, hypernatremia increases osmolality of ECF> movement of water from ICF to ECF> cellular dehydration. Conversely, hyponatremia leads to movement of water into the cell and consequent cellular edema.

Plasma *vs* interstitial fluid: Interstitial fluid is derived from plasma, filtered through the semi-permeable capillary bed at the arteriolar end. However, most of it returns back to plasma at venular end, while the rest is carried back to vascular space via lymphatics. Important determinants of fluid movements between plasma and interstitium are:

- *Hydrostatic pressure* in capillary bed that facilitates water movement from plasma to interstitial space;
- *Osmotic pressure* of plasma that prevents or reverts this movement; and
- *Capillary permeability*.

In normal conditions, osmotic gradient between plasma and interstitial space (28 – 4.5 = 23.5 mm Hg) and capillary permeability is virtually constant, and water movement between these compartments is mainly decided by hydrostatic pressure, as follows:

- *At the arteriolar end* of capillary bed, hydrostatic pressure is more in vascular space than in interstitial space. Consequently, net hydrostatic pressure gradient (25 – (–7) = 32 mm Hg) exceeds osmotic gradient (23.5 mm Hg) and water moves out into interstitial spaces.
- *At venular end,* hydrostatic pressure in vascular space drops to 9 mm Hg. Consequently, net hydrostatic pressure gradient (9 – (–7) = 16 mm Hg) is less than osmotic gradient and water moves back in vascular space. Some interstitial fluid is collected by lymphatics, ultimately to return in vascular compartment.

Two important pathological abnormalities of fluid imbalance in children are edema and dehydration, discussed in following sections.

7.1.2 EDEMA

Edema is a clinical term to denote *excess accumulation of fluids in interstitial fluid compartment*, which normally contributes to ~15% of TBW.

Etiology: Edema is caused by any factor that: (a) reduces plasma oncotic pressure, (b) increases hydrostatic pressure, (c) increases capillary permeability, and (d) prevents lymphatic return **(Table 7.2)**.

Diagnostic approach: Although the edema *per se* is a clinical diagnosis, etiological diagnosis requires detailed history, clinical examination and relevant investigations. Important differentiating features of edema include:

- ***Onset:*** Allergic *or* toxic edema due to increased capillary permeability develops rapidly within a few hours, while other causes lead to gradual and progressive edema.
- ***Distribution:*** Generalized edema is usually nutritional, renal or cardiac in origin. Renal edema typically begins from face as periorbital puffiness, while cardiac or nutritional edema is most prominent over dependent parts, e.g. legs in older children and sacrum in infants.

  Localized edema is seen in: (a) lymphatic obstruction, (b) allergic conditions, e.g. angioneurotic edema, (c) localized vascular compressions, and (d) early stages of generalized edema.
- ***Diurnal variation:*** Renal edema is maximum in morning due to overnight fluid retention, while cardiac edema is more prominent in evening due to gradual decompensation after physical activity.
- ***Pitting vs. non-pitting edema:*** While severe edema is grossly visible, presence of mild/moderate edema may be confirmed by compressing on a bony part, e.g. shin of the tibia for >10 sec. Pitting subcutaneous edema indicates interstitial fluid accumulation.

  Non-pitting edema is rare in children, seen in: (a) hypothyroidism or myxedema, (b) obesity, and (c) long-standing edema with secondary changes, e.g. lymphatic filariasis.
- ***Co-existing features*** of primary disease also help in differential diagnosis, e.g. itching (allergic causes), jaundice (hepatic disease), anuria/oliguria (renal disease), cardiac signs, etc.

TABLE 7.2: Causes of edema

a. Reduced oncotic pressure *(hypoproteinemia)*
- Nutritional kwashiorkor (↓ intake)
- Malabsoprtion syndrome (↓ absorption)
- Chronic liver disease (↓ synthesis)
- Nephrotic syndrome (↑ renal loss)
- Protein-losing enteropathies (GIT loss)
- Burns (↑ skin loss)
- Pleural effusion/peritonitis (third space loss)

b. Increased hydrostatic pressure
- *Cardiac:* CCF, pericarditis, hypertension
- *Extra-cardiac:* Budd-Chiari syndrome, mediastinal mass
- *Water retention:* Renal failure, steroids, fluid overload

c. Increased capillary permeability
- *Allergic:* Urticaria, angioneurotic edema
- *Toxic:* Septicemia, epidemic dropsy
- *Inflammatory:* Infections, burns

d. Lymphatic obstruction
- *Congenital anomalies:* Lymphangioma
- *Acquired:* Filariasis, traumatic, surgical

7.1.3 DEHYDRATION

Dehydration denotes *loss of TBW from extracellular and/or intracellular compartments*, due to reduced intake *or* more likely, excessive losses via urine, stools, lungs or skin. As these losses are predominantly from ECF compartment, ECF dehydration dominates in early stages. ICF dehydration usually develops after redistribution of fluids.

Etiology: Acute diarrhea *and/or* vomiting is the commonest cause of dehydration in children, apart from other causes, listed in **Table 7.3**.

Pathogenesis: As water loss is almost always associated with loss of other electrolytes, specially sodium, pathophysiological changes in dehydration can be broadly divided into three categories:

a. ***Isonatremic dehydration*** (50%), i.e. proportionate loss of water and sodium, e.g. in osmotic diarrhea, with *normal* serum osmolality. In established isotonic dehydration, usually 60% of fluid loss is from ECF and remaining 40% is from ICF.

b. ***Hyponatremic dehydration*** (30–40%), i.e. disproportionately higher loss of sodium than water, e.g. in secretory diarrhea. Serum osmolality falls with consequent movement of water from ECF to ICF,

TABLE 7.3: Common causes of dehydration

a. Excessive losses
- *GIT:* Diarrhea, vomiting, gastric aspiration
- *Urine:* Polyuria (e.g. diabetes insipidus)
- *Lungs:* Tachypnea (respiratory disorders)
- *Skin:* Fever, excessive sweating, burns
- *Third-space losses:* Paralytic ileus, gross ascites

b. Poor intake
- Unconscious/sick child
- Starvation
- Psychogenic

c. Re-distribution of fluids
- Edema (intravascular > interstitial fluid)
- Hyperosmolar states, e.g. DKA (ECF > ICF)

DKA: Diabetic ketoacidosis

leading to: (a) further depletion of ECF, and (b) cellular overhydration, e.g. cerebral edema. Clinical signs of dehydration in these cases are disproportionately more than the estimated fluid loss.

c. ***Hypernatremic dehydration*** is rare (<5%), usually attributed to erroneous fluid therapy with concentrated oral rehydration fluids or hypertonic parenteral fluids. In these cases, higher serum osmolality leads to movement of water from ICF to ECF with: (a) partial compensation of ECF loss by ICF fluids, and (b) cellular dehydration. Signs of dehydration in these cases are disproportionately less than estimated fluid loss.

Clinical features of dehydration depend on its severity and indicate:
- *Compensatory mechanisms* to restore/conserve body water, e.g. excessive thirst, oliguria, dry skin/mucus membranes, etc.;
- *Circulatory decompensation*, e.g. weak and thready pulse, hypotension and shock; and
- *Cellular dehydration*, e.g. loss of skin turgor and mental changes.

Important clinical indicators of the severity of dehydration are given in **Table 7.4**.

Severity of dehydration is likely to be overestimated in marasmic children due to severe wasting (confused with turgor) or underestimated in obese children or kwashiorkor. *Urine output is the most reliable indicator in these cases.* Severity may also be misinterpreted in cases with hyponatremic or hypernatremic dehydration, as discussed earlier.

Hypernatremic dehydration is characterized by: (a) typical doughy skin, and (b) excessive irritability, rather than drowsiness in iso-/hypo-natremic dehydration.

Laboratory evaluation: Although clinical signs are cornerstones to evaluate the presence and severity of dehydration, following investigations are essential at least in severe cases to assess co-existing electrolyte imbalance and renal dysfunction.

TABLE 7.4: Severity assessment of dehydration

Feature	*Mild*	*Moderate*	*Severe*
Behavior*	Alert	Drowsy	Stupor/coma
Thirst	Thirsty	Marked	Absent
Eyeballs	N	Sunken	Sunken
Tears	Present	Absent	Absent
Tongue	Dry	Dry	Parchmenty
Skin turgor	N	Lost**	Lost
Pulse	N	Rapid	Thready
Respiration	N	Rapid	Acidotic
BP	N	N	Hypotension
Urine output	N	Oliguria	Anuria
Wt loss (<1 yr)	~ 5%	~ 10%	~ 15%
Wt loss (>1 yr)	~ 3%	~ 6%	~ 9%

*Irritable in hypernatremic dehydration
**Doughy feel in hypernatremic dehydration.

- Serum electrolytes, e.g. Na^+, K^+, HCO_3^- and Cl^-,
- Renal parameters, e.g. blood urea, serum creatinine.
- Urinalysis, including specific gravity.
- Hemogram including hematocrit.
- Relevant etiological investigations.

Management of dehydration involves oral or parenteral fluid therapy. While oral fluid therapy is discussed in Ch 14.10, general principles of parenteral fluid therapy are discussed in Ch 7.7.

7.2 SODIUM DISORDERS

Sodium is the principle *cation* in extracellular fluid, responsible for maintenance of osmolality in intravascular and interstitial fluid compartments. About 45% of total body sodium is present in body fluids, rest being in bones, cartilages and connective tissues. Most of the tissue sodium is not in exchangeable form, with limited role in sodium homeostasis. *Normal serum sodium concentration is 135–145 mEq/L.*

Physiology: Kidney is the prime regulator of sodium balance in body. While sodium is freely filtered through glomeruli, ~2/3rd of it is reabsorbed in proximal tubules and loop of Henle. Remaining sodium is also reabsorbed in distal tubules and collecting ducts and only <1% of filtered sodium is actually excreted in urine. Renal reabsorption of sodium is an active process, facilitated by renin-angiotensin mechanism and aldosterone secretion; and opposed by the atrial natriuretic hormone.

Hyponatremia is the commonest electrolyte abnormality in hospitalized children, defined as *S. sodium levels <135 mEq/L*, though it is rarely symptomatic till levels fall <125 mEq/L.

Causes: Gastrointestinal loss in diarrhea or vomiting is the commonest caus of hyponatremia in children, apart from other causes **(Table 7.5)**. In critically sick

TABLE 7.5: Causes of hyponatremia

Primary sodium deficit:
Extra-renal losses
GIT: Diarrhea, vomiting, nasogastric drainage
Skin: Burns, cystic fibrosis
Third space: Paralytic ileus
Renal losses
Prematurity: Poor concentration capability
Forced diuresis: Diuretics, diabetes mellitus
Renal: Renal tubular acidosis, acute tubular necrosis
Adrenal: Congenital adrenal hyperplasia (salt-loosing)
Disproportionate water retention:
Syndrome of inappropriate ADH secretion (SIADH)
Excess intake: Psychogenic, Na^+ free IV fluids
Renal: Nephrotic syndrome, renal failure
Congestive cardiac failure
Pseudo-hyponatremia *due to hyperlipidemia*
Nephrotic syndrome
Diabetic ketoacidosis

TABLE 7.6: Causes of hypernatremia

Increased sodium intake:
- Concentrated ORS or formula feeds
- Hypertonic IV fluids
- Near-drowning in sea water
- Use of common salt for emesis
- Intentional salt poisoning

Relative water deficit:
- Diabetes insipidus
- Diabetes mellitus
- Gastroenteritis
- Reduced oral intake—intentional, psychogenic
- Increased insensible loss—respiratory distress

children, excess ADH secretion, i.e. SIADH, may lead to disproportionate water reabsorption from kidneys and *dilutional hyponatremia.*

Etiologically, hyponatremia is also classified as:

- *Hypovolemic hyponatremia* with sodium loss in excess of the fluid loss due to renal or extrarenal losses;
- *Normovolemic or euvolemic hyponatremia* with proportionate loss of sodium and water, e.g. in SIADH or due to drugs, e.g. cyclophosphamide, vincristine, carbamazepine, etc;
- *Hypervolemic hyponatremia* due to excess water retention, e.g. in CCF, nephritic syndrome, cirrhosis, renal failure, etc.

Pathophysiology: Hyponatremia leads to decreased ECF osmolarity and consequent movement of water from ECF to ICF, leading to cellular edema including cerebral edema. Brain also attempts to adapt hyponatremia by extrusion of intracellular electrolytes and osmolytes (glutamine, aspartate, etc.), which are neuroexcitatory and can produce seizures, even without cerebral edema.

Clinically, symptomatic hyponatremia predominantly presents with signs of cerebral edema, e.g. altered sensorium and seizures. Severe cases may also present with hypertension, pulmonary edema and heart failure.

Hyponatremic encephalopathy is relatively more common in children than adults due to larger brain size (versus intracranial volume) and may lead to irreversible brain damage, if left untreated.

Asymptomatic prolonged hyponatremia in preterms may lead to poor growth, development and sensorineural hearing loss.

Treatment of hyponatremia depends on the cause, severity and duration:

- *Asymptomatic or dilutional hypernatremia,* e.g. in SIADH, does not require specific correction except fluid restriction and treatment of primary cause.
- *Acute symptomatic hyponatremia* should be treated with IV 3% NaCl as a bolus of 2 ml/kg over 10–15 minutes (or 3–5 ml/kg over first hour), which may be repeated to maximum 100 ml, till the symptoms resolve. Serum sodium level should be monitored every 2 hours, with an objective to raise them by ~5–6 mEq/L in first 1–2 hours.
- *Chronic or left-over hyponatremia after acute correction* should be treated more slowly with IV 3% NaCl, in doses calculated with following formula:

  Sodium deficit (mEq) = (125 – actual S. sodium) × body weight × 0.6

  Whereas 125 is desired Na^+ level and 0.6 is distribution coefficient of sodium in body.

Rapid correction of hyponatremia should be avoided to prevent pontine/ extra-pontine osmotic myelinolysis, once serum sodium levels approach 125 mEq/L and no more than 10 mEq/L deficit should be corrected in 24 hours. As a thumb rule, 12 ml/kg of 3% NaCl raises S. Na^+ levels by ~10 mEq/L.

Hypernatremia is relatively less common than hyponatremia, defined as serum sodium levels >145 mEq/L.

Causes: Hypernatremia in children is usually *iatrogenic* in origin, due to use of concentrated oral rehydration/ parenteral fluids. *Concentration hypernatremia* is seen in disorders with excessive water loss, e.g. diabetes insipidus **(Table 7.6)**.

Pathophysiology: Hypernatremia increases osmolarity of the ECF, leading to movement of water from ICF to ECF and consequent cellular dehydration. In acute severe hypernatremia, this osmotic shift may lead to shrinkage of the brain, tearing of meningeal vessels and intracranial hemorrhage.

Clinically hypernatremia present with features of cellular dehydration. Increased thirst is the earliest compensatory response and clinical indicator to developing hypernatremia, followed by:

- *Neurological* signs, e.g. irritability, twitching and seizures.
- *Skin* signs, e.g. dry skin with typical doughy consistency, which may mask signs of dehydration.

Thrombotic complications due to intracellular dehydration and consequent hypercoagulability may develop in severe cases, including strokes, renal vein thrombosis and deep vein thrombosis.

Investigations: All cases of hypernatremia should be assessed for serum and urine osmolality and urinary sodium, along with blood urea, serum creatinine and electrolytes. Neuroimaging for intracranial pathologies and hormonal assays for endocrinal causes, e.g. serum aldosterone, cortisol, ADH and ACTH may be necessary in cases with occult etiology.

Treatment: Hypernatremia is generally well tolerated as brain generates idiogenic osmols to increase the intracellular osmolarity. Rapid correction of hypernatremia should be avoided to prevent sudden decrease in ECF osmolarity, which may lead to rapid movement of water within the cells and consequently cause cerebral edema with seizures, pulmonary edema and congestive cardiac failure. As general rule, *the rate of sodium correction should never exceed 0.3–0.5 mEq/L per hour or 8–12 mEq/L per day.*

Important considerations in correction of hypernatremia include:

- Recommended IV fluid is N/2 saline in DW 5% (with added 20 mEq/KCl after passage of urine). Sodium-free fluids should *never* be used to avoid rapid correction.
- Replacement fluid volume should be ~1.5 times of maintenance requirement + deficit correction as 3–4 ml/kg for each mEq/L of serum Na^+ above 145 mEq/L, infused over recommended period. Ongoing losses should be added as required. Oral rehydration should be started as early as possible.
- Sodium levels should be monitored every 1–2 hourly to limit the rate of fall <0.5 mEq/L/hour.
- If child develops seizures due to rapid correction, administer 3% Nacl 4–6 ml/kg over 30 minutes.
- Peritoneal dialysis is indicated for serum Na^+ exceeds 180 mEq/L, using high glucose-low sodium dialysate.
- In cases presenting with hypotension/shock on admission, hypernatremic correction should start after one or two boluses of 20 ml/kg. Normal saline over 20 minutes for restoration of intravascular volume.

7.3 POTASSIUM DISORDERS

Potassium is the principle *intracellular* cation, essential to maintain resting membrane potential of cells (along with major extracellular cation - sodium) and consequently, adequate excitability of neurons and contractility of muscles.

Normal serum potassium levels are 3–5 mEq/L. More than 90% of potassium is present in body fluids, rest being in bones, cartilages and connective tissue.

Physiology: Dietary intake of potassium is usually adequate and rarely affects serum potassium levels. Maintenance of normokalemia mainly depends on:

- Renal excretion, regulated by serum K^+ levels, blood pH and hormones, e.g. aldosterone.
- Transcellular movements during blood pH changes- Potassium moves out of the cell during acidosis (leading to ECF hyperkalemia) and into the cell during alkalosis (leading to ECF hypokalemia).

Hypokalemia is the commonest electrolyte abnormality in sick children, defined as *S. potassium levels <3 mEq/L.*

Causes: Severe diarrhea or vomiting is the commonest cause of acute hypokalemia, while persistent hypokalemia usually indicates underlying renal disease **(Table 7.7)**.

Pathophysiology: Low extracellular potassium levels slow down the post-depolarization return of potassium into the cells, delaying process of repolarization and leading to impaired neuromuscular excitability.

Clinically, hypokalemia presents with signs of impaired neuromuscular excitability, as follows:

- *Skeletal muscle involvement*, e.g. limb weakness, hypotonia, hyporeflexia, abdominal distension and respiratory muscle paralysis. Rhabdomyolysis is a rare but important complication.
- *Smooth muscle involvement*, e.g. paralytic ileus, orthostatic hypotension, bradyarrhythmia.
- *Characteristic ECG changes*, which may precede clinical features in hypokalemia and include: (a) low voltage, (b) ST depression with flat/inverted T waves, (c) prolonged QTc interval, and (d) prominent U waves.

Prolonged hypokalemia also affects renal concentration capability, manifesting as polyuria, polydipsia, metabolic alkalosis *with* secondary failure to thrive and nephrosclerosis.

Treatment: *Symptomatic* **or** *severe* hypokalemia (<2.5 mEq/L) must be treated with slow potassium chloride infusion (2 mEq/ml) in IV fluids as 0.5–1 mEq/kg over

TABLE 7.7: Causes of hypokalemia

a. Extrinsic losses:
- *GIT:* Diarrhea, vomiting, nasogastric drainage
- *Urinary*:*
  Renal: Renal tubular acidosis, Bartter syndrome
  Endocrinal: Cushing syndrome, hyperaldosteronism
  Iatrogenic: Diuretics, *e.g.* furosemide
  Metabolic: Diabetic ketoacidosis
- *Skin:* Profuse sweating
- ↓ *muscle mass:* Severe malnutrition

b. Transcellular redistribution**
- Alkalosis/rapid correction of metabolic acidosis

c. **Others:** Familial hypokalemic periodic paralysis

*Urinary K^+ <15 mEq/L indicate extra-renal loss of potassium.
**In acidosis, K^+ moves out of the cell. Rapid correction leads to return of K^+ intracellularly, causing hypokalemia.

1–2 hours, with monitoring every 2–4 hours. Potassium concentration in the infusate should never exceed 60 mEq/L.

Prolonged hypokalemia due to renal diseases or diuretics may be prevented or treated with oral potassium chloride (20 mEq/15 ml) given as 2–4 mEq/kg/day, along with treatment of primary cause.

Hyperkalemia is defined as *S. potassium levels >5.5 mEq/L.* Serum potassium levels of >8.5 mEq/L are often fatal.

Causes: Acute renal failure is the commonest cause of hyperkalemia in children, apart from other causes given in **Table 7.8**.

Pathophysiology: High ECF potassium in hyperkalemia resists further efflux of potassium from the cells during depolarization, leading to slow membrane depolarization.

Clinically, these cases present with signs of neuromuscular irritability, as follows:

- *Neurological signs*, e.g. muscular weakness, paresthesia, tetany, etc.
- *Cardiac signs*, e.g. bradycardia, shock and tachyarrhythmia.
- *Characteristic ECG changes* in hyperkalemia may precede clinical features and often correlate with serum potassium levels, including: (a) peaked *'tented'* T waves, (b) prolonged PR interval, (c) wide QRS complexes, and (d) flat or absent p waves in severe cases.

Treatment of hyperkalemia is an *emergency* in cases with serum levels >6.5 mEq/L or presence of ECG changes and must be treated with:

- Discontinuation of all potassium containing fluids and medications;
- IV calcium gluconate 10% (0.5–1 ml/kg) with cardiac monitoring to stabilize myocardial cell membrane and counteract cardiac toxicity of potassium.
- IV insulin infusion (0.3 U/kg) in 1 ml/kg of DW50% over 1 hour to enhance cellular uptake of potassium, co-transported with glucose.

TABLE 7.8: Causes of hyperkalemia

a. Decreased renal excretion
- Acute/chronic renal failure
- Hypoaldosteronism, salt-loosing CAH
- Use of potassium-sparing diuretics

b. Increased intake
- *Iatrogenic:* Potassium salts, penicillin
- Blood transfusions (sp. old blood)

c. Hypercatabolic states *(release from tissues)*
- *Medical:* Burns, *tumor lysis syndrome**
- *Surgical:* Extensive trauma, major surgery

d. Transcellular distribution**
- Metabolic acidosis
- Familial hyperkalemic periodic paralysis

e. Pseudohyperkalemia: Hemolysed sample

*during chemotherapy, ** shift of K^+ out of the cells.

- IV sodium bicarbonate (1–2 mEq/L over 30 min), to create an alkalotic state that facilitates re-entry of potassium into the cells.
- Dialysis in cases of refractory *or* life-threatening hyperkalemia, e.g. in acute renal failure or tumor-lysis syndrome.
- *Prolonged mild/moderate hyperkalemia*, e.g. in chronic renal disease/failure, may be treated with ion exchange resins, e.g. kayexalate or sodium polystyrene sulfonate given orally or rectally as 1 gm/kg/dose (Max 15 gm).

7.4 CALCIUM DISORDERS

Bones are main reservoir of calcium, containing ~99% of total body calcium. Normal plasma calcium level is *9–11 mg/dl*, which is ~60% is in *bound form* with albumin or other anions, e.g. phosphates, and the rest in *free ionic form* (4.0–5.2 mg/dl).

Calcium in extracellular fluids is in equilibrium with skeletal calcium and plays vital role in many physiological processes, e.g. neuromuscular transmission, coagulation and cellular functions. Calcium affects cellular functions through it binding regulatory protein – *calmodulin*.

RDA for calcium varies with age as 300 mg/day in infants, 500–600 mg/day in children and ~1000 mg/day in adolescents.

Sources: Dairy products are most important source of calcium along with millets, e.g. ragi and root vegetables, e.g. tapioca. Cow milk has more calcium than breast milk (1200 mg/dl *vs* 300 mg/dl), though later is absorbed better than former. Presence of phytates, oxalates and citrates in diet inhibits its absorption.

Physiology: Calcium homeostasis largely depends on renal reabsorption, mobilization from bones and intestinal absorption, regulated by various hormones, e.g. parathormone, vitamin D and calcitonin, as follows, **(Fig. 7.2)**:

- *Parathyroid hormone* (PTH) increases S. Ca^{++} levels by facilitating its absorption from gut, reabsorption from

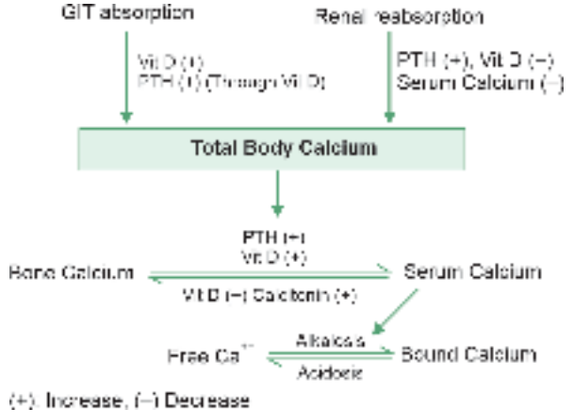

Fig. 7.2: Calcium regulation.

kidneys and mobilization from bones. PTH levels are controlled by a feedback mechanism, dependent on serum calcium levels.

- *Vitamin D* ($1,25(OH)_2D_3$) also increases gut absorption and renal reabsorption of calcium, *but* unlike PTH, facilitates its deposition in the bones rather than increasing serum levels.
- *Thyrocalcitonin hormone* from parafollicular cells of thyroid is antagonistic to PTH, decreasing bone resorption and increasing urinary calcium excretion.

Acid-base status predominantly affects ionic component without altering total serum levels. Ionic calcium levels are increased in acidosis due to movement of Ca^{++} out of the cell and decreased in alkalosis due to reverse movements. This *ionic component of plasma calcium is the prime determinant of its physiological activity*. As commonly measured serum levels include both the bound and ionic calcium, normal S. calcium levels do not exclude physiological hypo-/hypercalcemia. Ionic component may be normal despite low serum values, due to reduced bound fraction, e.g. in hypoproteinemia.

Hypocalcemia: Though the term 'hypocalcemia' is generally used to denote *S. calcium < 8.5 mg/dl* in children or <8 mg/dl in term newborns, clinical manifestations depend on ionic Ca^{++} levels (< 4.0 mg/dl).

If facility to measure ionic Ca^{++} is not available, it is worthwhile to measure S. albumin levels simultaneously. In normo-albuminic children, low S. calcium reflects ionic hypocalcaemia. However, in hypo-albuminic states, disproportionately low S. calcium levels should be demonstrated to identify ionic hypocalcaemia *(for each 1 gm/dl fall in S. albumin below 4 gm/dl, S. calcium levels fall by ~0.8 mg/dl)*.

Ionic Ca^{++} levels are also altered in acid–base imbalance, i.e. increased in acidosis and decreased in alkalosis (0.1 unit change in pH = 10% change in ionic calcium levels).

Causes: Hypocalcaemia is rarely dietary except in top-fed infants, where high phosphate content of formula feeds prevents adequate calcium absorption. Common causes of hypocalcaemia are listed in **Table 7.9**.

Clinically, latent or manifest *tetany* is the typical manifestation of symptomatic hypocalcaemia (discussed below), though generalized seizures are common in infancy. Less severe cases may present with irritability and cramps/twitching.

Management: Hypocalcaemic seizures *or* tetany is treated as follows:

- *Immediate* IV calcium gluconate 10% (2 ml/kg) infusion slowly over 8–10 minutes with cardiac monitoring for bradycardia or arrhythmia. IV site should be observed carefully during the injection as subcutaneous effusion may cause local necrosis.

TABLE 7.9: Causes of hypocalcemia

a. Vitamin D deficiency:
- Nutritional
- Malabsorption
- Chronic liver *or* renal disease

b. Decreased parathormone (PTH) activity:
- Hypoparathyroidism
- Pseudohypoparathyroidism

c. Hyperphosphatemia:
- Formula feeding
- Familial *or* chronic renal disease

d. Magnesium deficiency

e. Alkalosis *or* over-correction of acidosis

- *Immediate therapy should be followed by* IV calcium boluses as above repeated every 6–8 hours till next 24–48 hours. In mild cases, oral calcium supplementation (40–80 mg/kg/day) is enough, preferably with vitamin D.
- *In cases refractory to calcium boluses, concurrent* hypomagnesemia is likely and must be treated with IV magnesium sulphate 50% infusion as 25–50 mg/kg diluted 5–10 times in normal saline, which may be repeated every 6 hours, if required.
- Reduction of phosphate content in formula feeds may be necessary to reduce the risk of recurrence.

Tetany is a clinical entity, indicative of *neuronal hyperexcitability* due to abnormal concentration of various ions in the fluid bathing nerve cells.

Causes: Tetany is caused by:

- Hypocalcaemia (S. ionic Ca^{++} < 3.0 mg/dl)
- Hypomagnesemia (S. Mg^{++} < 1.0 mg/dl)
- Alkalosis: Respiratory *or* metabolic.

Clinical manifestations: *Carpopedal spasm* is the hallmark of tetany, though latent tetany is more common. Important signs of latent/manifest tetany are as follows:

- ***Latent tetany:***
  - *Chvostek sign*—facial twitching after tapping over the facial nerve at angle of mandible;
  - *Trousseau sign*—carpopedal spasm after squeezing of upper arm or during blood pressure measurement;
  - *Peroneal sign*—carpopedal spasm, after tapping over the peroneal nerve behind lateral malleolus;
  - *Erb's sign*—lower excitatory threshold on electrical stimulation of peripheral nerves;
  - Prolonged QTc interval (> 0.45 sec)
- ***Manifest tetany:***
  - *Carpopedal spasms,* i.e. flexion of wrists, extension of fingers, adduction of thumb with/without extension and adduction of feet **(Fig. 7.3)**;
  - *Laryngeal spasms* with stridor, croup or sudden death due to choking;
  - *Paresthesia,* i.e. tingling and numbness of fingers and toes;
  - *Generalized seizures* in infancy.

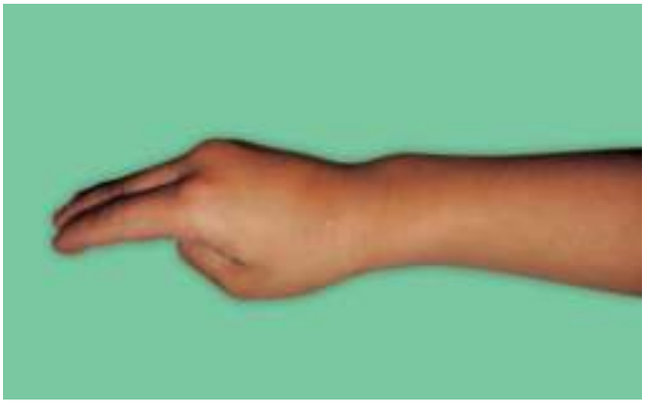

Fig. 7.3: Tetany—carpopedal spasm.

Treatment depends on the urgent correction of primary metabolic defect, e.g. hypocalcemia, hypomagnesemia or alkalosis. Careful re-breathing into an overhead bag to increase pCO_2 may control alkalotic tetany.

Hypercalcemia is relatively less common, defined as *S. calcium >11 mg/dl.*

Causes: Hypercalcemia is usually a chronic metabolic abnormality, secondary to *increased* parathyroid hormone or vitamin D activity or *low* phosphates to bind free calcium **(Table 7.10)**.

Clinically hypercalcemia presents with:

- Impaired urinary concentration, leading to polyuria and polydipsia;
- Hypercalciuria with nephrocalcinosis, tubulointerstitial nephropathy and nephrolithiasis;
- Lethargy, confusion, headache and coma in severe cases
- Arrhythmia, due to sudden hypercalcemia following IV calcium administration.

Treatment is indicated only when S. calcium levels cross 12 mg/dl and includes:

- Normal saline infusion along with diuretics, to increase calcium excretion in acute cases.
- Bisphosphonates, e.g. pamidronate or etidronate to block bone resorption and treat chronic hypercalcemia, e.g. in malignancies, immobilizations and hyperparathyroidism. IV calcitonin (4–8 U/kg q6hr) may also be used in some cases.
- Peritoneal dialysis in selected cases, specially in those with renal failure.
- Surgical intervention may be needed in cases with hyperparathyroidism with persistent hypercalcemia (> 12.5 mg/dl) and recurrent renal stones.

TABLE 7.10: Causes of hypercalcemia

- Primary hyperparthyroidism
- Hypervitaminosis D (Iatrogenic)
- *Bone demineralization:* Immobilization, malignancy
- Iatrogenic calcium overdose
- *Low phosphate intake:* LBW, milk-alkali syndrome
- *Increased phosphate excretion:* Thiazide diuretics
- *Others:* William syndrome*, thyrotoxicosis

*Elfin facies, hypercalcemia and supravalvular aortic stenosis.

7.5 MAGNESIUM DISORDERS

Magnesium is the second most important intracellular ion after potassium, responsible for maintenance of normal cellular enzyme activity for protein and fat metabolism as well as electric activity in nerves and muscles. *Normal serum magnesium levels are 1.5–1.8 mg/dl.*

RDA for magnesium varies from 30 mg in infants to ~200–400 mg in older children and adolescents.

Sources: Magnesium is present in plant chlorophyll, with green vegetables, e.g. legumes, nuts and whole grains as predominant source of dietary magnesium. Milk is a poor source.

Physiology: Since >99% of magnesium is intracellular, serum levels are unreliable indicators of magnesium status. Dietary intake usually exceeds normal requirements and physiological magnesium balance is mainly determined by its renal excretion from thick ascending loop of Henle and regulated by: (a) parathormone, (b) thyrocalcitonin, and (c) serum calcium levels. Parathormone enhances magnesium absorption from the gut and decreases excretion in the urine.

Hypomagnesemia: Although clinical severity may not correlate with serum levels, the term *hypomagnesemia* denotes S. magnesium levels <1.3 mg/dl.

Causes: Magnesium deficiency is rarely dietary except in cases of severe malnutrition or excessive consumption of junk foods (magnesium is eliminated during food processing). Secondary deficiency is common in malabsorption states and renal diseases **(Table 7.11)**.

Clinically hypomagnesemia induces skeletal resistance to parathormone, leading to hypocalcemia. Consequently, hypomagnesemia and hypocalcemia frequently co-exist and present with:

- *Neuromuscular irritability*, e.g. tetany, seizures and tremors, and
- *Cardiac* arrhythmia or ECG changes.

Severe hypomagnesemia may lead to mental changes, e.g. irritability and disorientation as well as respiratory paralysis. Hypokalemia and acidosis is also common in severe hypomagnesemia. Hypomagnesemia should always be suspected in a case of tetany, which does not respond to IV calcium therapy.

Treatment: Severe hypomagnesemia or hypomagnesemic tetany is treated with slow infusion of IV magnesium sulphate 50% as 25–50 mg/kg (2.5–5 mg/kg of elemental

TABLE 7.11: Causes of hypomagnesemia

a. Reduced absorption/intake
- Malabsorption syndrome
- Prolonged IV therapy (without magnesium)
- Protein-energy malnutrition

b. Increased urinary losses
- Hypoparathyroidism
- Renal tubular acidosis
- Nephrotoxic drugs
- Hyperaldosteronism
- Hypercalcemia

c. Familial hypomagnesemia

d. ***Others:*** Bartter syndrome, mitochondrial disorders

magnesium), diluted 5–10 times in normal saline, which may be repeated every 6 hours to the maximum of 200 mg/kg/day. Lower doses should be used in cases with renal disease. Concurrent hypocalcemia and hypokalemia also needs correction. Asymptomatic cases may be treated with oral magnesium supplements.

Hypermagnesemia is uncommon, sometimes seen in cases with chronic kidney disease or prolonged used of magnesium containing antacids. Symptoms are non-specific with nausea, vomiting and weakness in milder cases, though severe cases may develop altered sensorium, respiratory depression and arrhythmia.

Treatment involves removal of the source along with IV calcium therapy in severe cases to antagonize cardiac and neuromuscular effects of extracellular magnesium excess. Rarely, dialysis may be needed in very severe and symptomatic hypermagnesemia.

7.6 ACID–BASE DISORDERS

Normal acid–base regulation in body revolves around the concentration of hydrogen (proton) ions in body fluids, denoted as *pH*-the negative algorithm of free H^+ concentration.

Normal blood *pH* ranges between *7.35 and 7.45*. H^+ ions are continuously produced during various metabolic activities including dissociation of body *acids* (H^+ donor), e.g. H_2CO_3 and neutralized by body *bases* (H^+ acceptor), e.g. –OH, $–HCO_3$, NH_3, phosphates, etc.

Maintenance of normal blood pH depends on the rate of H^+ ion production and their neutralization. Excess production or deficient neutralization of H^+ ions lowers blood pH (*acidosis*), while reduced production or over-neutralization leads to increased pH (*alkalosis*).

Thus, actual blood pH depends on a ratio between its bases and acids, also depicted by *Henderson-Hasselbalch equation*, i.e.

$$pH = pK + \log \text{base/acid}$$

*pK is a constant, derived from dissociation of acid–base pair.

7.6.1 NORMAL ACID–BASE REGULATION

As H^+ ions are produced and eliminated at a variable rate, continuous regulation of normal acid–base balance depends on:
- Immediate *buffering mechanisms* to prevent rapid changes in pH, and
- Subsequent *compensatory mechanisms* to correct the actual biochemical change.

A. Buffering mechanisms: Immediately after production, H^+ ions are neutralized by certain body *buffers*, i.e. the substances that resist sudden pH changes by accepting or releasing extra H^+ ions.

The principal buffer in extracellular compartment (ECF) is *bicarbonate-carbonic acid system*, denoted by following bi-directional equation:

$$(H^+) + (HCO_3^-) \rightleftharpoons H_2CO_3 \rightleftharpoons H_2O + CO_2$$

The direction in which this equation runs, depends on the rate of H^+ production and their concentration in ECF. From the above equation it is obvious that:
- Rightward movement of this equation leads to excessive clearance of H^+ ions (*alkalosis*), while leftward movement leads to accumulation of H^+ ions (*acidosis*)
- Excess production of H^+ *or* depletion of HCO_3^- – due to any cause, leads to excess of H^+ ions in body (*metabolic acidosis*)
- Excess accumulation of HCO_3^- *or* depletion of H^+ due to any cause, leads to deficit of H^+ ions in body (*metabolic alkalosis*)
- Retention of CO_2 due to any cause drives this equation towards left, leading to inadequate buffering of H^+ ions (*respiratory acidosis*)
- Hyperventilation with CO_2 wash-out derives this equation to the right, leading to rapid clearance of H^+ ions (*respiratory alkalosis*)

Other important, though less efficient, buffer systems in body include, e.g. hemoglobin, proteins, phosphates, ammonia-ammonium buffer, etc.

B. Compensatory mechanisms: Abovementioned buffering mechanisms prevent rapid fluctuations in blood pH *but* do not correct the actual acid-base imbalance. Further, this neutralization leads to excess HCO_3^- utilization, disturbing normal CO_2/HCO_3^- ratio and limiting further buffering capacity.

Actual correction of acid–base imbalance after initial buffering is a slow process, which aims to normalize pCO_2/HCO_3^- ratio and eliminate excess H^+ ions by:
- *Pulmonary regulation*, i.e. increased/decreased excretion of CO_2, by changes in respiratory rate/depth;
- *Renal regulation* by:
  - increased/decreased reabsorption of HCO_3^- in proximal tubules and ascending loop of Henle,

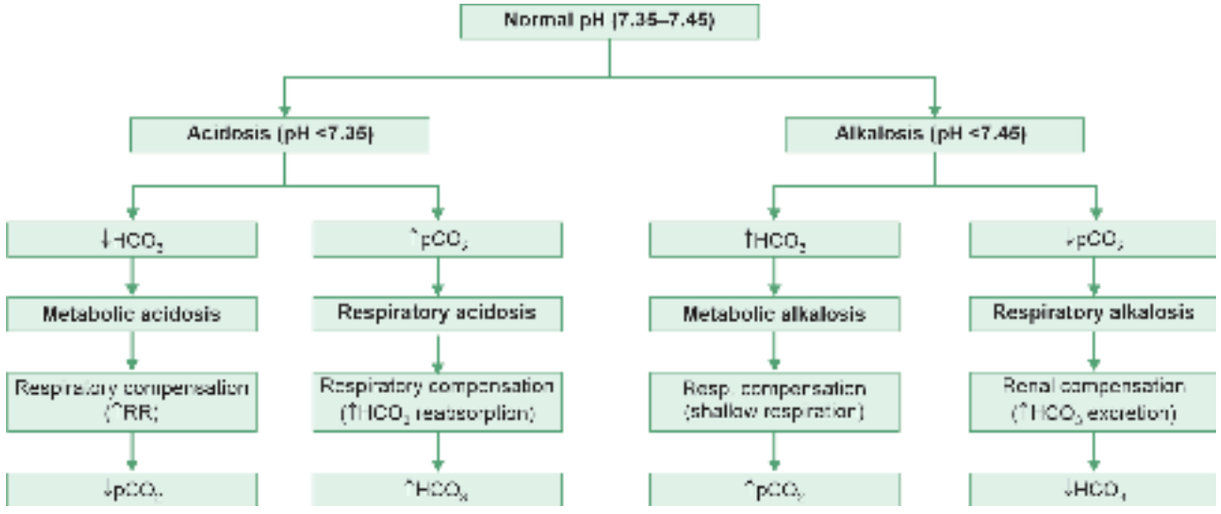

Fig. 7.4: Pathophysiology of simple acid–base disorders

– replacement of depleted HCO_3^- by production of new HCO_3^- in distal tubules and collecting ducts,
– actual H^+ excretion/secretion in distal tubules and collecting ducts.

In general, metabolic acidosis *or* alkalosis is compensated by pulmonary mechanisms, i.e. via increased or decreased CO_2 excretion respectively, while respiratory acidosis *or* alkalosis is compensated by renal mechanisms, i.e. increased or decreased HCO_3 excretion, respectively.

Thus, any acid–base imbalance is corrected by a two-step process:

a. changes due to initial buffering mechanism (*primary parameter*) during early stages, and
b. changes due to compensatory mechanism (*secondary parameter*) after some time.

As a thumb rule, in uncompensated pH disturbance, primary parameter is altered but secondary parameter is normal. On the other hand, in compensated state, primary as well as secondary parameter move in same direction. *For example*, in uncompensated metabolic acidosis, primary parameter (HCO_3) is reduced but pCO_2 is normal, while in compensated state, both HCO_3 and pCO_2 are reduced.

Figure 7.4 summarizes important buffering and compensatory mechanisms in various acid–base disturbances.

7.6.2 EVALUATION OF ACID–BASE STATUS

Clinical diagnosis of acid–base imbalance needs evaluation of *three* parameters on arterial blood gas (ABG) report-*pH, HCO_3 and pCO_2*. Normal range of these parameters are given in **Table 7.12**.

TABLE 7.12: Important acid–base parameters in ABG report

Parameter	*Normal range*
pH	7.35–7.45
pCO_2	35–45 mm Hg*
HCO_3	21–28 mEq/L

*Also denoted as torr units: 1 torr = 1 mm Hg.

Interpretation of an ABG report involves answers to following questions:

a. **Whether blood pH normal or abnormal?**

Normal blood pH varies from 7.35 to 7.45. Lower pH <7.35 indicates acidosis, while higher pH >7.45 indicates alkalosis. However, *normal pH does not exclude underlying acid–base imbalance*, as it could return to normal after some time due to compensatory mechanisms despite persistence of physiological abnormality.

b. **Whether pH abnormality is metabolic or respiratory in origin?**

Answer to this question requires study of two major pH determinants—HCO_3 or pCO_2, to identify primary altered parameter and direction of change. Predominant changes in HCO_3 values indicate either metabolic acidosis (↓ HCO_3) *or* metabolic alkalosis (↑ HCO_3). On the other hand, predominant changes in pCO_2 values indicate respiratory acidosis (↑ pCO_2) or respiratory alkalosis (↓ pCO_2). In later stages however, it may be difficult to identify primarily altered parameter due to compensatory change in other parameter. In such situations, clinical clues help to identify origin of pH abnormality.

c. **Whether any compensatory change has occurred?**

As the pH is a primarily a ratio between HCO_3 and pCO_2 (excluding effects of other buffers), compensatory mechanisms attempt to change the secondary parameter in the *same direction* as the primary abnormality, to restore normalcy. For example, ↓ HCO_3 in metabolic acidosis is compensated

by increased respiratory efforts to ↓ pCO_2; or ↑ pCO_2 in respiratory acidosis is compensated by excess renal bicarbonate reabsorption to ↑ HCO_3. Normal values of secondary parameter indicate absence of compensation, while altered values indicate partial or adequate compensation, discussed in next step.

d. **Whether compensation is adequate or inadequate?**

e. Efficacy of compensatory mechanisms depends on the time available for compensation and adequate pulmonary or renal functions. For example, metabolic acidosis may not be adequately compensated in a poorly ventilated child, who is unable to eliminate extra CO_2 for compensation. Compensation is considered as *adequate* if the secondary parameter has changed in following proportions to the change in primary parameter:
   - In metabolic acidosis, 1 mEq/L drop in HCO_3^- is compensated by 1.2 mm Hg drop in pCO_2.
   - In metabolic alkalosis, 1 mEq/L rise in HCO_3^- is compensated by 0.7 mm Hg rise in pCO_2.
   - In respiratory acidosis, 10 mm Hg rise in pCO_2 is compensated by 3.5 mEq/L rise in HCO_3^-.
   - In respiratory alkalosis, 10 mm Hg drop in pCO_2 is compensated by 5 mEq/L drop in HCO_3^-.

Proportionately lesser change in second parameter indicates inadequate compensation.

Following ***examples*** illustrate the interpretation of an ABG report:

- pH 7.25, pCO_2 58, HCO_3^- 25: Low pH indicates acidosis, high pCO_2 indicates respiratory acidosis and normal HCO_3 indicates *uncompensated respiratory acidosis*.
- pH 7.48, pCO_2 20, HCO_3^- 17: High pH indicates alkalosis, low pCO_2 indicates respiratory alkalosis and simultaneous reduction in HCO_3 indicates *compensated respiratory alkalosis*.
- *pH 7.2, pCO2 40, HCO3⁻ 18:* Low pH indicates acidosis, low HCO_3^- indicates metabolic acidosis and normal pCO_2 indicates *uncompensated metabolic acidosis*.
- *pH 7.5, pCO_2 39, HCO_3^- 30:* High pH indicates alkalosis, high HCO_3^- indicates metabolic alkalosis and normal pCO_2 indicates *uncompensated metabolic alkalosis*.

7.6.3 SPECIFIC ACID–BASE DISORDERS

Salient features of major acid–base abnormalities are as follows:

Metabolic acidosis: Primary abnormality in metabolic acidosis is decreased in HCO_3^- levels, either due to external losses or excess utilization to titrate H^+ ions during buffering process. During the compensatory phase, low HCO_3^- levels are compensated by increased elimination of CO_2 via respiratory route. Bicarbonate losses via kidney or gastrointestinal tract are also compensated by relative increase in chloride levels (hyperchloremia).

TABLE 7.13: Causes of metabolic acidosis

With normal anion gap (Hyperchloremic acidosis):
- Renal loss of HCO_3^-: Proximal RTA, renal failure
- GIT loss of HCO_3^-: Diarrhea
- ↓ H^+ excretion: RTA type I/IV, potassium sparing diuretics
- ↑ H^+ production: TPN, ammonium chloride poisoning

With high anion gap (Normochloremic acidosis)
- ↑ acid production/accumulation
  - *Lactic acidosis:* Sepsis, shock, hypoxia
  - *Ketoacidosis:* Diabetes ketoacidosis, starvation
  - *Others:* IEM, organic acidemia, salicylate poisoning
- Failure of acid excretion, e.g. renal failure
- Dilutional hypobicarbonatemia (HCO_3^- free fluid therapy)

RTA: Renal tubular acidosis; **TPN:** Total parenteral nutrition; **IEM:** Inborn errors of metabolism.

Etiology: Metabolic acidosis may be with: (a) *normal anion gap* due to loss of bicarbonates or accumulation of H ions or with, (b) *increased anion gap* due to accumulation of other acids, e.g. lactic acid or ketoacids, etc. *Relative HCO_3^- deficiency* due to bicarbonate-free fluid therapy (*dilutional hypobicarbonatemia*) may also lead to metabolic acidosis with normal anion gap **(Table 7.13)**.

Clinically, acute metabolic acidosis presents with signs of:

- Compensatory respiratory effort, e.g. *Kussmaul's breathing* – rapid and deep respiration, and
- Acidosis *per se* leading to peripheral vasodilatation and consequently hypotension, pulmonary edema and tissue hypoxia.

Chronic metabolic acidosis may be asymptomatic or present with anorexia, weight loss, vomiting and muscle weakness.

Diagnosis of *acute* metabolic acidosis is indicated by lower pH < 7.35, and low HCO_3^- levels, while *compensated* state is also associated with low pCO_2 levels. For full compensation, 1 mEq/L drop in HCO_3^- is compensated by 1.2 mm Hg drop in pCO_2.

Anion gap: Next step in etiological evaluation of metabolic acidosis is calculation of anion gap, i.e. the difference between total measurable cations and anions, i.e. *serum Na^+ and K^+ on one side and serum HCO_3^- and Cl^- on other side.* Normally, cationic side exceeds anionic side by ~12 mEq/L, due to a pool of non-titrable acids (*), as shown in following equation:

$$(\text{Serum})\ Na^+ + K^+ = HCO_3^- + Cl^- + (*)$$

Anion gap is increased (>16 mEq/L) in metabolic acidosis due to accumulation of non-titratable acid (with corresponding fall in measurable anions), e.g. in renal failure, lactic acidosis, diabetic ketoacidosis, salicylate poisoning, inborn errors of metabolism, etc.

Anion gap remains normal in metabolic acidosis due to bicarbonate losses with: (a) corresponding increase in Cl^- levels (hyperchloremic acidosis), e.g. renal tubular acidosis, hypoadrenal states, etc. or (b) corresponding drop in K^+ levels, e.g. diarrhea.

Management of metabolic acidosis mainly includes correction of underlying cause, though *alkali therapy* may be necessary in severe acidosis (pH <7 or HCO_3^- <5 mEq/L or salicylate poisoning) as follows:

- Calculate precise HCO_3 requirement by following formula:

  = (desired HCO_3 – actual HCO_3) × weight × 0.6*

  (*distribution coefficient for bicarbonates in body).
- Infusion only half of this amount as 7.5% $NaHCO_3$ over 3–4 hours (1 ml = 0.9 mEq/L) along with fluid correction for hypotension/shock.

IV bicarbonate correction should be done slowly, as rapid correction of acidosis may precipitate tetany due to intracellular movement of calcium. In addition, these cases should be treated for primary cause, along with IV fluids to manage hypotension and shock.

Metabolic alkalosis: Primary event in acute metabolic alkalosis is actual *or* relative (due to H^+ ion depletion) increase in HCO_3^- levels, which is partly compensated by respiratory depression to retain CO_2. However, this compensatory response is always inadequate, limited by increasing hypoxia.

Etiology: Metabolic alkalosis is mainly caused by: (a) excessive GIT losses of H^+ ions with chlorides, e.g. loss of gastric acids in vomiting, or (b) bicarbonate excess, due to exogenous administration *or* increased renal reabsorption **(Table 7.14)**. Infantile hypertrophic pyloric stenosis (IHPS) is an important cause of hypochloremic metabolic alkalosis.

Metabolic alkalosis is also classified as *Chloride-responsive* when caused by gastrointestinal losses of H^+ and Cl^- ions, and *chloride-resistant* when due to renal causes.

TABLE 7.14: Causes of metabolic alkalosis

Increased loss of H^+ ions (hypochloremic/Chloride-responsive)
- Persistent vomiting
- Prolonged nasogastric aspiration
- Infantile hypertrophic pyloric stenosis
- Others: Cystic fibrosis, chloride losing diarrhea
- Severe dehydration: Diuretics

Increased reabsorption of HCO_3 (chloride-resistant)
- Congenital adrenal hyperplasia*
- Cushing syndrome*
- Hyperaldosteronism*
- Renovascular diseases*
- *Others:* Bartter syndrome, Gitelman syndrome

Exogenous intake of bicarbonates
- IV/oral bicarbonate therapy
- Milk–alkali syndrome
- Large blood transfusions (citrate blood)

*With hypertension

Clinically, metabolic alkalosis presents with:

- S*hallow respiration* due to compensatory respiratory depression, and
- *Signs of hypocalcemia,* e.g. neuromuscular irritability, perioral paresthesia and alkalotic tetany, as alkalosis promotes calcium-binding with albumin, leading to ionic hypocalcemia.

Diagnosis of *acute* metabolic alkalosis is indicated by: (a) higher pH >7.45 and (b) elevated HCO_3^- levels, while *partially compensated* state is associated with some rise in pCO_2 levels. For full compensation, 0.7 mm Hg rise in pCO_2 is expected for each mEq/L rise in HCO_3 levels, though it is rarely achieved.

Urinary chloride levels may be used to differentiate between chloride-responsive (<10 mEq/L) and chloride-resistant (> 20 mEq/L).

Management depends on the primary cause. Chloride-responsive metabolic alkalosis may be corrected with replenishment of contracted ECF with normal saline and added potassium chloride to bring pH <7.55 and biocarbonate levels < 40 mEq/L.

Chloride-resistant metabolic alkalosis is difficult to treat and treatment includes: (a) acetazolamide therapy to promote urinary bicarbonate excretion, (b) cautious administration of IV hydrochloric acid (0.5 x weight x desired fall in plasma bicarbonates) or oral ammonium chloride supplementation, and (c) dialysis in severe cases.

Respiratory acidosis: Primary event in respiratory acidosis is *CO_2 retention* during acute phase ($PaCO_2$ >45 mm Hg), subsequently compensated by increased tubular reabsorption of bicarbonates as well as increased excretion of H^+ ions (as ammonium and titratable acids). Some cases may have coexistent metabolic acidosis, due to secondary effects of hypoxia and consequent lactic acidosis.

Etiology: Respiratory acidosis is usually caused by *inadequate CO_2 excretion* due to poor alveolar ventilation or rarely due to increased CO_2 production, e.g. high fever or extensive burns **(Table 7.15)**.

Clinically, these cases present with:

- Signs of respiratory distress due to primary cause, and
- Signs of hypercapnia (*CO_2 narcosis*), e.g. headache, vomiting and altered sensorium, due to consequent cerebral vasodilatation and raised intracranial pressure.

Diagnosis of *acute* respiratory acidosis is indicated by lower pH <7.35, and elevated pCO_2, while *compensated* state is associated with rise in plasma HCO_3^- levels. While compensation begins in 6–12 hours, full compensation may take 3–5 days and needs HCO_3^- levels to rise by 3.5 mEq/L for each 10 mm Hg rise in pCO_2.

TABLE 7.15: Cause of respiratory acidosis

Loss of central respiratory drive
- CNS infections, tumors, etc.
- Drugs, e.g. narcotics, alcohol

Weakness of respiratory musculature
- Chronic neuromuscular disorders
- Acute respiratory muscle paralysis

Pulmonary diseases
- Restrictive lung diseases, e.g. severe scoliosis
- Extensive lung/airway disease

Miscellaneous (Increased CO_2 production)
- High fever or extensive burns

Management includes adequate ventilation/perfusion for treatment of primary cause and ventilator assistance, if necessary. *Alkali therapy should never be used till adequate ventilation* is established as it will worsen CO_2 retention ($HCO_3^- + H^+ > H_2CO_3 > H_2O + CO_2$) and may produce hyperosmolality and cardiac failure.

Respiratory alkalosis: Primary change in the respiratory alkalosis is *decreased pCO_2*, subsequently compensated by decreased tubular absorption of bicarbonates.

Etiology: Respiratory alkalosis is caused by *excessive CO_2 wash-out*, due to hyperventilation, e.g. psychogenic causes, high fever, mechanical overventilation or early salicylate poisoning.

Clinically, these cases present with:
- Hyperventilation due to primary cause, and
- Signs of hypocalcemia, e.g. neuromuscular irritability, peri-oral paresthesia and alkalotic tetany, as alkalosis promotes calcium-binding with albumin, leading to ionic hypocalcemia.

Diagnosis of *acute* respiratory alkalosis is indicated by higher pH >7.45, and reduced pCO_2, while *compensated* state is associated with drop in HCO_3^- levels. Full renal compensation is rarely achieved and requires ~5 mEq/L drop in HCO_3^- for each 10 mm Hg drop in pCO_2.

Management depends on primary cause and correction of ventilatory settings. Acidifying agents, e.g. ammonium chloride are not indicated.

7.7 PARENTERAL FLUID THERAPY

Parenteral fluid therapy is the essential component of critical child care, required not only to correct dehydration but also to provide maintenance fluid/electrolyte requirements in children who cannot be given oral fluids due to critical sickness, surgery, persistent vomiting or any other reason.

7.7.1 PRINCIPLES OF FLUID THERAPY

Some general principles for parenteral fluid therapy are as follows, while therapy in specific circumstances is discussed later.

Indications: Parenteral fluid therapy is mainly indicated in children with:
- Severe dehydration, hypotension or shock, when immediate volume replacement is life-saving,
- Persistent vomiting, with poor tolerance to oral feeds.
- Critical illnesses, e.g. coma, seizures, respiratory distress, etc. when oral feeding is not possible or contraindicated.
- Pre-and post-surgery fluid therapy.
- Systemic disorders, e.g. renal failure or CCF, which require fine-tuning of fluid and electrolyte intake.

Routes: Parenteral fluid therapy requires secure IV access with a peripheral venous line. In emergency, intraosseous infusion may be used temporarily for rapid fluid correction till IV access is secured (Ch 32.3).

Fluid volume requirements of each child vary according to their age, body weight, presence/severity of dehydration and primary disease, though approximate requirements may be calculated as ***sum-total*** of following:
- ***Maintenance requirements,*** essential for basal metabolism as well as to replenish normal fluid losses via urine, stools and insensible means, e.g. lungs and skin. Though dependent on metabolic rate (1 ml water for each caloric expenditure), maintenance fluid and electrolyte requirements may be practically calculated by actual body weight as per *holiday and segar* formula **(Table 7.16)**. In smaller children (6–15 kg) maintenance volume must preferably be calculated with body surface area as 1400–1500 ml/m^2.

  Calculated fluid requirements must be *increased* by 20–30% in conditions with higher insensible losses, e.g. fever, hyperventilation, warmer care, etc.; and *decreased* by 20–30% in cases with oliguria or less insensible losses, e.g. hypothermia.
- ***Deficit requirements*** depend on the severity and type of dehydration (iso-/hypo-/hyper-natremic), though generally calculated as 10 ml/kg for each percent of expected weight loss due to dehydration, i.e. ~5%, 10% and 15% for mild/moderate/severe dehydration in infants and ~3%, 6% and 9% respectively in older children.

  For example, if a 4 years child weighs 15 kg and has moderate dehydration, his/her weight loss is expected to be 6% and fluid deficit is expected to be 15 × 6 × 10 = 900 ml. **Table 7.16** gives fluid and electrolyte requirements in dehydration of variable severity. Electrolyte requirements have been calculated assuming 60:40 fluid loss from ECF and ICF, as common in isotonic dehydration.
- ***Concomitant fluid and electrolyte losses*** in stools, gastric aspirate, etc. need periodic assessment

TABLE 7.16: Fluid requirements in normal children

A. For maintenance:
Water:
(BW<10 kg) : 100 ml/kg
(BW 10–20 kg) : 1000 ml + 50 ml/kg for wt >10 kg
(BW>20 kg) : 1500 ml + 20 ml/kg for wt >20 kg (max 2400 ml)

B. For deficit:
Water (10 ml/kg of expected wt loss* due to dehydration)
Mild dehydration : 30 ml/kg (50 ml/kg in infants)
Moderate dehydration : 60 ml/kg (100 ml/kg in infants)
Severe dehydration : 90 ml/kg (150 ml/kg in infants)

C. Concomitant losses

*Expected wt loss is ~ 3% in mild, ~6% in moderate and ~9% in severe dehydration; (higher—~ 5%, 10%, 15%, in infants).

TABLE 7.17: Composition of external abnormal fluid losses

Fluid loss	*Sodium (mEq/L)*	*Potassium (mEq/L)*	*Chloride (mEq/L)*
Diarrheal stools	60	25	15
Vomiting/gastric aspirate	60	10	90
Ileostomy loss	130	10	115
Burns*	140	5	110

* and 3–5 gm/dl of protein

and replacement with suitable fluids. Electrolyte requirements for this replacement depend on composition of body fluid/s, which are being lost **(Table 7.17)**. About 10 ml/kg is considered as the concurrent loss for each large watery stool, and ~2 ml/kg for each vomiting.

Choice of parenteral fluids depends on the estimated electrolyte requirements, need for nutrition (dextrose *vs* non-dextrose fluids) and primary disease. Various IV fluids with different electrolyte/dextrose concentrations are available commercially *or* can be prepared in hospital pharmacy under strict aseptic precautions **(Table 7.18)**.

- *For maintenance therapy*, isotonic fluids, e.g. normal saline in DW 5% are recommended at present in all children except in neonates <28 days or those with cardiac/liver/renal disease, burns, malignancies or undergoing neurosurgery.

  Earlier recommendations of maintenance fluid therapy with hypotonic N/2 or N/5 saline in Dextrose 5% are no longer valid due to risk of hyponatremia.
- *For deficit correction,* choice of fluid varies according to the route of fluid-loss, e.g. stools, gastric aspirate, etc. *and* laboratory electrolyte values. In general, *Ringer lactate (Na^+ 131 mEq/L)* is preferred for this purpose in usual cases of diarrhea induced dehydration, with additional advantage of containing lactate that is converted into bicarbonate and prevents metabolic acidosis.

Monitoring: All cases on IV fluids should be monitored for changing needs of fluids/electrolytes, possibility of switch over to oral rehydration therapy and complications, e.g. overhydration, electrolyte disturbances, infection, thrombophlebitis or local extravasation.

TABLE 7.18: Electrolytes in common IV fluids

	Na^+	*K^+*	*Cl^-*	*Glucose*
Dextrose 5% (D5)	–	–	–	50
Dextrose 10% (D10)	–	–	–	100
Normal saline (NS)	154	–	154	–
Dextrose saline (DS)	154	–	154	50
N/2 saline in D5	77	–	77	50
N/5 saline in D5	30	–	30	40
Ringer lactate*	131	5	111	50
Isolyte P	25	20	22	50

Na, K and Cl values in mEq/L, glucose in gm/L
*also contains lactate 29 mEq, which is *in vivo* metabolized into bicarbonate to prevent acidosis

7.7.2 FLUID THERAPY IN CLINICAL PRACTICE

Fluid therapy in children requires precise calculations of fluid/electrolyte requirements, as the volume, composition and rate of administration for parenteral fluids varies with indication, circulatory status and laboratory values of electrolytes. Important determinants for initial fluid therapy include:

- Whether patient is dehydrated *or* requires only maintenance therapy?
- If dehydrated, what is its severity and type?
- What is the source of fluid loss?
- Whether and which electrolyte abnormalities are present?
- What is the state of renal and cardiac functions?

Standard fluid therapy is based on the type and severity of the dehydration as follows:

Isonatremic dehydration, the commonest type of dehydration, is characterized by fluid loss from both ECF and ICF in a ratio of ~60:40. More acute is the dehydration, greater is the proportion of ECF losses.

Parenteral fluid therapy in these cases aims for: (a) rapid correction of ECF-deficit and restoration of plasma volume in first few hours followed by, (b) slower correction of remaining deficit *plus* infusion of maintenance and concomitantly lost fluids, till oral rehydration (ORS) is possible. Though different protocols are followed in different institutions, a simple one is as follows:

Step I. Infuse 20 ml/kg of *Ringer lactate* or *normal saline* as bolus over 20 minutes to restore the intravascular volume, which may be repeated in cases of severe dehydration or shock. However, maximum rate of infusion should never exceed 30 ml/kg/hr to avoid volume overload. *Potassium is usually withheld in this*

phase. By the end of this phase, child is expected to be circulatory stable.

Step II. Calculate 24-hour fluid requirements as s*um total of maintenance + deficit needs*, as discussed earlier.

Step III. Subtract the volume already infused in step I from this 24-hr fluid requirement calculated in step II and infuse remaining volume over next 24 hours using Isotonic saline in DW 5%. Add 20 mEq/L of potassium in IV fluids after the urine output is established. In moderate to severe dehydration with fluid losses exceeding 5%, remaining volume should be infused more slowly over 48–72 hours, if switch-over to ORS is not possible.

Concomitant losses via stools, vomitus or gastric aspirate, etc. must be added to the calculated volume. IV $NaHCO_3$ (2–3 mEq/kg) may be added, if acidosis is suspected clinically but biochemical estimation is not possible.

Step IV. Gradual switch over to ORS, as soon oral feeds are acceptable.

Table 7.19 provides a representative example for calculation of fluid requirements in a one-year old child, weighing 10 kg with severe isotonic dehydration.

Hyponatremic dehydration: While ECF losses are relatively higher in hyponatremic dehydration due to fluid movements from ECF to ICF, fluid therapy is similar to that for isotonic dehydration, *except* that calculated sodium deficit should be gradually corrected over first 12–24 hours, using high-sodium IV fluids, e.g. Ringer lactate or N/2 dextrose saline. S*erum sodium correction should never exceed 10 mEq/L/24 hours.* Only *symptomatic* hyponatremia with seizures is treated with 3% NaCl infusion at the rate of 1–2 ml/min (max 12 ml/kg) till seizures are controlled.

Hypernatremic dehydration: As ECF losses are comparatively less in hypernatremic dehydration due to osmotic withdrawal of fluids from ICF, only 3/4th fluid correction is required in these cases, using low-sodium fluids, (e.g. N/2 dextrose saline). Sodium-free fluids should never be used in these cases due to risk of rapid drop in ECF sodium, osmotic fluid movement from ECF to ICF and cerebral edema. In any case, s*erum sodium fall should not exceed 8–12 mEq/L/24 hours.*

TABLE 7.19: Correction of severe dehydration in 10 kg child

Assumptions:
- Age: 1 year; weight: 10 kg
- Severe dehydration
- Isotonic dehydration

Total fluid requirements:
For maintenance : 100 x 10 = 1000 ml +
For deficit : 150 x 10 = 1500 ml
Total 24 hour : 2500 ml

Schedule of infusion:
- IV bolus (20 min) : 200 ml[1] as Ringer lactate/NS, no potassium
- Remaining fluids : 2500–200 ml = 2300 ml
- Next 24–48 hrs (slow IV)* : 2300 ml as NS with DW 5%, with potassium 20 mEq/L
- Add concomitant losses in later half of infusion

[1] 20 ml/kg * Switchover to ORS as soon as possible.

7.7.3 FLUID THERAPY IN SPECIFIC SITUATIONS

General guidelines for fluid therapy in specific situations are discussed as follows:

Fluid therapy in diarrhea may be considered as prototype of fluid and electrolyte therapy in pediatric practice, as diarrhea is the commonest cause of dehydration in children. Two methods of fluid therapy in diarrhea are in vogue—*Standard fluid therapy,* discussed earlier, and *rapid rehydration method*-later being more simple, practical and adequate in most cases.

Traditional fluid therapy in diarrhea, requires complex calculation, which is neither practical nor necessary in most cases as: (a) prompt restoration of ECF will itself facilitate physiological corrective mechanisms, and (b) most cases tolerate ORS soon after initial correction and do not need prolonged IV therapy.

At the peripheral community level with limited resources, recent studies have proved safety and efficacy of simpler *rapid rehydration* in moderate to severe dehydration (WHO plan C, Ch 14.10).

This strategy involves a *rapid infusion of Ringer lactate 30 ml/kg during first 30 min (1 hour in infants), followed by N/5 Dextrose saline ~ 70 ml/kg in next 2½ hours (5 hours in infants) and switch over to ORS, as soon as possible.*

Fluid therapy in gastric losses: Loss of gastric juices is the major cause of dehydration in cases with persistent vomiting, e.g. congenital hypertrophic pyloric stenosis *or in* children requiring continuous nasogastric aspiration, e.g. intestinal obstruction. As gastric fluid contains relatively less sodium and more chlorides and potassium, *hypokalemia and hypochloremic alkalosis* are most important electrolyte disturbances in these cases. Fluid therapy in them is similar to traditional fluid therapy, except that:
- N/2 dextrose saline may be preferred for deficit correction in these cases.
- Potassium replacement should begin as soon as the child has passed urine.
- Hypochloremic alkalosis may be corrected by high-chloride IV fluids, e.g. isolyte G; or NH_4Cl supplements after correction of hypokalemia.

Fluid therapy in critically sick children: Children with critical illnesses, e.g. acute neurological disorders (meningoencephalitis, head injury, hypoxic-ischemic injury, etc.), acute pulmonary disorders (pneumonia, asthma, respiratory failure) or those on ventilators, are likely to have fluid retention due to SIADH. A simple and reliable indicator of this problem is the presence of hyponatremia despite concentrated urine with urinary

sodium exceeding > 20 mEq/L. Important aspects of fluid therapy in these cases after initial fluid/electrolyte corrections, include:

- *Restriction of maintenance fluid* volume to 2/3rd of calculated requirements; and
- *Correction of hyponatremia*: No correction is necessary for asymptomatic hyponatremia as fluid restriction itself allows a gradual recovery of serum sodium levels. However, cases with symptomatic or severe hyponatremia require slow correction with relatively hypertonic fluids, e.g. Ringer lactate, along with a diuretic, e.g. furosemide to enhance free water excretion. Rapid correction with 3% NaCl infusion (1 ml/min to max 12 ml/kg) is indicated only in cases with hyponatremic seizures.

Fluid therapy in surgery: Most common error during peri-operative fluid therapy is the overhydration, specially with plain dextrose fluids without electrolytes.

- ***Pre-operative fluid therapy*** in children for elective surgery aims to provide adequate carbohydrates for sustenance and maintenance requirements of fluids and electrolytes, which may be met with *N/5 saline in dextrose 10%*. However, children for emergency surgery need pre-operative fluid and electrolyte correction according to primary disease and laboratory investigations.
- ***During surgery***, maintenance requirements should be given as isotonic normal saline *or* dextrose saline (without potassium), while surgical losses may be replaced with blood or plasma. As hyperkalemia is common during or immediately after surgery due to release of intracellular potassium after tissue trauma, potassium supplements should be avoided in this period.
- ***Post-operatively***, SIADH is common and maintenance fluids should be restricted to 2/3rd of usual requirements during first 24 hours. Ringer lactate is the preferred fluid during this period. Potassium supplementation is indicated only after first 24 hours, unless warranted by laboratory reports.

Fluid therapy in malignancy: These cases, specially those beginning with induction therapy, are at risk of tumor-lysis syndrome with hyperkalemia, hyperphosphatemia, hypocalcemia and hyperuricemia. Fluid therapy in these children should include additional maintenance fluids (usually 2–2.5 times) to ensure a urine output of 4ml/kg/hour, using *potassium-free fluids*.

CHAPTER

8

Immunological Disorders

Mukesh Agrawal

Initial host-defense mechanisms against invasion by a pathogen include: (a) *anatomical* skin and mucosal integrity, (b) *physiological* milieu of the tissues, e.g. acidic gastric pH, (c) *mechanical* clearance of cell debris, e.g. mucociliary movements, and (d) *normal microbial colonizing flora* that competitively oppose invading pathogens. Once these barriers are breached, second line of defense is presented by *immunological system*, which is a complex interplay of various components, acting in unison to eliminate the invading pathogen *or* even an aberrant host-antigen, e.g. tumor cells.

8.1 BASIC CONSIDERATIONS

The hallmark of immune defense is recognition of a foreign or non-self antigen, as well as tolerance of own tissue antigen or self-antigen. Some basic concepts in immunology are as follows:

Antigen: The term *antigen* refers to a molecule recognizable by immunological cells, which have specific binding sites (receptors) for these molecules. Only a small portion of antigen (*epitope*), e.g. cell-wall component or DNA-nucleotide sequence, etc. is recognized by antigen-specific receptors, though complex antigens have many such epitopes. All antigens are not equally immunogenic. Proteins antigens are more immunogenic than carbohydrates, e.g. lipopolysaccharides (*haptens*). However, immunogenicity of haptens may be enhanced by conjugating them with protein vehicles, e.g. tetanus toxoid, as done in conjugate vaccines.

All cells have antigens, including viruses, bacteria, etc. and even the host's own cells. However, tolerance to self-antigens develops during early fetal life by selective elimination of those T-cells (*apoptosis*), which do not recognize self-antigens, i.e. major histocompatibility complex (MHC) antigens.

Major histocompatibility complex (MHC) is the surface antigen (glycoprotein), present on most human cells, including leukocytes (*human leukocyte antigen* or HLA). These antigens may be broadly divided into two types: *MHC class I molecules* (HLA-A, B, C) present on most the nucleated body cells and platelets; and *MHC class II molecules* (HLA-DP, DQ, DR), present on macrophages, dendritic cells and B cells.

HLA type of a person is determined by a cluster of genetic loci on short arm of 6th chromosome and denoted as HLA-B27, HLA-D8, etc. Major significance of HLA antigens lies in: (a) tissue typing before transplants to select suitable donor, and (b) their association with many autoimmune disorders.

Types of immunity: Immune-defense mechanisms may be broadly divided into:

- ***Innate immunity***, which is *antigen non-specific* and attempts to eliminate any invading pathogens before the development of antigen-specific adaptive immunity. It is provided by: (a) physical, chemical and mechanical barriers, (b) inflammatory response to bring *cellular elements* at the site of invasion, e.g. phagocytes and natural killer cells, to engulf and kill invading organisms, and (c) release of *chemical mediators,* e.g. cytokines and chemokines.

  Innate immune system also triggers development of adaptive immunity by processing the pathogen by *antigen-presenting cells,* i.e. macrophages and dendritic cells, and transport them to T-lymphocytes, largely present in lymph nodes.
- ***Adaptive (Acquired) immunity*** is *antigen-specific*, develops over few days/weeks after the first exposure and persists throughout the life due to development of memory B-cells, though not necessarily in protective range. Mediated by T cells ***(cell-mediated immunity)*** and/or B cell generated immunoglobulins ***(humoral immunity)*** adaptive immunity is responsible for clearance of primary infection and prevention of disease during subsequent exposures. Adaptive immunity may be induced by natural exposure (infection) or artificial exposure (vaccine).

Components of Immune System

As stated earlier, immunological mechanisms are mediated by various cellular and humoral components of immune system, as follows:

- *Antigen non-specific* components, e.g. phagocytes, dendritic cells, natural killer cells, complements, etc.
- *Antigen-specific* components, e.g. T-cells and B-cells (immunoglobulins).

There is considerable interdependence between these immunological mediators, which act in coordinated manner to induce adequate immune response.

I. Phagocytic system is the first line of immunological defense to: (a) engulf and digest foreign antigens, and (b) process them for presentation to antigen-specific cells.

It is mediated by two different cell types: (i) *circulatory phagocytes,* i.e. neutrophils and (ii) *tissue phagocytes,* i.e. macrophages, which are derived from monocytes and populate tissues like lung, liver, kidney, spleen, brain and lymph nodes. Neutrophilic phagocytes mainly act against pyogenic bacteria, while macrophages are predominantly involved in killing of intracellular organisms, e.g. mycobacteria, toxoplasma, etc. and inducing T-cell mediated immune response.

Phagocytosis of a foreign element involves a cascade of activity, including: (a) *recognition* of the invader as a non-self-antigen, (b) *chemotaxis*, i.e. recruitment of more phagocytic cells, mobilized from other sites as well as bone marrow, (c) *phagocytosis*, i.e. attachment and entrapment of antigen within phagocytes by a process of vacuolization, and (d) *microbiocidal activity* within the phagocytes to eliminate entrapped pathogens by various oxidative, hydrolytic or *defensins* mediated systems.

Phagocytosis is facilitated by: (a) specific antibodies on phagocytes, which act as *ligands* to bind them with pathogen, and (b) *opsonins* in serum-products of complement system, which neutralize anti-phagocytic factors on bacterial cells.

II. Dendritic cells are *antigen-presenting cells* widely distributed in skin, lungs and other tissues, which primarily act against *extracellular antigen*, e.g. microbial cell-wall components, dead host-cells, etc. These cells recognize a foreign antigen, collect a sample by endocytosis to process it into smaller peptide fragments and then migrate to regional lymph nodes to present them to T and B cells. Thus, these cells may be considered as *antigen-priming cells* for induction of acquired immunity.

III. Natural killer (NK) cells are lymphocytes *without T-cell receptors*, which primarily act against *intracellular antigens*, e.g. virus-infected cells and malignant cells, i.e. aberrant host cells and killing them. Recognition of intracellular antigen by these cells depends on: (a) antibody-coating on virus-infected cells, and (b) suppression of MHC molecules on aberrant/malignant host cells to render them as foreign antigens. Intracellular killing by NK cells is a complex process involving injection of target cells with cytotoxic granzymes.

IV. Complement system consists of many non-specific, heat-labile interacting protein components, which contribute to ~10% of total plasma globulin fraction.

These components are numbered (C_1, C_2 …, etc.) in order of the discovery and not in sequence of their activation. Complements and their by-products act as a principle mediator of inflammatory response, after nonspecific *or* specific antigenic challenge. Various components of complement system are activated in sequentially by two different pathways:

a. ***Classic pathway,*** which is primarily stimulated by immunological mechanisms, i.e. fixation of C_1 to Fc portion of antibody (antigen-specific) or C-reactive proteins (antigen-non-specific).
b. ***Alternative or properdin pathway,*** which is mainly stimulated by non-immunological stimuli, e.g. endotoxins, leukocyte degradation products, etc. *Or* after activation of a component of the classic pathway C_{3b}.

Both pathways converge at the level of C_3 activation, followed by a common sequence to generate highly active complement components, e.g. opsonins (C_{3b}), chemotactic factors (C_{5a}), mast-cell activators, i.e. anaphylatoxins (C_{3a}, C_{5a}), cell lysis activity (membrane attack complex). C_3 is most abundant and crucial component of complement system.

Complement system plays a vital role in both innate and adaptive immunity with: (a) neutralization of viruses, (b) opsonization of bacteria, (c) deactivation of endotoxins, (d) lysis of virus-infected or malignant cells, and (e) regulation of immune response by induction of granulocytosis or suppression of excessive antibody response.

Controlling mechanisms to prevent excess consumption of complement activity involve simultaneous activation of various complement inhibitors during complement cascade, e.g. C_1 inhibitor and others.

V. Cytokines *or* chemokines are glycoproteins, synthesized and released by immunologically activated lymphocytes (lymphokines), macrophages, monocytes and vascular endothelium.

Cytokines predominantly act as *immune messengers* to regulate immune response, i.e. to localize, limit or facilitate it, depending on the type of cytokines produced. Important cytokines are: *Interleukins* ($IL_{1–18}$), *interferons* (IFN-β, γ), *tumor necrosis factors* (TNF-α), *colony stimulating factors* (GM-CSF, G-CSF, M-CSF) and *erythropoietin*, etc.

Cytokines also participate in regulation of hematopoiesis and inflammation. Most of the cytokines act as both—facilitator *or* inhibitor of immune response, depending on the target cells.

VI. Acute phase proteins may be: (a) *pro-inflammatory*, e.g. C-reactive protein, which assists in recognition of pathogen/damaged cell, complement activation and cytokine production, or (b) *anti-inflammatory*, e.g. proteinase inhibitors or coagulation proteins, which help in wound healing.

VII. T lymphocytes may be considered as the *orchestra director* of acquired immunity, which not only mediate cellular immunity but also activate B-cell for immunoglobulin production.

Cell-mediated immunity (CMI) is mainly involved in: (a) immunity against intracellular organisms (viruses, mycobacteria), fungi and protozoa, (b) immune surveillance of cancer cells, and (c) graft-rejection or graft *versus* host disease.

T lymphocytes develop from stem cells in bone marrow, but migrate and mature in thymus. Thymic maturation involves three important changes: (a) *cluster differentiation*, i.e. switch-on of various surface markers-termed CD markers; (b) *positive selection*, i.e. development of T cells which recognize self-MHC antigens, and (c) *negative selection*, i.e. elimination of T cells which do not recognize self-antigens and may be self-destructive. Subsequently, these cells enter circulation and re-populate lymphoid organs, e.g. lymph nodes, spleen and Peyer's patches. Depending on their functions and CD markers, T cells may be divided into 2 major groups:

- ***T helper-inducer cells*** (CD_4 cells), which induce antibody production by B cells and regulate immune response by cytokines production. These cells are further divided into: *Th1 cells,* which are important for macrophage activation and cell-mediated immunity; and *Th2 cells,* which help in activation and differentiation of B cells and down-regulation of immune response. Th1 cells predominantly help in elimination of intracellular pathogens, e.g. viruses, while Th2 cells are more important for elimination of extracellular pathogens, e.g. helminths. *Excess Th1 or Th2 activity is a major contributing factor for autoimmunity and allergy, respectively.*
- ***Cytotoxic-suppressor cells*** (CD_8 cells), which are responsible for killing of virus-infected cells *or* tumor cells, as well as suppression of immune response.

VIII. B-lymphocytes are mediators of acquired humoral immunity, by production of antigen-specific or non-specific *immunoglobulins*.

Like T-cells, B-cells also develop from stem-cells in bone marrow. However unlike them, human B-cells mature in bone marrow itself (bursa of fabricius in birds), before circulating and populating lymphoid follicles in spleen, liver, tonsils and Peyer's patches. B-cells comprise 5–15% of total circulating lymphocytes. On antigenic stimulus, these cells differentiate into *plasma cells*, to produce various immunoglobulins.

B-cells are of two types: B_1 (CD_5) cells, which produce non-specific IgM immunoglobulins against variety of antigens; and B_2 cells which produce specific IgM, IgE and IgA antibodies in response to specific antigenic challenge.

IX. Immunoglobulins (Ig) or antibodies are serum proteins, produced by B-cells, which: (a) inactivate, agglutinate or opsonise antigens for phagocytosis, and (b) activate complement system for cytolysis. These immunoglobulins are present on the surface of B-cells (*surface immunoglobulins*) or secreted in extracellular medium (*secretory immunoglobulins*). Depending on their properties and role in immune system, immunoglobulins may be divided into 5 types:

- ***IgM*** constitutes ~10% of serum immunoglobulins and mainly remains within the circulatory compartment. IgM antibodies are the first class of immunoglobulins secreted after antigenic challenge, though levels decline soon after the infection is controlled within 2–3 months. Thus, *raised IgM levels indicate acute infection. IgM does not cross the placenta and high IgM levels in newborn indicate true fetal infection.*
- ***IgG,*** most abundant serum immunoglobulin (~70%), is produced later than IgM after primary antigenic exposure and persist longer for many months or years but in declining titers. Thus, *IgG levels may be high due to past infection and not necessarily indicate acute infection.* However, on a subsequent challenge with same antigen, IgG response is anamnestic, profound and persistent.

While predominantly present in serum, IgG diffuse well in tissues as well as *cross the placenta t*o transfer the maternal immunity to baby. Hence, *raised IgG titers in fetus or newborn may be due to maternal transmission and not necessarily indicate fetal infection.*

Four major subclasses of IgG are IgG_1, IgG_2, IgG_3 and IgG_{4C}. Of these, IgG_2 is unique, as it also responds to polysaccharide antigens.

- ***IgA*** contributes to ~15–20% of serum immunoglobulins (*serum IgA*), as well as also present in various body secretions (*secretory IgA*), e.g. nasobronchial or gut secretions, saliva, lacrimal fluid and colostrums (protective antibody in human milk).

  Secretory IgA is predominantly responsible for *local immunity*, i.e. clearance of antigen from mucosal sites. IgA does not activate complement system or provoke inflammatory response.
- ***IgE*** is present in miniscule amounts in serum but acts as principal mediator of immediate hypersensitivity (allergy) as well as also has some role in immunity against helminths.

  Two types of IgE antibodies are – *non-specific IgE*, present in serum/tissues of normal individuals which appear to defend against parasitic invasion; and specific or *reaginic* antibodies, synthesized on exposure to a specific allergen.
- ***IgD*** accounts for <1% of serum immunoglobulins with indefinite role, probably as an antigen receptor site on circulating B-cells.

Physiology of Adaptive Immune Response

Immune responses are initiated by the exposure to an antigen that carries a *danger signal*, e.g. bacterial products, endotoxin, viral DNA *or* tissue necrosis. Important steps in development of immune responses **(Fig. 8.1)** are as follows:

- **Innate immunity** directly attempts to eliminate invading pathogen by itself using: (a) physical, chemical and mechanical barriers, (b) inflammatory response to bring cellular elements, e.g. phagocytes and natural killer cells at the site of invasion to engulf and kill invading organisms as well as macrophages and dendritic cells (antigen-processing cells) to process the antigen/s of pathogens, and (c) release of chemical mediators, e.g. cytokines and chemokines.
- ***Antigen-processing***: Innate immunity also triggers development of adaptive immunity using these *antigen presenting cells,* to process the pathogens and express their antigen/s on the surface for recognition by immune cells. Processed antigens are transported to T lymphocytes, largely present in lymph nodes.
- **T-cell dependent response** is triggered by processed antigens and induce: (a) direct killing of virus-infected or tumor cells by cytotoxic or NK cells, (b) further activation of macrophages and cytotoxic cells by Th_1 cells, (c) differentiation of antigen-specific B-cells by T-helper or Th_2 cells, and (d) secretion of various cytokines, which act as immune messenger or regulator.

  Activate T-helper cells also stimulate B-cell differentiation to develop as plasma cells and produce specific immunoglobulins and memory B cells. Memory cells directly recognize the offending agent on re-exposure for accelerated immunoglobulin production.
- ***T-cell independent response*** is usually seen against organisms covered by a polysaccharide capsule, (e.g. *H. influenza* B, pneumococci, meningococci). This capsule resists ingestion of organism by phagocytes, preventing expression of antigen and T-cell activation. In such cases, naïve B cells themselves recognize the pathogen and get activated to produce antibodies. Antibodies produced against T-cell independent responses are largely of IgM class, and no memory cells develop for anamnestic response on re-exposure.

Immunological Disorders

The term immunological disorders includes three distinct abnormalities, discussed elsewhere:

a. Immunodeficiency states, i.e. *inability to recognize or clear foreign antigens* leading to recurrent or opportunistic infections (Ch 8.2).

b. Hypersensitivity reactions, i.e. *inappropriate or disproportionate immune response*, which may be predominantly IGE mediated, IgM/IgG mediated or cell-mediated (Ch 8.4).

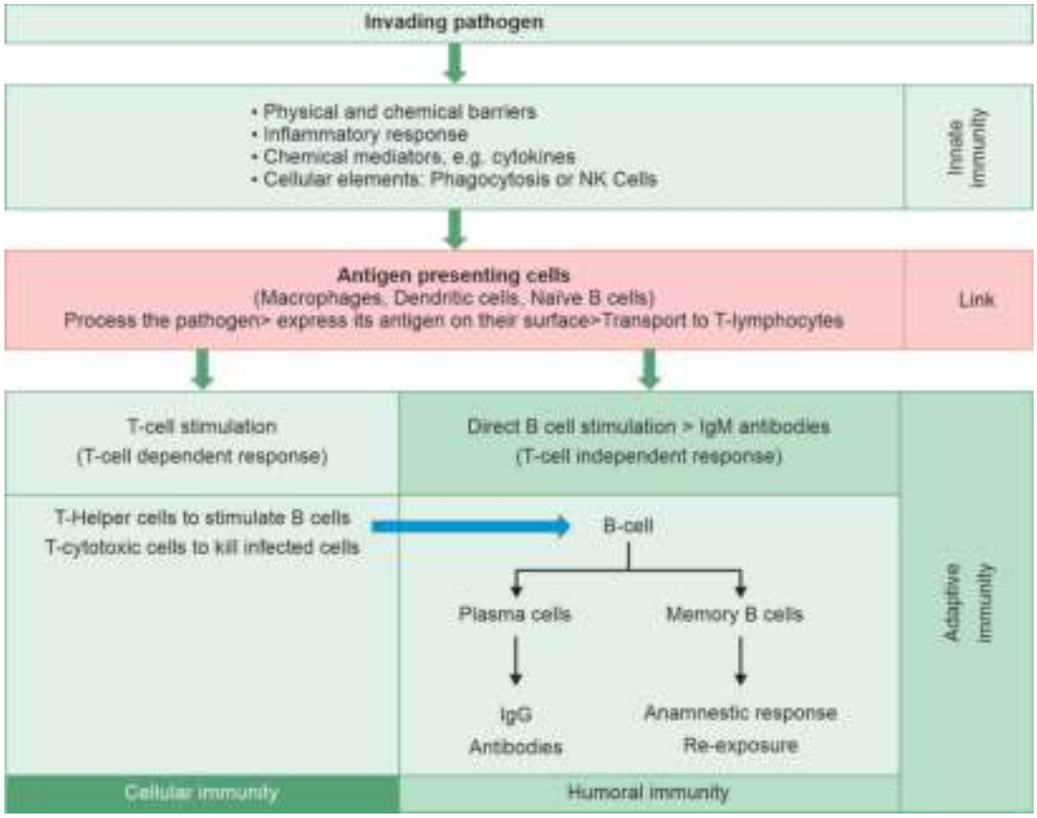

Fig. 8.1: Immunological defense mechanisms.

TABLE 8.1: Common immunodeficiency disorders/states in children

Primary or inherited	*Secondary or acquired*
A. Phagocytic defects	***A. Developmental***
– Cyclic neutropenia	– Prematurity
– Chronic granulomatous disease of childhood	– Newborns (? complement deficiency)
– Chediak-Higashi syndrome	***B. Nutritional***
– Lazy leukocyte syndrome	– Protein-energy malnutrition
– Hyper-IgE syndrome	– Zinc deficiency
– Enzyme defects (G6PD, myeloperoxidase)	***C. Infections***
B. Primary T cell defects	– HIV/AIDS
– DiGeorge syndrome	– *Others:* Measles, pertussis
– Chronic mucocutaneous candidiasis	***D. Impaired splenic function***
– Hyper-IgM syndrome	– Asplenia
C. Primary B cell defects	– Splenectomy
– Transient hypogammaglobulinemia	– *Dysfunction:* Sickle cell disease
– X-linked (Bruton) agammaglobulinemia	***E. Iatrogenic***
– Common variable immunodeficiency	– *Drugs:* Steroids, cytotoxic agents
– Selective IgA/IgG subclass deficiency	– Irradiation
D. Combined B and T cell defects	– Organ transplantation
– Severe combined immunodeficiency (SCID)	***F. Miscellaneous:***
– Wiskott-Aldrich syndrome	– *Protein-loss:* Nephrotic syndrome, burns
E. Complement defects (rarely primary)	– *Metabolic:* Diabetes mellitus, uremia
– Hereditary angioedema	

c. Autoimmune disorders, i.e. *inability to recognize self-antigen* that triggers the immune reactions against own tissues, e.g. rheumatoid disorders (Ch 24).

8.2 IMMUNODEFICIENCY DISORDERS

Increased susceptibility to usual or unusual infections (opportunistic infections) is the clinical hallmark of immunodeficiency disorders. These disorders may involve qualitative *or* quantitative deficiency of any one *or* more component of the immune system **(Table 8.1)**. For the sake of discussion, immunodeficiency disorders may be broadly divided into two categories:

a. Primary immunodeficiency disorders (PID) are rare genetic defects with overall frequency of ~1/10,000 children, including B-cell defects (50%), T-cell defects (30%), phagocytic disorders (18%) and complement disorders (<2%). Family history of similar illness or consanguinity is often present in these cases. Till date over 400 PIDs are known and the list is expanding. **Table 8.2** lists warning signs for suspecting PIDs in children.

b. Secondary immunodeficiency states are relatively more common and usually involve more than one component of immune system. *Viral infections*, e.g. measles, *malnutrition* and *steroid therapy* are three important causes of transient immunodeficiency, while more severe and persistent defects are seen in HIV/AIDS, splenic dysfunction and malignancies.

Common congenital immunodeficiency disorders are discussed here, while acquired defects have been discussed in relevant chapters on primary diseases.

TABLE 8.2: Warning Signs for Primary immunodeficiency disorders (PID) in children

- Four or more new ear infections within one year
- Two or more serious sinus infections within one year
- Two or more months on antibiotics with little effect
- Two or more pneumonias within one year
- Failure of an infant to gain weight or grow normally
- Recurrent, deep skin or organ abscesses
- Persistent thrush in mouth or fungal infection on skin
- Two or more deep-seated infections including septicemia
- Family history of primary immunodeficiency (PID)

I. Phagocytic Disorders

Phagocytic disorders include *quantitative* phagocytic cell deficiency, e.g. neutropenia or *qualitative* functional defects of these cells.

Clinically, these defects usually present with recurrent mucus membrane infections, e.g. gingivitis, *or* superficial/deep abscesses due to pyogenic or gram-ve organisms. *Absence of pus formation despite severe infection is a hallmark of leukocyte migration defect.* Other indicators of phagocytic disorders are *poor wound healing* and *delayed separation of umbilical cord* in newborn.

Diagnosis of phagocytic defects depends on: (a) abnormal neutrophil count and morphology, (b) nitroblue tetrazolium test for intracellular phagocytic capacity, and (c) *in vitro* tests for neutrophil functions, e.g. chemotaxis, phagocytosis and microbiocidal activity.

Persistent neutrophilia or persistent neutropenia are indicative of leukocyte adhesion deficiency-I or severe congenital neutropenia-II important phagocytic defects, respectively.

Management of these disorders include: (a) Long-term antibiotic prophylaxis or recombinant interferon (IFN-γ) therapy, (b) colony stimulating factors (G-CSF, GM-CSF) in leukopenic states, and (c) stem cell transplantation in selected cases.

Some important inherited phagocytic disorders are as follows:

Chronic granulomatous disease of childhood (CGDC) is an X-linked or autosomal recessive disorder, characterized by defective intracellular killing of microbes within phagocytes due to abnormal oxidative metabolic responses. Most cases present in early infancy with: (a) serious, recurrent or persistent infections, (b) perioral/anal eczema, and (c) hepatosplenomegaly.

Chédiak-Higashi syndrome is an autosomal recessive disorder of defective chemotaxis, degranulation and intracellular killing. Apart from recurrent infections in early childhood, these cases are associated with: (a) oculocutaneous albinism, (b) neurological abnormalities, e.g. mental retardation, pyramidal/cerebellar signs, peripheral neuropathy, etc. and (c) neutrophils with *giant cytoplasmic granules.*

Cyclic neutropenia is an autosomal dominant disorder, characterized by *cyclical fluctuations in peripheral neutrophil counts* between normal and neutropenic values (<500/mm^3) with mean oscillatory period of 21 days. During neutropenic phase, child may suffer from mild problems, e.g. oral ulcers, pharyngitis, lymphadenopathy, etc. *or* more serious infections, e.g. pneumonia. Cycles become less noticeable with advancing age, changing into chronic neutropenia.

Hyper IgE syndrome (Job's syndrome) is a rare disorder of chemotaxis and opsonization, characterized by elevated IgE levels (>2000 mg/dl), eosinophilia, recurrent staphylococcal abscesses of skin/deeper tissues and atopic dermatitis.

Lazy leukocyte syndrome is a rare disorder of chemotaxis and neutrophil migration from bone marrow, despite adequate bone marrow reserves.

II. Complement Disorders

Complement disorders are rarely congenital, seen more commonly as acquired defects due to:

- *Deficient production*, e.g. in newborns, PEM and chronic liver diseases,
- *Defective function*, e.g. in sickle cell disease,
- *Increased consumption or loss*, e.g. in septicemia, burns, SLE and nephrotic syndrome.

Clinically, these cases present with recurrent pyogenic or neisserial infections, frequently associated with immune complex disorders (lupus-like illness) and vasculitis syndromes.

Diagnosis is established by assessing CH_{50} activity with control or direct C_3–C_4 immunoassays. Genetic workup is needed to identify inherited complement disorders, most of whom are autosomal recessive except *properdin deficiency* (X-linked).

Management is non-specific, as complement replacement therapy is not available and includes: (a) prolonged antibiotic therapy during infections and (b) immunization against capsular organisms, e.g. pneumococci or meningococci.

Hereditary angioedema is an important autosomal dominant defect of *C_1 inhibitor deficiency* with unrestricted complement activity. Clinically, these cases presents with recurrent self-limiting episodes of non-pitting edema due to vasodilatory effect of kinins released by uncontrolled breakdown of C_4 and C_2. Each attack lasts for 2–3 days and may be fatal. Antihistaminics and steroids are not effective and acute attacks need to be treated with supportive measures, e.g. tracheostomy. Prophylactic oral attenuated androgen (stanozolol) therapy may be useful in frequently recurrent cases.

III. B-Cell Disorders

B-cell disorders, also termed *humoral deficiency states*, may involve all or selective antibody classes, either due to abnormal B-cell differentiation (quantitative) *or* inability to respond against a specific antigen (qualitative). Many cases are secondary to T cell defects.

Clinically, these cases present with variable severity of recurrent sinopulmonary infections or bacteremia, usually due to encapsulated organisms, e.g. *S. pneumoniae, H. influenzae* and *Staph. aureus*. *These disorders do not manifest in first 3 months of life* due to presence of transplacental antibodies from mother.

Diagnosis is usually established by measured nonspecific immunoglobulin levels or specific antibody titers after vaccination, e.g. DPT.

Management of these cases includes: (a) IVIG therapy (400–500 mg/kg/month) and (b) prophylactic antibiotics. Some important and common B-cell disorders are as follows:

Transient hypogammaglobulinemia indicates developmental delay in immunoglobulin production during early infancy, perhaps due to delayed maturation of T helper cells. This leads to accentuated physiological nadir in immunoglobulin levels at 3–5 months (<200 mg/dl), with spontaneous recovery by 18–24 months.

Bruton (X-linked) agammaglobulinemia, seen only in males, is a maturation defect from pre-B-cell stage to mature B-cell stage, characterized by severe hypogammaglobulinemia and absence/hypoplasia of lymphoid tissue, manifesting in late infancy or early childhood.

Common variable immunodeficiency disorder (CVID) is a maturation defect from mature B-cell stage to plasma cell differentiation, characterized by: (a) late onset after the first decade of life, (b) normal or enlarged lymphoid tissue, (c) frequently associated with splenomegaly, autoimmune disorders, e.g. thrombocytopenic purpura or haemolytic anemia, and malignancies.

Selective IgA deficiency is commonest (1:600) but rarely a symptomatic B-cell defect, characterized by low serum IgA levels (<5–10 mg/dl). Symptomatic cases present with recurrent sinopulmonary infections, food allergy and autoimmune/rheumatologic disorders.

Hyper IgM syndrome is characterized by inability to produce antigen-specific antibody response despite elevated IgM and normal IgG/IgA levels, due to a genetic T-cell defect in activating B-cell response. Apart from sinopulmonary infections, hematologic autoimmune disorders or intracellular infections, e.g. tuberculosis are common.

IV. T-cell Disorders

T-cell defects present with widest clinical spectrum, due to their role in activating almost all immunological components.

Clinically, these patients usually present with: (a) fungal or intracellular infections, e.g. mycobacteria, due to defective phagocytic activation, (b) viral infections due to decreased NK-cell activity, and (c) opportunistic infections due to impaired B cell activation and immunoglobulin production.

Diagnosis of T cell defects depend on quantitative T cell and sub-cell counts, *in vivo* T-cell function tests, e.g. tuberculin test, candida skin test, phytohemagglutination assay (PHA), and *in vitro* tests, e.g. lymphokines assay, etc. Many of these defects may be diagnosed prenatally, e.g. Severe combined immunodeficiency disorders or Wiskott-Aldrich syndrome.

Treatment of choice for severe T-cell defects is bone marrow transplant, though gene therapy has been successful in some cases. IVIG therapy is indicated in cases with co-existing humoral immunodeficiency. Common T-cell defects are rarely isolated, usually associated with other immune disturbances and include:

DiGeorge syndrome is characterized by: (a) thymic aplasia due to 3rd/4th pharyngeal arch dysgenesis, (b) hypocalcemic tetany due to parathyroid dysgenesis, (c) cardiac cono-truncal *or* aortic arch abnormalities, e.g. Fallot's tetralogy or truncus arteriosus, *and* (d) typical facial features with micrognathia, hypertelorism, notched pinna, lowest ears, etc., apart from T cell defects of variable severity.

Severe combined immunodeficiency disorders (SCID) is a heterogeneous group of genetic disorders, characterized by: (a) absent T-and NK-cells in peripheral blood, (b) severe hypogammaglobulinemia despite normal B cell count, and (c) severe lymphoid hypoplasia. Most cases present since neonatal period with failure to thrive, severe bacterial infections, chronic mucocutaneous candidiasis, intractable diarrhea, opportunistic infections, e.g. *Pneumocystis jiroveci* pneumonia and eczematous skin disorders.

Wiskott-Aldrich syndrome is an X-linked defect of T-and B-cell dysfunction, associated with thrombocytopenia and eczema. IgE and IgA levels are raised, with low IgM levels. Most patients manifest in early infancy with severe bleeding *or* opportunistic/recurrent infections.

Chronic mucocutaneous candidiasis is an autosomal recessive defect of T-cell proliferation and function with normal B-cell count, presenting as chronic/recurrent mucocutaneous candidiasis in early childhood, with autoimmune endocrinopathies, e.g. Addison's disease or hypoparathyroidism.

8.3 OPPORTUNISTIC INFECTIONS

Opportunistic infections (OIs) are defined as *"infections with unusual frequency, microbial etiology or natural course, in a host with impaired normal defence mechanisms".*

Incidence of these infections has substantially increased in recent years due to better survival of immunocompromizsed patients, increasing use of invasive devices, implants, transplants and use of immunosuppressive therapy, etc., along with better diagnostic facilities.

OIs may manifest as: (a) recurrent infections by common organisms, or (b) single or recurrent infections by pathogens, normally considered as non-pathogenic, *or* (c) unusual course or treatment resistance of a common infection.

Recurrent infections are otherwise also common in early childhood due to environmental factors, and *all cases of recurrent infections do not indicate impaired host-defence*.

Predisposing factors: Normal host-defence mechanisms include many physical *or* immunological barriers against infections. Any congenital or acquired disease *or* environmental factor that impairs one or more of these barriers may cause OIs **(Table 8.3)**. Thus, all OIs do not necessarily mean immunosuppressive state and many of them are due to impaired anatomical or physiological barriers.

Microbial etiology: Any organism is a potential pathogen in immunocompromised host. Common microbial profile of OIs includes infections due to:

- Low virulence organisms from normal human flora, e.g. coagulase negative staphylococci, enterococci, etc.
- Organisms generally considered as non-pathogenic in normal settings, e.g. *Pneumocystis jiroveci, Candida*, etc.

TABLE 8.3: Predisposing factors for opportunistic/recurrent infections

a. Impaired skin/mucosal barriers
- Congenital dermal sinuses and tracts
- *Acquired:* Burns, trauma and surgery
- *Foreign body:*
  - *Catheters:* Vascular, urinary, dialysis catheter
  - *Implants:* VP shunts, cardiac/orthopedic devices
- ? Vitamin A deficiency

b. Impaired mechanical clearance
- *Mucus drainage:* Cystic fibrosis, undrained cavity
- *Ciliary function:* Post-viral, Immotile cilia syndrome

c. Altered normal flora
- Prolonged/partial antibiotic therapy

d. Congenital immunodeficiency states
- Phagocytic disorders
- B- or T-cell defects
- Complement deficiency
- *Impaired local immunity:* IgA deficiency

e. Acquired immunodeficiency states
- Severe malnutrition
- *Post-infective:* Measles, pertussis
- HIV/AIDS
- *Disease:* Malignancy, sickle cell disease
- *Iatrogenic:* Transplants, drugs*, splenectomy

*For example, anti-malignancy drugs, antibiotics, steroids.

- Organisms prevalent in local hospital setting, e.g. *Pseudomonas*, *Klebsiella*, etc.
- Polymicrobial infections, and
- Multi-drug resistant infections.

Clinical spectrum of OIs depends on the primary etiology, site of infection, causative pathogen and extent of immunosuppression. However, some general characteristics are as follows:

- Fever is a sensitive, specific and often the only sign of OIs. Contrary to general view, febrile response is rarely masked, even in severe immunocompromised states.
- Other signs of infection or inflammation, e.g. erythema, exudation, etc. may be minimum or absent in immunocompromised host. These cases may have severe pneumonia with normal X-ray, meningitis with normal CSF and cellulitis without swelling.
- Frequency and severity of OIs directly correlates with severity indicators of immunosuppression, e.g. neutrophil counts (<500 mm^3) or CD_4 counts.
- OIs are usually generalized or multi-systemic, except tissue-tropic infections, e.g. *P. jiroveci* pneumonia or Cryptosporidium diarrhea.
- Serological tests, e.g. antibody titers or skin tests, e.g. tuberculin test, are unreliable in these cases and negative tests do not exclude corresponding infection.

Some important OIs are as follows:

A. OIs due to impaired physical barriers: Skin and mucus membranes are not only the physical barriers but also offer mechanical (mucociliary clearance), chemical (bacteriostatic fatty acids in skin), enzymatic (lactoferrin, lysozyme secreted by mucus membranes), immunological (secretory IgA in mucus membranes) and microbial (normal colonizing flora) protection against infections. These barriers may be impaired in congenital anomalies, e.g. dermal sinuses/tracts or acquired lesions, e.g. trauma, surgery, burns, etc.

- *Burns* patients are susceptible for OIs due to broken skin/mucosal barriers, presence of necrotic tissue and altered normal flora following antimicrobial therapy or vascular catheterizations. Most of these infections are caused by nosocomial or human flora pathogens, e.g. *Pseudomonas*, *Staph. aureus* or CONS and present with severe septicemia or pneumonia.
- *Surgical infections* are at specific risk for anaerobic infections, due to migration of normal colonizing flora at wound-sites.
- *Dermal sinus tracts* are usually colonized or infected by *Staph. epidermidis* or *diphtheroids*.

B. Device-related infections: Indwelling vascular/other catheters, shunts and implants act as nidus for localization of infection or the infection may be introduced at the time of insertion.

- *Vascular catheter-related infections* are more common with central than peripheral lines, risk being directly proportional to the duration of cannulation. Over half of them are caused by *Staph. epidermidis*, followed by gram-negative bacilli and Candida. Frequent change of catheters and catheter site is essential to prevent these infections. Diagnosis is based on identical growth on blood and catheter-tip culture.
- *CSF shunt infections* are predominantly caused by *Staph. epidermidis* (>70%) and present with: (a) shunt colonization, (b) shunt infection with wound infection/dehiscence, (c) shunt infection with ventriculitis, and (d) shunt infection with peritonitis. Shunt removal is often necessary, followed by antibiotics. *Vancomycin* is the drug of choice for shunt infections.
- *Urinary catheter-related infections* are common with indwelling catheters, usually caused by gram –ve bacilli or enterococci. These cases present with persistent bacteriuria or symptomatic urinary tract infections. Catheter removal alone is sufficient for asymptomatic bacteriuria, while antibiotics are necessary in symptomatic cases. Prophylactic antibiotics do not reduce the risk of catheter-related urinary tract infection.
- *Peritoneal dialysis catheter-related infections* are usually due to *Staph. epidermidis or aureus* and present with local *exit-tunnel infection* or peritonitis. Vancomycin *with* a third generation cephalosporin or aminoglycoside is the drug of choice in these cases.
- *Orthopedic or cardiac valvular implants* are usually infected by CONS or *Staph. aureus*, presenting as wound infection or endocarditis, respectively.

- *OIs due to nebulization/ventilator therapy* usually present with pneumonia due to *Pseudomonas, Serratia* or legionella.

C. Acquired immunodeficiency states may be due to the disease, (e.g. PEM, HIV, malignancy) or iatrogenic (steroid/cytotoxic therapy, splenectomy, bone marrow transplants).

- *Severely malnourished children* are prone for gram-negative septicemia as well as severe disease with common infections, e.g. measles, varicella and tuberculosis, due to impaired T cell function, phagocytic activity and complement activity.
- *Post-infective transient immunosuppression* for 2–3 months is common after measles and pertussis infection, which may lead to reactivation of underlying tuberculosis.
- *Transplanted individuals* are highly susceptible for OIs due to immunosuppressive drug/radiation therapy, prolonged invasive devices, surgical injury, and graft versus host disease (GVHD). The type of OIs in these cases depends on time-course of transplant—bacterial infections in pre-operative preparatory phase, anaerobic infections in peri-operative period, *and* viral (CMV, RSV) or PCP infections in post-operative period. While septicemia and pneumonia is common in marrow transplants, children with renal/liver transplant are additionally susceptible for urinary tract infections and cholangitis, respectively.
- *Malignancy* is a common cause of OIs due to primary *or* iatrogenic immunosuppression as well as nosocomial infections. Microbial profile in these cases varies according to absolute neutrophil counts, as follows:
  - *Non-neutropenic cases:* Viral and fungal infections, PCP and toxoplasmosis.
  - *Neutropenic cases:* Serious bacterial infections due to gram +ve cocci, e.g. *Staph. aureus,* CONS, enterococci, etc. *or* gram-negative bacilli, e.g. Pseudomonas, Klebsiella, etc.
    Note that meningitis is unusual in granulocytopenic patients.

D. Inherited immunodeficiency disorders are rare (Ch 8.2), but should be suspected in cases with warning signals **(Table 8.2)**, *without an acquired cause* for impaired host-defence.

Diagnostic evaluation of suspected OI aims to confirm the microbial etiology as well as to identify the predisposing factors and includes:

- ***History,*** including: (a) review of medical records to confirm the frequency and nature of recurrent infections, (b) family history of similar illnesses, TB/HIV or consanguinity (for inherited defects), (c) past history of immunosuppressive infections, e.g. measles, pertussis, etc. (d) treatment history of prolonged steroid/cytotoxic therapy or splenectomy, and (e) epidemiological history for environmental causes for recurrent infections.
- ***Pattern of infections*** may provide important clues to the nature of immunodeficiency, as follows:
  - Recurrent bacterial infections indicate probable B-cell defects.
  - Atypical course of mycobacterial, viral, fungal or intracellular infections, e.g. toxoplasmosis indicate probable T-cell defects.
  - Recurrent staphylococcal or gram-ve infections, as well as mucocutaneous infections indicate probable defects in phagocytosis, which are also characterized by *inadequate pus production*.
  - Recurrent infections due to capsular organisms, e.g. Pneumococci, *H. influenzae* or Salmonella indicate splenic dysfunction or complement deficiency.
- ***Co-existing illnesses*** are important diagnostic clues for secondary immunodeficiency disorders (malignancies, malnutrition, sickle cell disease, nephritic syndrome) as well as inherited immunodeficiency disorders **(Table 8.4)**.
- ***Laboratory evaluation*** in these cases includes baseline screening tests for common defects and search for microbial etiology, followed by more selective investigations, guided by clinical suspicion **(Table 8.5)**.

Management depends on the identified cause, though some broad principles in management of immunocompromised children include:

- Avoidance of unnecessary microbial exposure, e.g. overcrowding.
- Avoidance of live vaccines in severe cases.

TABLE 8.4: Physical indicators of inherited immunodeficiency disorders

Typical facies	*DiGeorge syndrome*
Albinism	*Chédiak-Higashi syndrome*
Atopic dermatitis	*T-cell or phagocytic defects*
Alopecia	*SCID*
Red hair	*Job's syndrome*
Persistent thrush	CMC
Absent tonsils	*SCID, XL agammaglobulinemia*
Large tonsils/LNs	*CVID*
Telangiectasia	*Ataxia telangiectasia*
Weeping ears	*CGD, Wiskott-Aldrich syndrome*
Hepatosplenomegaly	*CGD*
Recurrent respiratory infections	*Hypogammaglobulinemia*
Thrombocytopenia	Wiskott-Aldrich syndrome

SCID: Severe combined immunodeficiency disorders; **CMC:** Chronic mucocutaneous candidiasis; **CGD:** Chronic granulomatous disease; **CVID:** Common variable immunodeficiency

TABLE 8.5: Laboratory investigations in OIs

Step I: Base line screening tests:
- *Hematological:*
  - Leukocyte count[1]
  - Leukocyte morphology[2]
  - Platelet count[3]
  - Howell-Jolly bodies[4]
  - ESR for chronic infection, TB
- *Radiological:* Chest, sinuses, mastoid, etc.
- Microbiological cultures from suspected sites
- *Immunological tests:* Serology, TT (unreliable)
- Relevant tests for predisposing illness

Step II: Specific immunological screening tests:
- *Suspected B-cell defects*
  - S. IgA, IgG and IgM levels[5]
  - S. IgG subclass measurements
  - Isohemagglutinin (anti-A and B) titers[6]
  - Vaccine-antibody titers (tetanus, diphtheria)[7]
  - B-cell count
- *Suspected T-cell defects (Only if ALC is low)*
  - T-subpopulation count (by flow cytometry)
    Absolute CD4 count
    CD4/CD8 ratio (N: >4:1)
    NK cell counts
  - T-cell function tests
    In vivo: Tuberculin, candida skin tests
    In vitro: Lymphokines assay
- *Suspected phagocytic defect*
  - Nitroblue tetrazolium dye test (NBT)
  - Leukocyte function tests
- *Suspected complement deficiency*
  - CH_{50} activity with control
  - Direct C_3–C_4 immunoassays

Step III: Molecular tests (inherited defect)
  - Index case
  - Prenatal diagnosis

[1]Neutropenia, T-cell defects, eosinophilia in hyper IgE syndrome
[2]Abnormal in Chédiak-Higashi syndrome
[3]Thrombocytopenia in Wiskott-Aldrich syndrome
[4]In splenic dysfunction or asplenia
[5]Hypergamaglobulinemia indicates HIV or CGDC;
[6]Indicative of IgM function
[7]Indicative of IgG function

- Prophylactic vaccinations for capsular organisms, e.g. pneumococci, meningococci, *H. influenzae*, etc.
- Prophylactic *or* early antimicrobial therapy.
- Adequate drainage of infection site, e.g. abscess, empyema, etc.
- Replacement therapy with plasma (complement deficiency) or IV immunoglobulins in select cases.
- Specific therapy *or* bone marrow transplantation (T-cell defects), interferon, etc.

8.4 HYPERSENSITIVITY DISORDERS

8

Hypersensitivity, in context of immunology, denotes *untoward and inappropriate immunological response* to a foreign antigen involving antigen-specific antibodies and memory cells. According to immunopathogenesis, hypersensitivity reactions may be divided into four types:

1. Type I (IgE mediated) reactions, also termed allergy, are triggered by the binding of an allergen to *specific or reaginic IgE antibodies* attached on the surface receptors of circulatory basophils and tissue mast cells. (Ch 8.4.1)

2. Type II (cytotoxic) reactions are characterized by abnormal binding of IgM or IgG antibodies to *self-antigens*, modified by external insult, (e.g. drugs or infections), with complement activation and consequent target tissue injury. Discussed in relevant chapters, these reactions are usually *tissue-specific*, e.g. autoimmune hemolytic anemia or thrombocytopenia (target antigen-cell membrane), myasthenia gravis (target antigen-acetylcholine receptor) or Graves' disease (target antigen-TSH receptors).

3. Type III (immune-complex) reactions involve formation of soluble antigen-antibody complexes, which are either removed to reticuloendothelial organs or deposited at target tissues, e.g. glomerular basement membrane, skin and synovium. Immune-complex mediated complement activation leads to attraction of polymorphs at these sites with local inflammatory reactions and tissue damage, i.e. *Arthus reaction;* or more systemic and widespread reactions, i.e. **serum sickness.** Other common examples of these reactions are proteinuria in nephrotic syndrome and vasculitis syndromes, e.g. Henoch-Schönlein purpura.

Serum sickness presents as fever, arthralgia, urticaria, lymphadenopathy and proteinuria, usually after 7–14 days of the administration of animal-derived antisera, e.g. equine anti-snake venom, anti-tetanus serum, etc. or drugs, e.g. penicillin, cephalosporins, etc.

4. Type IV (delayed hypersensitivity) reactions are mediated by antigen-specific T cells and macrophages, due to recognition of antigen-peptide on antigen processing cells by T memory cells and release of inflammatory cytokines. These reactions peak after 24–48 hours of antigen exposure and include tuberculin reactions, contact dermatitis, transplant rejection and graft *versus* host disease, etc.

8.4.1 GENERAL CONCEPTS IN ALLERGY

Allergy denotes a specific type of hypersensitivity reactions mediated by IgE antibodies and provoked by specific antigens, i.e. allergens.

Allergen denote a substance capable of inducing IgE mediated reactions on exposure. The term allergen and antigen are not synonymous, as all allergens are not good antigens, (e.g. rag-weed pollens) and conversely all antigens are not necessarily allergens, (e.g. vaccines).

Atopy denotes an *inherited or familial predisposition* for allergic disorders.

General pathophysiology: Allergic reactions are triggered by the binding of an allergen to specific or

reaginic IgE antibodies, attached on the surface receptors of circulatory basophils and tissue mast cells.

These reaginic antibodies are formed after an earlier exposure to same allergen, i.e. *sensitization*. On subsequent exposure, antigen-IgE binding on the surface of basophils/mast cells provokes two different types of reactions:

a. ***Early-phase reactions*** within 20 minutes, due to degranulation of mast cells and release of pre-formed chemical mediators, e.g. histamine and eosinophil chemotactic factors, presenting as urticaria, pruritis, sneezing, wheezing and hypotension, e.g. anaphylaxis, asthma, allergic rhinitis or insect allergy.
b. ***Late-phase reactions*** after 4–12 hours, due to influx of other allergic (basophils, eosinophils, mast cells) and inflammatory cells (polymorphs, lymphocytes) at the site of allergen exposure and consequent release of other chemical mediators, e.g. leukotrienes and prostaglandins. These mediators amplify allergic inflammation and facilitate further differentiation of allergic cells and IgE-producing B cells. Late-reactions have been implicated in development of long-term nasobronchial hyperreactivity in allergic individuals.

General principles in diagnosis: Clinical spectrum of allergic disorders is extremely wide, ranging from life-threatening *anaphylaxis* to system-specific disorders, e.g. *asthma, allergic rhinitis, atopic dermatitis or urticaria*. Allergic disorders are usually characterized by following common features:

- Chronic course with intermittent exacerbations.
- Cause-effect relationship with allergen.
- Family history of atopic disorders.
- *In vitro* laboratory abnormalities, e.g.
  - Peripheral eosinophilia (AEC >600 cell/mm^3)
  - Presence of eosinophils in body secretions
  - Elevated IgE levels (N: 10–20 IU/ml)
  - Presence of allergen-specific IgE antibodies
- *In vivo* positive challenge tests, e.g.
  - Allergen skin testing
  - Provocation tests.

Allergen skin test is an important diagnostic tool to identify causative allergen in many allergic disorders, e.g. asthma or allergic rhinitis. These tests involve intradermal injections of miniscule quantities of a battery of commercial available allergens, (e.g. mites, dusts, pollens, danders and fungi), along with a negative (saline) and a positive (histamine) control, over forearm or back. Local response to each allergen injection, i.e. erythema and wheel size is noted and compared with controls, after 10 minutes (*early response*) and 2–3 hours (*late response*). Severity of response indicates strength of cause-effect relationship, though false-positive and false-negative results are common and results must be correlated with clinical observations.

Provocation or challenge tests involve deliberate exposure of the affected mucus membrane to suspected allergen, which may induce the allergen-specific clinical reaction. Commonly used provocation tests include *bronchial provocation test* in asthma (nebulization of suspected allergen to see spirometric changes) and oral provocation tests in food allergy or atopic dermatitis (ingestion of suspected food item to see reappearance of diarrhea or skin lesions). Although useful in cases with equivocal *in vitro* laboratory results or skin testing, these tests are rarely used due to the risk of life-threatening reactions.

General principles of management in allergic disorders include: (a) avoidance of suspected allergens if possible; (b) immunotherapy (desensitization) against unavoidable allergens; (c) specific pharmacotherapy to block the release or action of chemical mediators.

While specific therapeutic measures in management of individual allergic disorders have been discussed in respective chapters, some general principles are as follows:

a. Avoidance of allergens: Common allergens may be divided into 3 categories:

1. Inhalant allergens, e.g. pollens, dust, dust-mite, danders and fungi,
2. Ingestant allergens, e.g. food, and
3. Contactant allergens, e.g. synthetic fabrics or elastics.

In addition, viral infections and smoke exposure, though not allergenic by themselves, are common triggering events for precipitation of acute attacks in children.

As the dictum goes, *anything above the earth and below the sky may be allergenic*. Further, atopic children are often allergic to many allergens at the same time. Considering this biological diversity, it is often difficult to identify and avoid specific allergens, though following precautions may be helpful:

- *Avoidance of outdoor allergens*, e.g. dust exposure, visit to flowery gardens, etc.
- *Avoidance of indoor allergens* with wet mopping of floor (dust); removal of indoor plants, soft toys and carpets (mites), avoidance of pets (danders), regular cleaning of AC filters (fungi), pest control (cockroaches), etc.
- *Avoidance of suspected dietary substance*s is often overemphasized, without much scientific basis. However, a proven cause-effect observation with particular food stuff may be indication to avoid canned foods with preservatives, coloring agents, etc.
- *Avoidance of other triggering factors*, e.g. smoke exposure, viral infections, etc.

b. Immunotherapy: Some allergens are unavoidable, e.g. pollens, dust mites, etc. Immunotherapy is an option to desensitize the child against these identified but unavoidable allergen/s, by repeated intradermal

injections of the increasing dose of allergen/s as an aqueous extract (up to 10 allergens may be combined in same solution), once/twice a week (interval is increased gradually), till the optimal maintenance dose is reached and continued for another 3–6 months.

Although with a sound physiological basis, immunotherapy is often ineffective due to: (a) inadequate quality and unknown doses of currently available commercial allergen extracts, (b) frequent reappearance of hypersensitivity after discontinuation of maintenance doses, (c) change-over hypersensitivity from one to another allergen in inherently atopic child, and (d) poor compliance to multiple injections. However, it may be tried in selected cases of asthma or allergic rhinitis, where avoidance of suspected allergen is not possible.

c. Pharmacotherapy of allergic disorders may be broadly divided into *preventors*, i.e. drugs to prevent the attacks and *rescuers*—drugs to combat acute response. These drugs aim to:

- *Block the release of chemical mediators*, e.g. mast cell stabilizers, e.g. cromolyn sodium, nedocromil sodium, lodoxamide, olopatadine (last two for topical use only in allergic conjunctivitis),
- *Block the action of these mediators*, e.g. antihistaminics, steroids, leukotriene inhibitors, (montelukast, etc.)
- A*ntagonise the physiological response of mediators*, e.g. β-agonists, acetylcholine inhibitors, etc.

While first two groups of drugs prevent the allergic attack and are used on long-term basis, the last group is useful only to control acute clinical manifestations. Important pharmacological agents in various atopic disorders have been discussed in respective chapters.

Antihistamines are competitive antagonists for H_1 histamine receptors, more effective in preventing than reversing the action of histamine. Consequently, these drugs are more effective in preventing, rather than treating, an established attack. As histamine is not the only chemical mediator of allergic response, these drugs are poorly effective in asthma or atopic dermatitis.

However, antihistamines are extremely valuable in the management of acute allergic rhinitis or anaphylaxis which are predominantly histamine-mediated. While large number of antihistamines are available with near-comparable efficacy, second generation histamines, e.g. cetirizine, loratidine, terfenadine are preferable due to less side-effects, e.g. drowsiness.

8.4.2 ANAPHYLAXIS

Anaphylactic reactions are acute, life-threatening hypersensitivity reactions, provoked by variety of injected, inhaled or ingested foreign substances. Note that the term *anaphylactoid reaction* denotes clinically similar reactions to certain agents, e.g. radio-contrast dyes, which are *not* immunologically mediated.

TABLE 8.6: Precipitating agents for anaphylaxis

- Drugs, e.g. *penicillins, blood, equine sera, etc.*
- Foods, e.g. *sea-food, egg, nuts, additives, etc.*
- Insect stings and venoms
- Biological contact agents, e.g. *latex, wool, etc.*
- Exercise-induced
- Idiopathic

Causes: Common precipitating agents for anaphylaxis are enumerated in **Table 8.6**, though the cause remains unidentified in many cases.

Pathogenesis: Anaphylactic reactions are type I hypersensitivity reactions, mediated by specific IgE antibodies, formed in response to previous sensitization. These antibodies are present on surface of basophils and mast cells and subsequent exposure to the same allergen leads to degranulation of mast cells and release of numerous chemical mediators.

Final effect of these mediators may manifest immediately with a few minutes (*acute phase reaction*) or after many hours (*late phase reaction*), with *three main clinical components* of anaphylaxis—acute bronchospasm, increased vascular permeability and increased secretory activity of mucous glands.

Clinically, these reactions usually begin within few minutes of exposure to offending allergen, presenting with sudden onset of:

- *Dermatologic manifestations* involving skin and mucus membranes, e.g. urticaria, pruritus, flushing, perioral tingling, red/itchy eyes, sneezing/rhinorrhea and extreme diaphoresis;
- *Respiratory manifestations,* e.g. wheezing, stridor and/or respiratory distress;
- *Cardiovascular manifestations,* e.g. hypotension, bradycardia or shock and a general feeling of sinking or impending doom, with rapidly developing unconsciousness.
- *Gastrointestinal manifestations* in some cases with abdominal cramps, diarrhea and vomiting.

Many cases die rapidly due to airway obstruction or cardio-respiratory arrest, unless treated immediately.

Some patients after initial recovery develop recurrence (*biphasic reaction*) after 6–8 hours due to late-phase reactions.

D/D: While history of exposure to an offending agent and catastrophic clinical picture is characteristic, anaphylaxis needs to be differentiated from: (a) vasovagal attacks, (b) cardiac arrhythmia, (c) foreign body aspiration, (d) hypoglycemia, and (e) acute poisoning. Elevated IgE levels and eosinophilia differentiates anaphylaxis from *anaphylactoid* reactions.

Sudden development of clinical manifestations involving at least two of the three different systems-dermatological,

respiratory and cardiovascular system, is considered as strongly indicative of anaphylaxis.

Management: Anaphylaxis is a life-threatening emergency, which needs immediate resuscitative measures and subsequent hospitalization for at least 24 hours to watch for late-phase reactions. Immediate resuscitative measures include:

- *Subcutaneous adrenaline is the cornerstone of management of anaphylaxis, given as* 1:1000 aqueous preparation (0.1 ml/kg; max 0.5 ml) and repeated every 15–20 minutes till response. In superficial venom injections, e.g. insect stings, half of the SC dose (diluted in 2 ml saline) may be given locally at the site of injection.

  All public vaccination sites are provided with *anaphylaxis kit* containing adrenaline, insulin/tuberculin syringe, 24–25 G needle and instructions about age-wise doses of adrenaline – *0.05 ml < 1 year, 0.1 ml from 1–6 years and 0.2 ml from 6–12 years, 0.3 ml from 12–18 years and 0.5 ml in adults.*
- *Place the child in supine position* and assess the airway, breathing, circulation.
- *Respiratory support* with airway/oxygen/ventilatory support and tracheostomy, if needed.
- *Cardiovascular support* with IV fluids (normal saline 20 ml/kg bolus) and inotropes, e.g. dopamine, if required.
- *Nebulized epinephrine (0.5 ml/kg) or nebulized salbutamol (0.15 ml/kg)* in cases with stridor or wheeze respectively, which may be repeated after 10–15 minutes,
- *Antihistaminics*, e.g. diphenhydramine or chlorpheniramine for next 24–48 hours, have no role in the management of acute attack but may prevent late reactions.
- *Systemic steroids*, e.g. IV hydrocortisone (5 mg/kg 6-hourly), although controversial in acute management, may help to decrease the duration and severity of manifestations.
- If a *precipitating agent*, e.g. drug is identified, a clear warning should be noted on medical records to prevent further episodes.

System-specific allergic disorders, e.g. asthma, allergic rhinitis and atopic dermatitis, etc. have been discussed in respective chapters.

CHAPTER

9

Immunization

Mukesh Agrawal, Niranjan Shendurnikar

Since the global eradication of smallpox from May 8th, 1980, immunization has been established as the most cost-effective preventive measure against infectious diseases.

Immunization may be defined as *induction of specific immune response* by either: (a) deliberate inoculation of immunogens to stimulate *in vivo* antibody production ***(active immunization)***, or (b) administration of pre-formed antibodies, i.e. immunoglobulins ***(passive immunization).***

Although frequently used interchangeably, the terms *immunization* and *vaccination* have different connotations. Vaccination denotes a *process* to administer immunogenic agents for active immunization. A vaccinated child may not be considered as immunized, if the desired immune response is not induced due to faulty vaccine or technique.

9.1 BASIC CONSIDERATIONS

The term *immunity* in preventive pediatrics refers to *complete protection or at least partial resistance against an infection*, and may be classified as:

- ***Natural immunity,*** acquired by:
  - Transplacental transfer of maternal antibodies in fetal life, i.e. *natural passive immunity*, or
  - Clinical or sub-clinical infections in postnatal life, i.e. *natural active immunity.*
- ***Artificial immunity,*** acquired by:
  - Disease-specific vaccinations, i.e. *artificial active immunity,* or
  - Administration of specific or non-specific immunoglobulins, i.e. *artificial passive immunity.*

While active immunity persists for many years or even throughout the life, passive immunity does not last for more than few weeks. This chapter concentrates on artificial immunity, specially active immunization via vaccines, followed by some relevant aspects of passive immunization.

9.1.1 PHYSIOLOGY OF IMMUNIZATION

Primary objective of immunization is *to develop and sustain a disease-specific antibody titers above the protective threshold*, by exposing the host-immune system to *a deliberately introduced antigen, devoid of its pathogenic properties,* i.e. *vaccine*. Vaccine-induced antigenic exposure, like natural infection, initiates various host-immune responses, e.g. specific immunoglobulin production (*humoral response*) or T-cell activation (*cellular response*). Complex interaction of these responses has been discussed in Ch 8.1.

Development of protective immunity after vaccination may be considered as a two-step process—primary response and secondary response **(Fig. 9.1)**.

Primary response: After the first dose of vaccine, there is a lag period of several days before antigen-specific antibodies appear in the serum. However, these antibodies are mainly of IgM class with short life-span (21–28 days) and have no long-term protective value. On the other hand, IgG titers start rise after 2–3 weeks and remain high for many months before gradual decline. The most important event during primary challenge is the sensitization of B-cells, some of whom develop as antigen-specific *memory cells* and persist throughout the life.

Secondary response: When a sensitized host is re-exposed to the same antigen by subsequent vaccine-dose or natural infection, pre-existing *memory cells* activate a more rapid and pronounced IgG response, along with the short-lived IgM response. Antibodies titers, achieved during this phase, are much higher than that during the primary response (*anamnestic or booster response*) and remain protective for many years or throughout life.

Thus, the development of adequately protective antibody levels after vaccination requires at least two exposures at different time intervals, necessitating multiple doses, specially for inactivated vaccines. However in case of live vaccines, *in vivo* replication of organisms provides a sustained source of antigen, leading to merger of primary and secondary responses. Hence, usually single dose is enough for live vaccines.

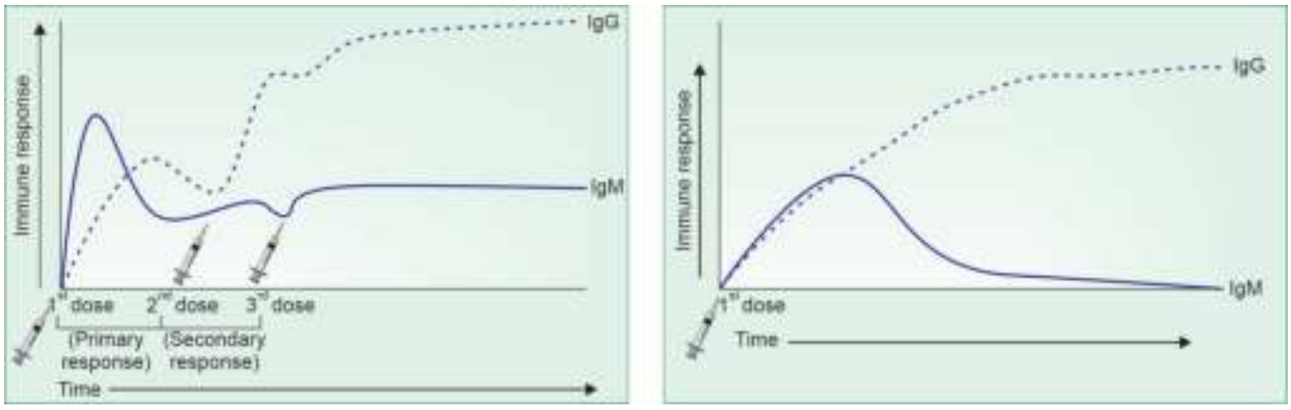

Fig. 9.1: Immune response following immunization with (A) Inactivated vaccines; (B) Live vaccines.

9.1.2 DETERMINANTS OF IMMUNE RESPONSE

Success of vaccination in an individual child is assessed by:

- ***Seroconversion,*** i.e. development of antibodies after administration of a vaccine or more than four-fold rise in pre-vaccination titers, if already present due to previous exposure.
- ***Seroprotection,*** i.e. development of antibodies in the pre-defined titers required for protection from the disease.
- ***Immunogenicity,*** i.e. ability of the vaccine to induce seroprotective titers or desired cell mediated response.
- ***Protective efficacy,*** i.e. ability of the vaccine to actually reduce the risk of disease in vaccinated population as compared to unvaccinated population, denoted in terms of percentage.

In brief, immunogenicity is a laboratory criteria to assess the effect of a vaccine, while protective efficacy is a real-life field result.

Important determinants of success after individual vaccination include:

- ***Type of the antigen:*** Live vaccines are highly immunogenic due to endogenous production of antigen due to *in vitro* multiplication of organisms, as compared to killed, subunit or toxoid vaccines that carry limited antigenic load per dose. Polysaccharide vaccines are poorly immunogenic as they produce only T-cell independent response of mainly IgM class with no development of memory cells, being gradually replaced by conjugated vaccines. Hence, while live vaccines are usually given as a single dose, inactivated vaccines, need multiple primary doses and boosters for adequate and sustained immune response.
- ***Number of doses:*** Increasing the number of doses increases immunogenicity and efficacy of a vaccine, specially in cases of inactivated vaccines. Immunocompromised child are often advised to take additional dose/s of these vaccines. While one dose is generally enough for most of live vaccines, additional dose are frequently advised to ensure better seroprotection, e.g. seroprotection rate after first dose on measles is 95–98% and nearly 100% after two doses.
- ***Dose of the antigen:*** Higher doses of antigen induce better immunity but with higher risk of side effects and hence, increasing the antigen content beyond a limit is not recommended. Still, higher (double dose) vaccinations are sometimes recommended in immunocompromised populations, e.g. for HBV vaccine.
- ***Immune status of host:*** Vaccination in preterms, malnourished and immunocompromised children may not produce adequate immune response due to relative immune incompetence. Although live vaccines may theoretically produce the disease in these cases, such complications are extremely rare and should not preclude the use of live vaccines except in severe immunodeficiency states.
- ***Time-interval between doses:*** A gap of less than one month between two doses of non-live vaccines may not produce adequate secondary response. Although an interval of two months produces best secondary response, need to complete the immunization as early as possible in the baby has necessitated use of one-month interval between two doses of DPT, etc.
- ***Time interval between different vaccines:*** When two live vaccines for different diseases are given at short interval (<1 months), early non-specific immune response to the previous vaccine may interfere with uptake of the subsequent vaccine. Hence, a minimum interval of one month is essential for adequate response to each live vaccine. However, multiple live vaccines, given on the same day produce parallel and adequate immune response for each of them and hence, use of combination vaccines is as effective as separate vaccinations.

No specific time-interval is needed between two inactivated vaccines or one-live and one inactivated vaccine,

barring few exceptions: (a) PCV should always precede PPSV by 8 weeks, when used together, and (b) PCV should precede meningococcal vaccine by 4 weeks, when used together.

- **Presence of maternal antibodies** during first 3–6 months of life interferes with successful active immunization by rapid elimination of the vaccine-antigen. Hence, most childhood immunizations are given after neonatal period. However, BCG (that produces cell mediated immunity), OPV (that produces local immunity) and HBV (maternal antibodies are absent or non-interfering) may be given at birth.

  Maternal antibodies interfere more with response to live vaccines than to inactivated vaccines. Hence, while inactivated vaccines, e.g. DPT, PCV can be given earlier at 6 weeks, live vaccines are usually not given before 9 months of age, e.g. MR or varicella.
- ***Route of administration:*** Parenteral vaccines mainly induce systemic immunity, while oral vaccines, e.g. OPV and Rotavirus vaccines mainly induce local immunity (secretory IgA-mediated). Local immunity prevents the invasion of pathogen itself, while systemic or IgG-mediated immunity eliminates the organism after invasion.

  Intradermal vaccination of some vaccines, e.g. IPV or Rabies vaccines, can induce antibody responses comparable to intramuscular or subcutaneous route with lesser dose of antigen.
- **Presence of pre-formed antibodies** after immunoglobulin therapy or after blood transfusions interferes with development of adequate immune response by rapid elimination of vaccine-antigen. Hence, a gap of many weeks to months is usually recommended between administration of these products and vaccines. However, as immunological protection by vaccines is delayed by several days. Some immunoglobulins, e.g. tetanus, hepatitis B and rabies immunoglobulins are given along with the first dose of vaccine due to the urgency of protection before appearance of vaccine-induced response.
- ***Contact immunity and herd effect:*** Some vaccines benefit even the unvaccinated population, through various ways, i.e. *Contact immunity* (shedding of the OPV virus in stools or influenza virus in nasal secretions after respective vaccinations, unintentionally vaccinating the contacts) and *Herd effect* (reducing the transmission of disease by decreasing the number of susceptible population). In these cases, the actual protective efficacy of the vaccine might be higher than that expected from the vaccine.

9.1.3 IMMUNIZATION AGENTS

Immunological agents include products for both – active immunization, i.e. vaccines, and passive immunization, i.e. immunoglobulins (discussed later).

TABLE 9.1: Common types of vaccines

I. Live attenuated vaccines	
– Bacterial	BCG, Typhoid
– Viral	OPV, RV, MR/MMR, Varicella, JE, Yellow Fever
II. Inactivated vaccines	
– Bacterial	Pertussis (Whole cell), Cholera, Typhoid
– Viral	IPV, HAV, HBV, HPV, JE (Inactivated), Influenza, ARV
III. Toxoids	Diphtheria, Tetanus
IV. Subunit vaccines	
– Protein	Pertussis (acellular)
– Polysaccharride	PPSV, MPSV, TPSV
– Conjugated	Hib, TCV, PCV, MCV

OPV: Oral polio vaccine; **RV:** Rotavirus vaccine; **MR:** Measles-Rubella; **MMR:** Measles, Mumps, Rubella vaccine; **IPV:** Inactivated polio vaccine; **HBV:** Hepatitis B vaccine; **HAV:** Hepatitis A vaccine; **HPV:** Human papilloma virus vaccine; **JE:** Japanese encephalitis vaccine; **Hib:** *H. influenzae* B vaccine; **PPSV:** Pneumococcal polysaccharide vaccine; **MPSV:** Meningococcal polysaccharide vaccine; **TPSV:** Typhoid polysaccharide vaccine; **TCV:** Typhoid conjugate vaccine; **PCV:** Pnuemococcal conjugate vaccine; **MCV:** Meningococcal conjugate vaccine

Vaccines are biological formulations containing live or killed pathogens, their subunits or their toxins, minus their virulence. Currently available vaccines may be classified, based on the viability of organisms, contents and the methods of production **(Table 9.1)**.

Some commonly used terms in vaccine technology are as follows:

Live vaccines contain viable organisms with attenuated virulence and hence: (a) are highly immunogenic, (b) require stringent storage conditions to maintain viability of organisms, and (c) cannot be used in severely immunocompromised persons due to risk of severe/disseminated disease. These vaccines are usually supplied in lyophilized form to increase their stability and have to be reconstituted before use.

Killed or inactivated vaccines are prepared from organisms inactivated by heat or chemicals to remove the virulence. These vaccines are: (a) less immunogenic and usually need multiple doses for adequate immune response, (b) relatively heat-stable on storage, and (c) can be used in immunocompromised children.

Polysaccharide vaccines using a polysaccharide antigen from cell wall or capsule, are poorly immunogenic due to lack of development of IgG response and memory cells. These vaccines are usually ineffective in younger children before 2 years of age and need re-vaccinations.

Conjugated vaccines are modified polysaccharide vaccines in which component polysaccharides are conjugated with some other potent antigen, termed *vehicle*, (e.g. mutant diphtheria or tetanus toxoid), to increase the immunogenicity. Conjugated vaccines can be used in children < 2 years of age and provide long-lasting immunity.

Polyvalent vaccines are the vaccines with two or more strains of the *same* organism, e.g. OPV, PCV HPV, etc. while monovalent vaccines are single antigen vaccines, e.g. varicella vaccine.

Combination vaccines are vaccines containing antigenic material from *different* organisms, e.g. DPT, MMR and others. These vaccines are useful to minimize the hospital visits, cost and number of pricks.

In addition to the basic antigenic material, vaccines may also contain other agents, collectively termed as excipients and include adjuvants, preservatives, stabilizers and diluents.

Adjuvants, e.g. *aluminium hydroxide or phosphate*, etc., are usually added in inactivated or sub-unit to augment the potency of vaccines to prolong the release of antigen and the attraction of immunocompetent cells around the injection site. Nearly all bacterial vaccines contain adjuvants while viral vaccines are usually adjuvant free, barring few exceptions.

Preservatives, e.g. *mercurial compounds* or *antibiotics*, e.g. neomycin, are added to prevent contamination of vaccines. These agents have been implicated in various adverse events of vaccines, earlier considered due to antigen component. Measles vaccine does not contain any preservative and hence, severe septic reactions, e.g. toxic-shock syndrome have been reported with its use beyond 3 hours of reconstitution.

Stabilizers, e.g. *magnesium chloride*, *sorbitol*, etc. are added to the vaccines to maintain the potency during storage of vaccine and during manufacturing process.

Diluents, e.g. distilled water, normal saline or others are used to reconstitute lyophilized vaccines before use. Only the diluents recommended or supplied by the manufacturers should be used. Some diluents are vaccine specific, e.g. *calcium carbonate* or *citrated sodium bicarbonate* for different RV vaccines.

9.2 INDIVIDUAL VACCINES

Vaccines may be broadly classified as:

- ***Essential vaccines included in National Immunization Schedule,*** i.e. BCG, HBV, OPV, IPV, DPT/Td, RV, PCV, MR and Hib along with Japanese encephalitis (JE) vaccine, which is administered in endemic districts.
- ***Additional vaccines recommended by Indian Academy of Pediatrics (IAP),*** i.e. Hepatitis A, Varicella, Typhoid, HPV and Influenza vaccine.
- ***Vaccines recommended in special circumstances to high-risk children,*** i.e. meningococcal, cholera, rabies, yellow fever and pneumococcal polysaccharide (PPSV) vaccine.
- ***Newer vaccines*** including those under development or not yet available in country, e.g. malaria and dengue vaccines.

9.2.1 VACCINES IN NATIONAL IMMUNIZATION SCHEDULE

NIS in India include routine vaccination of all children with nine vaccines, i.e. BCG, HBV, OPV, IPV, DPT/Td, Hib, RV, PCV and MR, along with additional Japanese encephalitis (JE) vaccine in selected endemic districts. Human papillomavirus vaccine (HPV) is likely to be introduced soon.

BCG vaccine *(bacille Calmette-Guérin vaccine)* is the oldest amongst currently used vaccines (earliest vaccine was smallpox, used in 1798), named after its developing scientists – *Leon Charles Albert Calmette* and *Camille Guérin* (1921).

Contents: It is a *live attenuated vaccine* containing 0.1–0.4 million viable bacilli per dose. In India, *Danish strain* of *Mycobaterium bovis* is used to prepare BCG.

Supply and storage: BCG is supplied as a freeze-dried power in multi-dose, dark-colored vials (light sensitive) and should be reconstituted by mixing with diluents supplied with vaccine or sterile *normal saline* (not with distilled water, which is irritant) just before use. As it is extremely heat and light sensitive, reconstituted vaccine must be used within 3 hours.

Un-open ampoules should be stored in top-most compartment of refrigerator at 2–8°C.

Immunization schedule: BCG is given preferably at birth or the earliest possible opportunity within 48–72 hours of birth (not later than 7 days). *Catch-up immunization* is provided till 1 year in NIS, but recommended up to 5 years by WHO/IAP.

BCG vaccination is not advised in older children due to high likelihood of natural infection but may be given to older children if they are tuberculin-negative, on request.

Dose and administration: BCG is given intradermally over left shoulder as 0.05 ml at birth or 0.1 ml in older infants > 1 month of age. However, WHO recommends 0.05 ml till 1 years of age.

BCG is given with a tuberculin syringe and 26 gauge needle, after cleaning the site with sterile wet swab. Spirit or alcohol swabs as should not be used as it may affect the viability of live vaccine bacilli. On correct administration, vaccine should raise a transient wheal of >5 mm over injection site. SC or IM injected vaccines are rapidly cleared by lymphatics and may not induce desired immune response or may cause local complications.

After vaccination, the wheel disappears after 20–30 minutes and nothing is visible at site, followed by progressive induration after 3–4 weeks, ulceration after 6–8 weeks and scar formation after 10–12 weeks. In some children, the process of ulceration may be repeated 2–3 times, before eventual scarring.

Protective efficacy: Unlike other vaccines, BCG protects by inducing *cell mediated immunity* rather than humoral

immunity. Protective value of BCG is controversial, generally accepted as ~70–90% for severe disease, e.g. miliary or neurotuberculosis and 50–60% against pulmonary tuberculosis.

Successful uptake of BCG vaccine may be judged after 8–12 weeks, by local scar formation, tuberculin conversion or specific tests for cell mediated immunity. However, absence of scar does not necessarily mean absence of cell mediated immunity, which may disappear over time after 5–10 years. If a child fails to develop the scar after 12–16 weeks of vaccination, BCG may be repeated on the opposite side.

Side effects are rare and include:

- *Local reactions* including secondary infection or keloid formation are seen in 1:1000–10000 vaccinees despite correct administration, depending on strain and bacillary load in the vaccine. Danish strain used in India is more reactogenic.
- *Regional* lymphadenitis after ~4–8 weeks is not uncommon due to lymphatic spread of viable bacilli and no treatment is required except reassurance. It regresses spontaneously in next few weeks or months. However, suppurative lesions need antibiotics. Surgical drainage should be avoided to prevent sinus formation though very large nodes may be removed after completion of antibiotics, if required. Antitubercular therapy is not required even if FNAC is positive for AFB, which is expected due to presence of bovine bacilli in the vaccine.
- *Disseminated disease (BCGiosis)* is extremely rare (1:1–4 million) but may develop in immunocompromised children.

Contraindications are none, except congenital or acquired immunodeficiency states, e.g. AIDS and steroid/cytotoxic therapy. In *asymptomatic HIV* infected children, BCG vaccination is safe and should be given as a routine, unless they have evidence of severe immunosuppression.

DPT (Triple vaccine) is a combination vaccine against three diseases: Diphtheria, tetanus and pertussis. Depending on the pertussis fraction, this vaccine is termed as DTwP (containing whole cell killed bacilli) used in NIS; and DTaP (containing acellular pertussis antigens). DTaP is not provided in NIS. Another triple vaccine containing low-dose of diphtheria toxoid with acellular pertussis antigens (Tdap) is also available for use in older children > 7 years but not in NIS.

Other related vaccines without pertussis component include DT, Td (Low-dose diphtheria for use in older children ≥10 years and mono-antigenic tetanus toxoid.

DTwP and DTaP vaccines are also available as combination vaccines with HBV and Hib (pentavalent), some also containing IPV (Hexavalent).

Contents: DTwP contains diphtheria toxoid (25 Lf) tetanus toxoid (5 Lf) and killed whole cell pertussis bacilli (20,000 million).

Supply and storage: DTwP in NIS is administered as a pentavalent vaccine with HBV and Hib and should be stored in middle compartment of refrigerator (2–8°C).

Dosage and administration: *0.5 ml* of vaccine is given IM over lateral aspect of thigh.

Immunization schedule: In NIS, Primary doses of DPT are given as pentavalent vaccine at 6th, 10th and 14th week of life, followed by two boosters of stand-alone DPT at 15–18 months and 4–5 years.

Catch-up immunization below 7 years include three doses of DTwP at 0,1,6 months with a booster after 6 months of last dose. Second booster is not required if the last primary dose was given after 4 years of age.

DTwP/DTaP vaccines should not be used above 7 years of age for boosters or catch-up immunization (Low-dose diphtheria vaccines, e.g. Td/Tdap are used in them, if required).

Protective value is 100% for diphtheria and tetanus and ~80% for pertussis.

Side-effects are *mainly due to pertussis fraction* and include:

- *Local reactions, e.g.* pain, swelling and tenderness, which may be relieved with cold compresses.
- *Transient fever* for ~24 hours, which may be treated with paracetamol. Occasionally, it may lead to febrile seizures.
- *Rare but serious neurological events*, e.g. inconsolable cry, hypotonic-hyporesponsive episodes, seizures and encephalopathy.

Frequency of local reactions increases and systemic reactions decreases with increasing order of doses.

Inconsolable cry refers to >1 hour of continuous, inconsolable cry within 24 hours of vaccination. It occurs more frequently after the first dose and recurrence is unlikely after subsequent doses.

Hypotonic-hyporesponsive episodes (HHE) refers to sudden onset of limpness, reduced responsiveness and pallor or cyanosis within 48 hours of vaccination, (also reported with PCV vaccine). Recovery is spontaneous with no sequelae. Further doses may be given safely without recurrence.

Contraindications include:

- History of anaphylaxis or encephalopathy with previous dose.
- Progressive neurological disease

No pertussis-containing vaccines (not even DTaP) should be given as further dose in these cases (use DT). Cases with other neurological events may be given

further doses, if required, under caution and longer observation period, preferably in the hospital.

DTaP vaccines, instead of whole cell bacilli, contain two or more of the following five separately purified pertussis antigens—*pertussis toxin (PT), filamentous hemagglutinin (FHA), pertactin (PRN), and fimbrial hemagglutinins 1,2 and 3 (FIM type 2 and 3)*. It is also available in combination as pentavalent or hexavalent vaccine.

Not used in NIS, DTaP can be used with similar dose schedule and have lower incidence of local pain and fever following vaccination. While DTwP vaccines are marginally more immunogenic, IAP recommends use of DTaP as a substitute of DTwP for primary as well as booster doses. DTaP may also be preferred to DTwP in children for booster doses due to lower reactogenicity and in those with history of severe adverse effects after previous dose of DTwP. It should be noted that serious side-effects, e.g. anaphylaxis and encephalopathy may develop even after DTaP, which should not be used for further doses after history of such events to previous dose of DTwP/DTaP .

Tdap vaccine, contains lower dose of diphtheria toxoid (2.5 Lf instead of 25 Lf). While not included in NIS, IAP recommends single dose of Tdap for:

- All fully immunized adolescents at 11–12 years,
- All pregnant women at 27–36 weeks irrespective of previous doses,
- Catch-up immunization in fully/partially unimmunized children older than 7 years as the first dose, followed by subsequent Td dose/s, if required.

Catch-up immunization is advised till 18 years and more than one dose of Tdap is not recommended except in pregnancy.

Td, a bivalent vaccine containing low dose of lower dose of diphtheria toxoid (Diphtheria toxoid 2 Lf) has ***replaced TT*** in NIS for (a) Booster doses in children at 10 and 16 years, and (b) Two doses 4 weeks apart in early pregnancy, (single dose, if last pregnancy dose received within 3 years)

IAP also recommends Td as: (a) subsequent dose for catch-up immunization after first dose as Tdap, (b) booster doses to fully immunized children every 10 years, and (c) instead of TT for wound care.

DT (Diphtheria toxoid 25 Lf, Tetanus toxoid 5 Lf), is no longer recommended except in rare instances when pertussis containing vaccine is contraindicated in children < 7 years.

TT (Tetanus toxoid 5 Lf) has been replaced by Td for all indications, except for wound care in some circumstances.

Polio vaccine: Two types of polio vaccines are available—a live, oral, ***Sabin vaccine (OPV)*** and an inactivated, parenteral ***Salk vaccine (IPV),*** named after their developers, each with its advantages and disadvantages.

After the elimination of poliomyelitis from the country, India is gradually and cautiously shifting from OPV to IPV to minimize the risk of vaccine-induced poliomyelitis, more common with OPV. However, only IPV schedule is not yet advisable due to risk of importing wild virus from endemic countries and OPV providing better local gut immunity than IPV.

Both OPV and IPV vaccines are used in NIS as well as in IAP recommended schedule, though with some differences.

Contents: OPV is a *live attenuated, bivalent* vaccine, containing only serotypes-I and III, while IPV is an inactivated trivalent vaccine containing serotypes I, II, III.

India has removed type II serotype from OPV since 2016, after it was declared eradicated globally in 2015. (Now type III has also been declared globally eradicated since 2019, and all cases of poliomyelitis at present are due to type I only).

Supply and storage: OPV is supplied as multi-dose vials with dropper. It is *extremely heat-sensitive* and maintenance of adequate cold chain is extremely vital. It should be stored at-20°C in large depots, in the freezer at clinic level and must reach immunization center at 2–8°C in vaccine carriers.

Each OPV vial is marked with *vaccine vial monitor*, i.e. a sticker with a lighter square inside a darker circle (see **Fig 9.5**). *If the color of square is darker or matching the outer circle, vaccine is probably not potent and should not be used.*

IPV is supplied as a multi-dose vial in NIS and as a single dose vial/prefilled syringe outside the program. Single dose IPV is usually in short supply as a stand-alone vaccine, but available as commercial combination vaccines with DTwP/DTaP + HBV and Hib vaccines. IPV should be stored in middle compartment of refrigerator at 2–8°C.

Dosage and administration: OPV is given as 2 drops orally while IPV is given either as: (a) Fractionated dose of 0.1 ml intradermally in NIS ($_f$IPV), or (b) Regular dose of 0.5 ml IM/SC in private set-up (usually as combination vaccine).

Immunization schedule: In NIS, total five doses of OPV are recommended - at birth (*zero dose*), three primary doses at 6–10–14 weeks and a single booster at 16–24 months; along with three doses of fractionated IPV at 6, 14 weeks and 9 months. Additional OPV doses given during pulse polio campaign should not be counted in routine immunization.

IAP recommends only single dose (zero dose) of OPV at birth; followed by five doses of IPV including three primary doses at 6–10–14 weeks and two booster doses at 4–6 years.

Protective efficacy: OPV mainly provides local mucosal immunity by engaging receptor sites in the gut with

TABLE 9.2: Common Vaccines at a glance

Vaccine	*Type*	*Dose*	*Schedule*	*Protective efficacy*	*Adverse events*	*Contraindications*
BCG	Live	ID 0.05 ml[1]	At birth	50-60%[2]	BCG adenitis	Immunodeficiency
OPV	Live	PO 2 drops	*NIS:* 0, 6,10,14 wk, 16-24 mo (B) *IAP:* Zero dose only (at birth)	65-70%	VAPP/ VDPV	–
IPV	Inactivated	ID 0.1 ml IM/SC 0.5 ml	*NIS (ID):* 6, 10 wk, 9 mo *IAP (IM):* 6,10,14 wk, 16-18 mo (B1), 4-6 yr (B2)	>85%	Local, AFI-	–
DTwP/ DTaP	Toxoids/ Inactivated	IM 0.5 ml	*NIS:* (DTwP) 6,10,14 wk, 16-24 mo (B1), 5-6 yr (B2) *IAP:* (DTwP/DTaP) 6,10,14 wk, 16-18 mo (B1) 4-6 yr (B2)	100% for DT 80% for P	Local, AFI, HHE, seizures Encephalopathy	Progressive CNS disease, Anaphyalxis/ Encephalopathy with previous dose
HBV	Subunit	IM 0.5 ml	*NIS:* 0,6,10,14 wk *IAP:* 0,6,10,14 wk (or 6 mo)	>95%	Very rare	–
Hib	Conjugated	IM 0.5 ml	*NIS:* 6,10,14 wk *IAP:* 6,10,14 wk, 16-18 mo(B)	95–100%	Local, AFI	–
RV	Live	PO 5 drops[3]	*NIS/IAP*: 6,10,14 wk	50-60%	Intussusception	H/o Intussusception with previous dose
PCV	Conjugated	IM 0.5 ml	*NIS:* 6,14 wk, 9 mo *IAP:* 6,10,14 wk, 15 mo(B)	>80-90%	Local, AFI, HHE	AFI, HHE, seizures
MR/MMR	Live	IM/SC 0.5 ml	*NIS* (MR): 9-12 mo, 16-24 mo *IAP*: (MMR) 9 mo, 15 mo, 4-6 yr	M: >95% R: >99% Mumps>90%	Rash, TCP, SSPE	Immunodeficiency, untreated TB
JE	Inactivated	IM/SC 0.5 ml	*NIS:* 9-12 mo, 16-24 mo (in endemic districts only) *IAP:* 0,6 mo after 1 yr of age	90%	Local, AFI	AFI ?
Influenza*	Subunit	IM/SC 0.5 ml	6 mo, 7 mo > annually till 5 yr	55-60%	Local, febrile seizures, GBS	Egg allergy, H/O GBS
HAV*	Inactivated/ Live	IM 0.5 ml	Inactivated: 12 mo, 18-19 mo *Live:* Single dose at 12 mo	90-95%	Local, AFI	None
TCV*	Conjugated	IM/SC 0.5 ml	Single dose 6-9 mo	>98%		None
Varicella*	Live	SC 0.5 ml	15-18 mo, then after 3-6 mo	98%	MVLI, VCZ	Immunodeficiency, salicylate therapy
HPV*	Inactivated	IM 0.5 ml	Age 9-14 yrs: Two doses at 0,6 mo Age >14 yrs: Three doses at 0,1/2, 6 mo	90%		None

Starred (*) vaccines are not included in NIS at present.
Figures in parentheses after NIS/IAP denote total number of doses, required to complete immunization
[1]0.1 ml after 1 mo of age, [2]Over 80-90% for Neuro/Miliary TB, [3]Doses of commercial preparations vary from 2.5-5 ml,
AFI: Acute febrile illness; **B:** Booster; **GBS:** Guillain-Barré syndrome; **HHE:** Hypotonic, hyporesponsive episodes; **MVLI:** Modified varicella like illness; **SSPE:** Sub-acute sclerosing panencephalitis; **TCP:** Thrombocytopenia; **VCZ:** varicella zoster

vaccinia virus, thus preventing attachment of wild virus strains. While it is a highly potent live vaccine, both serotypes may not be taken up during each dose. Consequently, efficacy of the vaccine increases with increasing number of doses.

Protective efficacy of OPV is relatively less in developing counties like India (~65–70% after 3 doses) than in developed countries (~100%), perhaps due to interference with maternal antibodies and frequent presence of enteric infections preventing uptake of the vaccine.

OPV also provides herd immunity, even in unimmunized population due to excretion of vaccine virus in stools for variable period, which can infect the contacts to provide immunization.

IPV predominantly provides systemic immunity with seroconversion rate of >85% after three intramuscular doses. Fractionated interdermal doses are almost equally immunogenic at lower cost.

Side-effects: IPV is very safe except minor local reactions in some cases, while OPV carries potential but very rare risk of causing vaccine-related disease, as follows:

Vaccine associated paralytic polio (VAPP) is an extreme rare complication (1 per 2–4 million doses), more common with the first dose and in developed countries. In India, VAPP risk is lower, perhaps due to presence of maternal antibodies, birth dose of OPV and lower "*take-up*" of the vaccine. Defined as *acute flaccid paralysis with residual weakness for 60 days after the onset with isolation of vaccine virus in stools* (not wild virus), VAPP is caused by loss of attenuating mutations and reversion to neurovirulence during replication of the vaccine virus in the gut. VAPP may develop in the vaccine recipient (within 4–40 days of receiving OPV (*recipient VAPP*) or in contacts of the recipients, who is shedding of virus in stools (*Contact VAPP*).

Vaccine derived polioviruses (VDPV) denotes mutation of parent vaccine virus and recombination in the human gut with 1–15% divergence. These modified viruses are not only neurovirulent, but also transmissible and capable of causing outbreaks. VDPV are also classified as–cVDPV with evidence of virus circulation in the population, *iVDPV* in the immunodeficient person and *aVDPV* of ambiguous origin isolated from environmental sources without evidence of circulation. VDPV is more common following vaccination of immunodeficient children. Almost 90% of VDPV cases were due to Type II serotype, which has now been removed from the vaccine.

Possibility of VAPP/VDPV should be considered in any cases of acute flaccid paralysis with: (a) OPV vaccination in preceding 30 days, (b) contact with recently immunized child in preceding 60 days, or (c) pulse polio campaign in the community in preceding 60 days.

Contraindications are none, except for OPV in severe immunodeficiency states due to potential risk of VDPV in them or contacts. IPV may be safely used in these cases.

Measles containing vaccines (MCV) are combination vaccines including MR (Measles and Rubella) and MMR (Measles, Mumps and Rubella). Stand-alone measles vaccine has been withdrawn from India since 2018. Another combination vaccine of MMR with varicella (MMRV) is also available commercially. In NIS, only MR is used, though some states/cities provide one dose of MMR instead of second dose of MR at 16–24 months from their own resources.

Contents: All MCVs are live attenuated vaccines, containing *Edmonston-Zagreb* or *Schwarz* strain, containing of measles virus and *Wister RA/3M strain of rubella virus* (MR), *with or without Urabe Am 9* strain of Mumps virus (in MMR).

Supply and storage: Both MR and MMR vaccines are available as single dose or multi-dose vial containing lyophilized powder along with diluent and should be reconstituted before injection.

All MCV Vaccines should be stored at 2–8°C and once reconstituted, should be used within *6 hour*. Severe reactions, e.g. *toxic-shock syndrome* have been reported after delayed use of contaminated vaccine, which does not contain anti-bacterial preservative.

Dosage and administration: 0.5 ml IM or SC over anterolateral aspect of thigh for both MR and MMR vaccines.

Immunization schedule: IN **NIS**, two doses of MR vaccine are recommended at 9–12 months and 16–24 months, while **IAP** recommends use of MMR instead of MR with three doses at 9 months, 15 months and 4–6 years.

MCVs are not recommended before 9 months due to potential interference with maternal antibodies, though it may be given as early as 6 months during outbreaks. However any baby, who has received MCV before 9 months, should receive additional dose at 9 months to ensure adequate seroconversion. No boosters are needed, as single dose confers life-long immunity.

For catch-up immunization after 1 year of age, two doses of MMR are recommended with minimum four weeks interval. In adolescent girls, pregnancy should be excluded due to risk of congenital rubella syndrome.

Protective efficacy: Seroconversion rate for measles in 80–85% if given at 9 months and >95%, if given after 12 months of age. Seroconversion rate for rubella is even better >95% and >99% when given before or after 12 months respectively.

Almost all children vaccinated with MR after 12 months do not required second dose. However, high epidemiological risk of measles in infants aged 9–12 months in India has necessitated to provide MR vaccine as early as possible, i.e. at 9 months, followed by second dose after 12 months to ensure adequate protection.

Seroconversion rate for mumps-component following MMR vaccination is also good at ~90%, though antibody titers decline with time and third dose of MMR is recommended by IAP at 4–6 years to ensure by IAP, to ensure life-long protection against mumps.

Side effects: All MCVs are very safe, except mild local reactions, transient morbilliform rash after a week in 2–5% cases and transient thrombocytopenia as well as immunosuppression, which are often asymptomatic.

However, maximum number of immunization-related deaths are reported with MR/MMR due to inadequate aseptic precautions and bacterial contamination of the vial due to use beyond 4–6 hours.

Sub-acute sclerosing panencephalitis or SSPE (Ch 18.15) has been very rarely reported (< 1 per million doses) following MCV vaccinations.

Contraindications include (a) severe immunodeficiency states as these are live vaccines, (b) pregnancy due to potential risk of congenital rubella syndrome and (c) active untreated tuberculosis, as MCVs induce transient immunosuppression, which may fare-up the disease. MCV vaccinations should be deferred till antitubercular therapy has been given for 4–6 weeks.

Hepatitis B vaccine (HBV): Currently available HBV are recombinant vaccines, available as stand-alone vaccines or as combination vaccine with DPT, DPT+Hib, DPT+Hib+IPV or HAV.

Contents: HBV contains a suspension of alum-adsorbed recombinant HbsAg particles as 20 µg/ml.

Supply and storage: HBV is available as single or multi-dose ready-use vials with pediatric and adult dose formulations. In NIS, it is provided as pentavalent vaccine with DTwP and Hib.

Dosage and administration: HBV in children is given as 0.5 ml IM over anterolateral aspect of thigh. A higher dose of 1.0 ml is required for adults > 18 years of age.

Immunization schedule: In **NIS**, four doses of HBV are given, first dose within 24 hours of birth as stand-alone HBV (*Birth dose*) and subsequently 3 primary doses at 6–10–14 weeks as pentavalent vaccine with DTwP and Hib. IAP recommends similar schedule, but with last dose at 6 months of age rather than at 14 weeks.

Immunological response to HBV may be poor in preterms and LBW < 2000 gm, in whom the birth dose may be deferred till chronological age of one month (provided mother is HBsAg negative) or alternatively, the birth dose is given but not counted.

Infants born to HbsAg positive mothers should also receive HBIG (IM 0.5 ml) within 24 hours of birth along with HBV at a different site (Ch 15.4).

While three doses are enough to complete HBV immunization, birth dose is given additionally in routine immunization to ensure some protection to newborns of HBV positive mothers.

For catch-up immunization, only three dose schedule of HBV at 0, 1 and 6 months is recommended.

No booster is required, except in immunocompromised or occupationally exposed persons, in who antibody titers drop below the protective level over time (<10 mIU/ml) and booster dose may be needed after estimation of antibody titers.

Protective value: Seroconversion rate after 3 doses is >95%, with immunity lasing for >20 years. While antibody titers may decline with time, periodic testing is recommended only in children of HBsAg positive mothers, health workers and those with co-morbidities.

Side-effects are very rare, except local pain/erythema and transient fever in some cases.

Contraindications are none, except in rare instances of serious allergic reactions to previous dose.

***H. influenzae* B (Hib) vaccine:** Hib vaccine is available a stand-alone vaccine or as a combination vaccine with DPT, DPT+HBV, DPT+HBV+IPV, etc.

Contents: Hib vaccines are conjugated vaccines, containing a purified polysaccharide component of the organism, conjugated with a carrier protein to boost immunogenicity. Depending on the carrier protein, three Hib vaccines are available—HbOC (carrier mutant *C. diphtheria* toxin protein), PRP-T (carrier tetanus toxoid) and PRO-OMP (carrier *N. meningitidis* protein outer membrane protein complex), though last one is not available in India.

Supply and storage: Stand-alone Hib vaccines are lyophilized vaccines, supplied as single-dose (10 µg/0.5 ml) vials with diluent, to be reconstituted just before the use and should be stored at 2–8°C. However stand-alone Hib vaccines are not freely available in India at present and combination vaccines have to used.

Dosage and administration: 0.5 ml IM or SC, after reconstitution.

Immunization schedule for Hib varies with age, requiring three primary doses at 6, 10, 14 weeks followed by a booster at 12–18 months in infants <6 months, two primary doses at 0,1 month with a booster at 12–18 months in infants aged 6–12 months, and one primary dose and one booster after 8 weeks in children aged 12–15 months. Only single dose is required after 15 months of age, without any booster.

Vaccination beyond 5 years is not justified due to rarity of Hib infection, except in high-risk children, e.g. those with asplenia, splenectomy, sickle cell disease, etc. (Ch 9.4).

However in *NIS*, Hib is given as pentavalent vaccine at 6–10–14 weeks without any booster, while *IAP schedule* recommends one booster at 16–18 months, usually with DPT and IPV as combination vaccine.

Protective value: 95–100% for one year against culture proven invasive Hib disease. Hib vaccination also provides *herd protection* by reducing nasopharyngeal carriage of organisms.

Side effects are uncommon except mild fever and local reaction.

Contraindications: None, though dose should be deferred during acute severe febrile illness.

Rotavirus (RV) vaccine: Despite the high morbidity and availability of suitable vaccines, RV immunization was not widely used till recently due to potential fear of intussusception with older vaccines. With new generation RV vaccines, this risk has been minimized to acceptable limits and NIS has included RV in universal immunization program since 2016.

Contents: Currently, four RV vaccines are available in India-human monovalent vaccine (RV_1), human-bovine pentavalent vaccine (RV_5), human-bovine monovalent vaccine ($RHBV_1$) and bovine-human reassortant pentavalent vaccine (BRV-PV). $RHBV_1$ has been developed from a strain derived from Indian newborns and is being used in NIS, though all vaccines are equally effective and safe.

Supply and storage: $RHBV_1$ and RV_5 are liquid ready-to-use vaccine, while RV_1 and BRV-PV are lyophilized vaccines to be reconstituted before use with given diluents. All RV vaccines must be stored at 2–8°C and not be frozen.

Dosage and administration: All RV vaccines are given orally but in different doses – 0.5 ml $RHBV_1$, 1.0 ml RV_1, 2 ml RV_5 or 2.5 ml BRV-PV. *However, in NIS, a different $RHBV_1$ formulation is used, given as only 5 drops orally.*

Immunization schedule in *NIS,* three doses of $RHBV_1$ vaccine is given at 6,10 and 14 weeks with catch-up immunization at one month interval till 1 year of age (though $2^{nd}/3^{rd}$ dose/s may be given later, if the first dose was given before 1 year of age). WHO recommends RV vaccination till 2 years of age.

IAP also supports similar schedule at 6–10–14 weeks (only two doses at monthly interval are required for RV_1). However, it recommends that RV vaccination should be not be initiated after 15 weeks of age due to safety concerns and all doses should be completed by 32 weeks.

Protective value: All RV vaccines are equally immunogenic and protective, with reported efficacy of ~50–60% against severe RV gastroenteritis (SRVGE), for at least two years. Protective efficacy is lower in developing countries than in developed countries (~80–90%), due to interference by maternal antibodies, widely prevalent malnutrition and co-infection with other enteric pathogens.

Side-effects are none except a definite but very small risk of acute intussusception (~1–2/lac vaccines), specially after the first dose. However, benefits of vaccination to prevent SRVGE outweigh this miniscule risk.

Contraindications are none, except past history of intussusceptions. Vaccine can be co-administered with OPV.

Pneumococcal conjugate vaccine (PCV): Two types of pneumococcal vaccines are available—conjugate vaccine (PCV) for routine immunization and polysaccharide vaccine (PPSV), as an additional vaccine for high-risk children. PCV has been included in NIS since 2017. Following information pertains to PCV vaccines.

Contents: Currently three PCV vaccines are marketed in India, containing 10, 13 and 14 pneumococcal antigens. PCV_{10} is used in NIS. However, PCV with more than 14 serotypes are also in pipeline.

Supply and storage: All PCV vaccines are available as ready-to-use suspension in vials/prefilled syringes, which must be stored at 2–8°C and not be frozen.

Dosage and administration: 0.5 ml/dose IM for all vaccines.

Immunization schedule varies with age, requiring three primary doses at 6,10,14 weeks followed by a booster at 12–15 months in infants <6 months, two primary doses at 4 weeks interval with a booster in second year in infants aged 6–12 months, and two doses at 8 weeks interval after infancy. PCV_{13} needs only single dose after 2 years of age.

However in ***NIS***, total three doses of PCV_{10} are given as two primary doses at 6 and 14 weeks and a booster at 9 months with catch-up immunization till 1 year of age.

IAP recommends total 4 doses for routine immunization at 6, 10, 14 weeks and booster at 12–15 months, with catch-up immunization till 5 years of age, using manufacturers' recommended schedule.

PCV_{13} is also licensed for use as a single dose in older children 6–17 years and adults >50 years.

Protective value: All PCVs are equally immunogenic with >90% seroprotection following primary doses. However, protective efficacy depends on the number of serotypes included in the vaccine and number of doses. PCV 10 and 13 cover ~70% and ~80% of serotypes respectively, with protective efficacy of ~48%, ~87% and ~100% after 1, 2 or 3 doses respectively.

In general, protective efficacy of PCV is estimated to be ~80% against invasive pneumococcal disease due to vaccine serotypes and ~60% against all cases irrespective of serotypes, provided all primary doses are given before 6 months of age. Protective value is relatively less (~25–35%) against pneumococcal pneumonia or otitis media.

Side effects are rare and comparable with both vaccines, except local reactions and mild fever. Hypersensitivity,

seizures and hypotonic-hyporesponsive episodes have been rarely reported.

Despite excellent efficacy of PCV vaccines, a major concern is the ***Serotype replacement disease,*** i.e. causation of disease due to serotypes not including in the vaccine, thus offsetting the benefits of immunization. Surveillance programs have documented this phenomena in countries with high immunization coverage, despite substantial reduction in invasive pneumococcal disease.

Contraindications are none except severe allergy to previous dose or carrier protein, e.g. diphtheria toxoid.

Pneumococcal polysaccharide vaccine (PPSV) is an unconjugated polysaccharide vaccine containing 23 serotypes, responsible for >80% cases of serious disease. However, it is poorly immunogenic in children <2 years and does not reduce nasopharyngeal carrier state. It is given as single dose (0.5 ml SC/IM), *only* to high-risk children, i.e. those with chronic lung/heart disease, CSF leakage, cochlear implant, anatomical/functional asplenia, sickle cell disease and immunodeficiency. Revaccination is required after 3 years, but more than two doses are not recommended due to immunological hyporesponsiveness.

IAP does *not* recommend use of PPSV alone in these cases, who should receive PPSV only after completing age-related PCV immunization, at least 8 weeks after the last PCV dose. High-risk children, even if already vaccinated with PPSV, should receive recommended PCV doses.

Japanese encephalitis vaccine: Government of India has identified ~268 endemic districts for JE, where this vaccine is included in NIS. IAP recommends it only to—(a) children residing in endemic regions and (b) travellers to these regions, staying for >4 weeks.

Contents: Currently, three JE vaccines are licensed in India—one *live attenuated vaccine* derived from SA14–14–2 strain and two *inactivated vero-cell derived vaccines* from different strains, i.e. SA14–14–2 strain and 825146XY strain from Kolar, India. Of these, only live attenuated vaccine is used in NIS, though others are commercially available.

Supply and storage: Live JE vaccine is a lyophilized vaccine, to be reconstituted before use. Both inactivated vaccines are liquid suspensions. All vaccines must be stored at 2–8°C, though live vaccine is heat-stable at 37°C for 7–10 days.

Dosage and administration: Live vaccine is given as 0.5 ml SC over left upper arm (Right upper arm is used for MR vaccination during same visit), while inactivated vaccines are given as 0.5 ml IM (0.25 ml for SA14–14–2 vaccine in children <3 years).

Immunization schedule: under *NIS*, two doses of live JE vaccine are given at 9–12 months and 16–24 months, with catch-up immunization till 15 years of age (or even more in some states).

IAP recommends two doses of inactivated vaccines at one month interval after one year of age with catch-up immunization till 18 years of age.

Protective efficacy: Efficacy of live vaccine is ~90% with two doses and > 90% with both inactivated vaccines, though titers may decline gradually.

Side effects: All JE vaccines are equally safe except transient fever and local reactions in few cases.

Contraindications are none, though vaccination should be avoided during acute febrile illness.

9.2.2 ADDITIONAL VACCINES RECOMMENDED BY IAP

In addition to vaccines discussed earlier, IAP also recommends some other vaccines, which are desirable in all children but current logistics preclude their inclusion in the NIS and have to be purchased by parents. While *often termed as optional, these vaccines are of no less importance and should be offered to all children* after one to one discussion with parents. Some of these vaccines are being gradually introduced in NIS.

Human papillomavirus (HPV) vaccines: HPV is the commonest sexually transmitted infection in adolescents and adults, associated with development of genital warts and cervical, anogenital and oropharyngeal cancers in later life. High-risk serotypes 16 and 18 cause ~70% cases of cervical cancers.

India plans to introduce HPV vaccine soon in NIS, using an indigenously developed vaccine.

Contents: All HPV vaccines are recombinant vaccines differing in the number of serotypes. Currently, three types of HPV vaccines are available—a *bivalent* vaccine (HPV_2) containing serotypes 16 and 18, a quadrivalent vaccine (HPV_4) containing four serotypes 6, 11, 16 and 18 and a nonavalent vaccine (HPV_9) containing nine serotypes. First indigenous HPV_4 vaccine has also been launched in 2023, expected to be used in NIS.

Supply and storage: All HPV vaccines are single dose 0.5 ml ready-to-use suspension, which must be stored at 2–8°C and not be frozen.

Dosage and administration: 0.5 ml/dose IM for all HPV vaccines.

Immunization schedule: In India, HPV vaccines are licensed for use only in females from 9 years to 26 years of age, with 3 doses at 0, 1, 6 months (for HPV_2) or 0, 2, 6 months (for HPV_4 and $_9$).

However, IAP recommends 2-dose schedule at 0, 6 months in girls < 15 years, which is equally immunogenic. For older or immunocompromized girls, standard 3-dose schedule is recommended.

NIS plans to introduce indigenous HPV_4 in two-dose schedule for girls aged 9–14 years.

IAP also recommends two doses of HPV_9 or Indigenous HPV_4 at six month interval to all boys aged 9–14 years to prevent genital warts and anogenital cancers (not beyond 14 years).

Protective value: All vaccines are equally immunogenic with ~90% protection against HPV infection/disease due to vaccine serotypes in females, not infected till the time of vaccination. Pre-adolescent immunization is superior to the immunization in older females as the vaccine does not alter outcome of HPV16/18 infection already acquired before vaccination.

Side-effects are rare except mild fever and local reactions. Syncopal attacks are common in adolescent girls, who must be observed for 30 minutes after vaccination.

Contraindications are none except allergic reaction to previous dose and should be avoided during pregnancy.

Typhoid vaccine: In India, two types of typhoid vaccines are available, both active against Vi-capsular polysaccharide antigen: (a) polysaccharide vaccine (TPSV), and (b) conjugate vaccine (TCV), using a carrier protein, e.g. tetanus or diphtheria toxoid to boost its immunogenicity.

Contents: All TPSVs contains 25 µg/dose of capsular Vi antigens, while antigenic dose in TCV varies 5 to 25 µg/dose.

Supply and storage: All vaccines are supplied as single dose vials, to be stored at 2–8°C.

Dosage and administration: All vaccines are given as 0.5 ml/dose IM or deep SC.

Immunization schedule: *Not included in NIS*, IAP recommends a single dose of TCV to all children at 6–9 months of age, with catch-up immunization up to 18 years.

TPSV is no longer preferred due to poor immunogenicity of polysaccharide vaccines in children < 2 years and need for revaccination every 3–5 years.

Protective value of TCV is >98% after 42 days of vaccination. While antibody titers decline with time, all vaccinees are protected for 3–5 years and then, the immunity is expected to be further boosted due to subclinical natural infections.

Despite the high seroconversion rate of >98% after TPSV vaccination, protective efficacy is only 55–70% for 2–3 years.

Side-effects are rare, except local pain and erythema. Vaccines do not interfere with widal test reports.

Contraindications: None, except past history of allergy.

Hepatitis A vaccine (HAV): While recommended by the IAP to all children, HAV vaccine is particularly important in high-risk children, e.g. those with chronic liver disease, hepatitis B/C carriers, immunodeficiency states, transplant recipients, institutionalized children and travelers to endemic regions. HAV vaccine can also be used for post-exposure prophylaxis in household contacts of a case, when given within 10 days.

Contents: Two types of HAV vaccines are available in India—*inactivated vaccines* derived from HM 175/GBM or RG-SB strain and a *live attenuated vaccine* derived from the H2 strain. It is also available as a combination vaccine with HBV.

Supply and storage: Inactivated vaccines are liquid and ready to use, available in different formulations for children (0.5 ml) and adults (1.0 ml). Live attenuated vaccine is a freeze-dried vaccine, to be reconstituted before use. All vaccines need to be stored at 2–8°C.

Dosage and administration: *Inactivated vaccines* are given IM as 0.5 ml in children and 1.0 ml in adults >19 years. *Live attenuated vaccine* is given as 0.5 ml SC.

Schedule: Not included in NIS, IAP recommends either two dose of inactivated HAV 6–18 months apart during 12 to 23 months of age *or* only a single dose of live vaccine at 12 months age. Catch-up immunization is recommended till 10 years.

For catch-up vaccination in older children/adolescents >10 years, IAP recommends pre-vaccination screening for HAV antibodies due to substantial chance of natural infection and immunity by this age.

Combined HAV+HBV vaccine needs three doses at 0, 1, and 6 months.

Protective value is >90–95% for at least 10 years with both vaccines, followed by natural boosting. Single dose of inactivated or live HAV may also be used as post-exposure prophylaxis.

Side effects are uncommon, except mild fever and local reaction.

Contraindications are none, though dose should be deferred during acute severe febrile illness.

Varicella vaccine: IAP recommends varicella vaccine to all children without previous disease, with special emphasis in high-risk children, e.g. those with chronic lung/heart disease, immunocompromised states and institutionalized children attending crèches, day-care centers, or orphanages. It may also be used for post-exposure prophylaxis in contacts of a case, when given within 3 days of exposure.

Contents: It is a live-attenuated vaccine, prepared from *Oka strain* of varicella-zoster virus, with each dose containing minimum 1350 PFU (plaque forming units) organisms.

Supply and storage: It is supplied as a single-dose lyophilized powder with diluent, which should be stored at 2–8°C.

Dosage and administration: 0.5 ml subcutaneously (not IM).

Immunization schedule: IAP recommends two doses – first at 15–18 months and second after 3–6 months of the first dose. High-risk children may be given two doses at shorter interval of 8 weeks.

Catch-up immunization is recommended till 18 years with two doses at 8–12 weeks interval.

Protective value is ~85–90% with one dose and >98% with two doses, better for moderate to severe disease than mild disease. Varicella vaccine is also known to reduce the incidence of herpes zoster by ~50% in adults.

Side-effects are mild and transient, including local reactions. Some children may develop transient and mild papulovesicular eruptions after 1–3 weeks, termed as *modified varicella like illness or MVLI*.

Breakthrough varicella, usually with milder disease, has been reported >6 weeks following immunization in 1–4% vaccines, specially those vaccinated <15 months of age or in late childhood.

Herpes zoster is also known to occur with vaccine, but incidence is far less than in unvaccinated children.

Contraindications: Being a live vaccine, it should not be given to severely immunocompromised children or during pregnancy. Salicylates should be avoided for 6 weeks post-vaccination due to potential risk of Reye syndrome.

Influenza vaccines: IAP recommends influenza vaccine to all children annually from 6 months to 5 years of age and to high-risk children beyond this age including those with immunodeficiency states, diabetes or chronic cardiac, pulmonary, hematologic, renal or liver disease.

Contents: All available influenza vaccines in India are trivalent or quadrivalent *inactivated* vaccines (IIV), containing two serotypes A and one or two serotypes B viral strains, recommended by WHO annually, depending on prevalent strains in previous season. All vaccines include Pandemic 2009 H1N1 strain. Live attenuated influenza vaccines are available, but not in India.

Biologically, IIV are either split-virion or sub-unit vaccines, produced from highly purified and inactivated virus grown on embryonated hen eggs.

Composition of the influenza vaccines is changed annualy due to phenomena of antigenic shift and drift (Ch 10.26). WHO recommends two different set of vaccine strains every year-one for northern hemisphere in February and another for southern hemisphere countries in September. While entire India is in northern hemisphere, southern hemisphere vaccines are considered as more appropriate here, especially for south India.

Supply and storage: IIVs contain 7.5 or 15 µg hemagglutinin of each component strain, supplied as 0.25 or 0.5 ml single-dose vials or prefilled syringes, to be stored at 2–8°C.

Dosage and administration: IAP recommends a *uniform dose of 0.5 ml for all children* above 6 months of age, though some manufacturers recommend a lower dose of 0.25 ml in children <3 years due to higher reactogenicity and risk of febrile seizures in younger age group.

Immunization schedule: Not included in NIS, IAP recommends Influenza vaccination to all children from 6 months to 5 years of age, and in high-risk children beyond this age. Two doses at 4 weeks interval are recommended in first year of vaccination in children <9 years, followed by a single dose annually preferably just before the onset of peak influenza season. In children aged 9 years or above, adolescents or adults, only single dose is recommended, even if not vaccinated earlier

Protective efficacy: Reported efficacy of IIVs is ~59% for confirmed influenza and 36% for all influenza-like-illnesses, for one year.

Side-effects: IIVs are generally safe except for local reactions, higher risk of febrile seizures and rare risk of Guillain-Barré syndrome in some cases.

Contraindications: IIVs should be avoided in cases with egg allergy or past history of Guillain-Barré syndrome, unless expected benefits outweigh risks.

9.2.3 VACCINES FOR SELECTIVE USE

These vaccines are not recommended for routine immunization of Indian children, but only in high-risk children. While discussed in detail in relevant chapters on infections, some important selective-use vaccines include:

- **Anti-rabies vaccine (ARV)** for post-exposure prophylaxis after dog-bite or pre-exposure prophylaxis to occupational animal handlers (Ch 10.27).
- **Meningococcal vaccines** for: (a) international travellers, e.g. students going abroad for studies or (b) high-risk children with complement deficiency, anatomical or functional asplenia, splenectomy or sickle cell disease, (c) health care workers likely to be exposed to infection and for post-exposure prophylaxis in some cases (Ch 10.10).
- **Cholera vaccine for** residents and travellers of highly endemic regions and high-risk circumstances for the outbreaks, e.g. Kumbh mela. (Ch 10.11).
- **Yellow fever vaccine** for travellers to some African/South American countries. It is a live attenuated vaccine, given as single dose 0.5 ml SC, which fulfills the travel requirements (International certificate of vaccination and prophylaxis) valid for life. Efficacy is ~100% for at least 10 years. While generally safe, yellow fever vaccine carries a rare risk of Yellow fever vaccine associated neurological disease (YELAND) or viscerotropic disease (YELAVD).

9.2.4 NEWER VACCINES

Newer vaccines is a loosely-defined term encompassing large number of vaccines which are: (a) already available but not yet licensed in the country or (b) still in trial phase under development.

These vaccines include either the alternatives to the existing vaccines or vaccines against the diseases for which no vaccine is available till now. While detailed discussion on these vaccines beyond the scope of this book two newer vaccines deserve mention.

Dengue vaccine: CYD-TDV (Dengvaxia®) is the first and only licensed vaccine against dengue, being used in some endemic countries of Asia and Latin America, though several other candidates are under development.

Contents: CYD-TDV is a live attenuated, recombinant tetravalent vaccine containing four recombinant dengue serotypes.

Supply and storage: It is a freeze-dried single-dose or multi-dose formulation, to be reconstituted using 0.4% sodium chloride diluent (0.9% for multi-dose vials), before use. It should be stored at 2–8°C and used within 6 hours of reconstitution.

Immunization schedule includes total three doses of 0.5 ml subcutaneously, given at 6 months interval. While vaccine is licensed for use between 9–45 years of age, the optimal age of vaccination depends on local disease epidemiology (see WHO recommendations below).

Efficacy: Immunogenicity of the vaccine is higher in vaccinees who are seropositive to any serotype, (i.e. had evidence of prior dengue infection) before vaccination than in baseline sero-negative vaccinees.

Protective efficacy in trial participants aged 2–16 years was reported to be ~43%–76.9% for different serotypes, higher against the hospitalization and severe disease than in preventing symptomatic disease of any severity.

Safety: Side-effects include transient local reactions and minor systemic reactions, e.g. myalgia, headache and malaise in about half of the cases.

Outcome of CYD-TDV vaccination differs in sero-positive and seronegative individuals at the time of vaccination. In seropositive individuals, the vaccine acts as second infection with an attenuated virus, thus offering the protection but without complications. In seronegative individuals, the vaccine acts as the first infection, eliciting immune response. If these vaccinated case acquires second infection by wild virus, disease tends to be more severe as in the case of second of two natural infections in unvaccinated individuals.

WHO Global Advisory Committee on Vaccine Safety (GACVS) recommends that individuals who have not been infected with wild dengue virus (seronegative), should not be vaccinated with CYD-TDV as it confers a low level of protection during first 2 years but later followed by an increased risk of hospitalized and severe dengue.

Contraindications include severe immunodeficiency or allergic reaction to previous doses, apart from pregnancy and lactation.

WHO Recommends that

- Countries should consider introduction of the dengue vaccine CYD-TDV *only* if the minimization of risk among seronegative individuals can be assured.
- For countries considering vaccination in dengue control program, *pre-vaccination screening* is the recommended strategy, followed by vaccination of *only* seropositive subjects.
- If pre-vaccination screening is not feasible, vaccination without individual screening could be considered in areas with seroprevalence rates of at least 80% by the age 9 years.

Malaria vaccine: RTS, S (Mosquirix®) is the only vaccine against malaria licensed on pilot basis (2019) in three sub-Saharan African countries – Ghana, Kenya and Malawi, which has shown significant reduction in prevalence as well as severity of falciparum malaria. Recently, an indigenous malaria vaccine developed by Serum Institute of India *(R21/Matrix-MTM)* has also received WHO approval, though yet to be launched.

Contents: RTS, S is a pre-erythrocytic stage hybrid recombinant protein vaccine containing *P. falciparum* sporozoite protein fused with HBV surface antigen.

Supply and storage: RTS, S is a freeze-dried powder and needs to be reconstituted before use. It must be stored at 2–8 C and used within 6 hours of reconstitution.

Immunization schedule: As of now, the vaccine has been used only in children aged 5–17 months, given as 0.5 ml IM with four dose schedule-three doses at one month interval, followed by a fourth dose after 18 months.

Efficacy: Vaccine induces humoral as well as cellular response to prevent maturation and multiplication of sporozoites in liver. It has shown ~39% efficacy against the disease *per se* and 29% against the severe malaria on four years follow-up, along with significant reduction in hospitalizations and need for blood transfusions. Vaccine does not offer any protection against *P. vivax* malaria.

Safety: Vaccine is well tolerated except local side effects and increased risk of febrile seizures.

COVID vaccines: While many COVID-19 vaccines are available for Indian adults, very few have received approval for use in children. COVID immunization of children in India <18 years was started 16th March 2022, and as of now four COVID vaccines have used *emergency use authorization* (EUA) from Drug Controller General of India (DCGI) for children, as follows:

- **Covaxin** (Bharat Biotech) is being given to children >15 years as two dose schedule at 4–6 weeks interval by the government, though it has also received EUA for children above 6 years of age. Vaccine is also available for private sector.

- **Corbevax** (Biological E Limited) is being given to children >12 years (even for 12–14 years age group) as two dose schedule at 28 days interval by the government, though it has also received EUA for children above 5 years of age. Vaccine is also available for private sector.
- **Covovax** (Serum Institute of India) can be used in children >12 years with two doses at 21 days interval, though it has also received EUA for children above 7 years of age. However, it is not available through government centers.
- **ZyCoV-D** (Zydus cadila), first needle-less and first DNA Plasmid vaccine has also received EUA for children >12 years, though not provided though government centers.

9.2.5 COMBINATION VACCINES

Combination vaccines are immunization products which contain antigens of multiple infectious agents, e.g. DPT or MMR. However, vaccines which contain multiple strains of the same infectious agent, e.g. PCV, are better described as ***polyvalent vaccines***.

Combination vaccines containing two to six antigens are available in India at present **(Table 9.3)** and many more combination vaccines are being introduced in market.

Main advantage of combination vaccines is less number of pricks and fewer immunization visits with better compliance. However, these vaccines carry potential disadvantage of cumulative risk of adverse events. Human immune system is capable to respond to large number of antigens simultaneously and efficacy of most vaccines is not altered by concurrent administration as combination vaccines.

IAP recommends use of combination vaccines with following caveats:

- All licensed combination vaccines have an immunogenicity, efficacy and safety profile similar to separately administered component vaccines;
- Multiple vaccines should not be mixed in the same syringe, to prepare indigenous combination vaccine, unless specifically recommended by manufacturers.

TABLE 9.3: Combination vaccines available in India

Number of antigens	*Combination*
Bivalent (Two antigen) vaccines	DT or Td*
	MR*
	HAV+HBV
Trivalent (Three antigen) vaccines	DTwP, DTaP
	MMR
Quadrivalent (Four antigen) vaccines	DTwP+Hib
	DTwP+HBV
	DTaP+IPV
	MMRV
Pentavalent (Five antigen) vaccines	DTwP+HBV+Hib*
	DTaP+HBV+Hib
Hexavalent (Six antigen) vaccines	DTwP+HBV+Hib+IPV
	DTaP+HBV+Hib+IPV

*Combination vaccines used in NIS

9.3 IMMUNIZATION SCHEDULES

Immunization schedules vary from country to country and need to be revised time to time, depending on the: (a) local disease prevalence, (b) epidemiological features, e.g. common age of infection, (c) availability of safe and effective vaccine, (d) economic feasibility and cost-effectiveness, and (e) logistic considerations.

An appropriate immunization schedule should cover (a) as many prevalent diseases as possible, (b) as early as possible before the exposure to infection and (c) with minimum number of clinic visits to avoid inconvenience to parents and *drop-outs*.

Currently, two immunization schedules are followed in India – *National Immunization Schedule (NIS)* for immunization of general population through public resources and *IAP Immunization Schedule* recommended by Indian Academy of Pediatrics, for use in an individual child through private sector. Both schedules are often complementary and not contradictory.

9.3.1 NATIONAL IMMUNIZATION SCHEDULE

National Immunization Schedule (NIS) in India presently aims to prevent eleven diseases, i.e. Tuberculosis, Diphtheria, Pertussis, Tetanus, Poliomyelitis, Hepatitis B, H. influenzae B, Rotavirus, Pneumococcal infections, Measles and Rubella using nine vaccines, i.e. BCG, HBV, OPV, Pentavalent V, IPV, RV, PCV, MR and Td vaccines, apart from Japanese encephalitis vaccines in selected endemic districts **(Table 9.4)**.

This schedule has been adopted in all national child health programs and vaccines are provided by the government, free of charge.

TABLE 9.4: National immunization schedule

Age	*Vaccine*
Birth*	BCG* + OPV_0+ HBV_0
6 weeks	$DTwP_1$ + HBV_1 + Hib_1 + OPV_1 + $_fIPV_1$ + RV_1 + PCV_1
10 weeks	$DTwP_2$ + HBV_2 + Hib_2 + OPV_2 + RV_2
14 weeks	$DTwP_3$ + HBV_3 + Hib_3 + OPV_3 + $_fIPV_2$ + RV_3 + PCV_2
9–12 months	MR_1 + JE_1** + $_fIPV_3$ + PCV_3 (with Vit A_1***)
16–24 months	DTwP (B_1) + OPV (B) + MR_2 + JE_2**
5–6 years	DTwP (B_2)
10 years	Td
16 years	Td
Pregnancy	Td-Two doses in early pregnancy at 0,4 weeks Single dose only, if 2 doses received in last 3 years

* At birth in institutional deliveries/or at 6 weeks. **$_f$IPV:** Fractionated IPV

** JE vaccine only in endemic districts.

*** Vitamin A to be repeated every 6 months till 3 years

9.3.2 INDIAN ACADEMY OF PEDIATRICS (IAP) SCHEDULE

Indian Academy of Pediatrics (IAP) schedule NIS is the most practical but not necessarily an ideal schedule, as many useful vaccines have been left-out due to cost considerations or given at less than most appropriate age due to logistic considerations of a public health program.

IAP recommends more comprehensive immunization schedule, **(Fig. 9.2)** revised time to time in view of current disease patterns. Important differences between these two schedules are as follows. IAP recommends:

- *Seven additional vaccines* for universal immunization other than those included in NIS, i.e. TCV, IIV, HAV, MMR, varicella, Tdap and HPV. However, HPV is likely to be included in NIS soon.
- *Only one dose of OPV* at birth instead of total five doses at different ages in NIS.
- *Five intramuscular IPV doses*, including three primary doses at 6, 10, 14 weeks and two boosters at 16–18 months and 5–6 years, instead of three intradermal fractionated IPV doses at 6 and 10 weeks and 9 months.
- Use of DTwP or *DTaP,* instead of DTwP used in NIS.
- Single dose of *Tdap* (a) to all fully immunized children at 11–12 years instead of Td booster in NIS, (b) in partially immunized children at 7 years, who had missed second DPT booster, and (c) as first dose of catch-up immunization 7 years of age. It also recommends to replace all Td doses in pregnancy with Tdap.
- *Last HBV dose* should be administered not before 24 weeks of age and at least 16 weeks after first dose, whichever is later, instead of 14 weeks of age in NIS.
- *Four doses of PCV* at 6,10,14 weeks with a booster at 15 months instead of three doses at 6 weeks, 10 weeks and 9 months in NIS.
- *First dose of RV should not be given > 15 months and no dose after 32 weeks.* NIS provides RV til 1 years of age, though subsequent doses may be given even later if first dose was given before 1 year.
- *Three doses of MMR* at 9 months, 15 months and 4–6 years instead of 2 doses of MR (no MMR) at 9–12 months and 16–24 months in NIS.
- IAP also prescribes *catch-up immunization for children above 5 years*, while NIS is largely focussed on infants and children below 5 years.

9.3.3 MISSED (CATCH-UP) IMMUNIZATION

Despite best efforts, overall immunization coverage in India for UIP vaccines is ~76% (NFHS-V 2020–21) and substantial number of children miss vaccinations on due ages. To immunize them at earliest possible opportunity, following principles must be followed for catch-up immunization:

- Catch-up schedule must be tailored to achieve age-appropriate immunization as early as possible with minimum number of visits but without compromising basic principles, e.g. minimum dose interval, etc.

Fig. 9.2: IAP immunization schedule.

a: Within 24 h after birth; **b:** Extra dose permitted in combination vaccine; **c:** Can be given as combination vaccine; **d:** Not required for RV1; **e:** Preferably pre-monsoon, then single dose annually till 5 years age; **f:** Single dose for live vaccine; **g:** Second dose after 3–6 mo; **h:** After 7 years of age if second DPT booster not received, else single dose at 10–12 years, use Td, if Tdap not available; **i:** Two doses <14 years, 6 mo apart; **j:** Three doses after 14 years or in immunocompromised persons, **k:** Menactra® is approved as 2-doses between 9–23 mo at 3 months interval, Menveo® as single dose only after 2 years age

TABLE 9.5 : Catch-up (Missed) immunization

Vaccine (age limit)	*Schedule*
BCG (5 yr)	Single dose
DPT (None)	Age < 7 yr: DTwP at 0,1,6 mo, B after 6 mo[1] Age >7 yr: Tdap > Td > Td at 0,1,6 mo
IPV (5 yr)	3 doses at 0,1,6 mo or 2 doses at 0,2 mo or Single dose if received only bOPV (born after 25.4.2016)
HBV (None)	Three doses at 0,1,6 mo
Hib (5 yr)	*Age 6–12 mo:* 2 doses at 0, 1 mo, B after 8 weeks Age 12–15 mo: Single dose, B after 8 weeks Age 15 mo-5 yr : Single dose, no booster
RV (32 wks)	Two/Three doses at monthly interval[2]
PCV (5 yr)	Age 6–12 mo: 2-doses at 0,1 mo-B in 2nd year Age >12–23 mo: 2-doses at 0,1 mo, no booster Age > 23 mo: 2-dose PCV 10 (0,2 mo)/1-dose PCV 13
MMR (None)	Two doses at 0,1 mo
JE (18 yr)	Two doses at 0,3 mo
HAV[4] (10 yr)	Two doses at 0,6 mo (Inactivated) or Single dose (Live HAV)
Varicella (18 yr)	< 13 yr: Two doses, 0,3 mo > 13 yr: Two doses, 0–1 mo
Typhoid (18 yr)	TCV single dose (or,TPSV every 3 years)

[1]If last dose was given before 4 years.
[2]RV *immunization* should not be initiated beyond 15 weeks of age and all doses must be completed by 32 weeks.
[3]Exclude pregnancy before vaccination in adolescent girls, due to potentially risk of CRS.
[4]Pre-vaccination screening recommended at 10 years.

Multiple vaccines may be clubbed together in same visit to reduce the catch-up time.

- Upper age limit for catch-up immunization varies with the individual vaccines, determined by the need and safety issues and must be strictly followed.
- Partially immunized children should re-start catch-up immunization from the dose which was missed earlier *and not afresh*, irrespective of the period lapsed.

NIS permits catch-up immunization till the specified age-limits for individual vaccines, i.e. till one year for BCG, PentaV, RV, PCV; five years for OPV, MR; 7 years of DPT booster and 15–16 years for Td and JE vaccine, using same number/s and interval of doses as for routine immunization. These age limits and dosage schedules have been decided for programmatic reasons to cover most vulnerable population with available resources and use a simplified uniform schedule which can be delivered through public resources.

IAP recommendations for catch-up immunization are based largely on scientific basis and hence, might differ from NIS. Upper age limits are usually higher in IAP schedule except for RV vaccines and dosage schedules may differ from those used for routine immunization **(Table 9.5)**.

TABLE 9.6: Adolescent immunization

A. Age-specific adolescent immunization	
HPV (in Girls)	Age-9–14 years: 2 doses at 0 and 6 months Age > 14 years: 3 doses at 0, 1/2. 6 months
Tdap	Single dose, then Td every 10 years[1]
B. Catch-up childhood immunization (to complete total...)	
MMR	Two doses at 4–8 weeks interval
HBV	Three doses at 0,1 and 6 months
HAV	Two doses at 0 and 6 months
TCV	Single dose
Varicella	Two doses at 4–8 weeks interval
J. encephalitis	Two doses at 0–3 months (in endemic districts)

[1]Adolescents, who have not been immunized with DPT previously, must receive two further doses of Td at one month and six month interval (0,1,6 month) to complete catch-up vaccination, which is recommended till the age of 18 years.

9.3.4 ADOLESCENT IMMUNIZATION

Many children remain unimmunized/partly immunized till they reach adolescence. Adolescent immunization offers another opportunity to fulfill these immunization gaps. It also aims to: (a) protect against diseases with higher morbidity during adolescence, e.g. Hepatitis A, varicella, (b) boost the waning immunity of early childhood vaccines, (c) counter upward shift of age-epidemiology following expanding childhood immunizations, and (d) provide vaccines more relevant in adolescent age groups, e.g. HPV or vaccines for travellers going abroad for studies.

Catch-up vaccination of adolescent girls also offers some protection to their prospective off-springs from diseases like pertussis and congenital rubella.

Table 9.6 provides a guiding schedule for adolescent immunization, though needs to be individualized.

9.4 IMMUNIZATION IN SPECIFIC SITUATIONS

In following situations, immunization schedule has to be modified according to the needs and risk of complications.

Immunocompromised children are in greater need for vaccines due to susceptibility for infections but benefits may not be optimal due to poor immunological response. Further, there is potential risk of developing active disease following administration of live vaccines. General rules of immunization in these children include that:

- Live vaccines are contraindicated in severe immunodeficiency, but may be given in mild/moderate immunodeficiency, provided benefits outweigh the risks;
- Inactivated vaccines may be given but the protective value is unreliable and must be checked periodically

with antibody titers. If necessary, doses need to be repeated. Higher quantity or number of doses may be used in such cases, e.g. double-dose HBV.

- Household contacts of immunocompromised child should also be fully immunized to reduce the risk of exposure. However, they should not be given transmissible vaccines, e.g. OPV.

All routine vaccines, including live vaccines, may be given to asymptomatic HIV positive children without laboratory evidence of immunosuppression. However, live vaccines, e.g. BCG, OPV, measles and varicella are contraindicated in seropositive children with clinical AIDS or severely low CD4 counts. Inactivated vaccines are safe. IPV may be used instead of OPV in these cases (Ch 10.28).

Cancer chemotherapy: All live vaccines are contraindicated for 6 months after completion of therapy and inactivated vaccines may be given but should not be counted as valid doses. General considerations for immunization of a child on chemotherapy are as follows:

- No vaccine must be given during chemotherapy including pulse polio doses, except influenza (annual dose) and HBV (in unimmunized/partly immunized children).
- Influenza and varicella vaccines are also recommended for the contacts, who should not receive OPV including Pulse polio dose (replace with IPV, if needed). If given by mistake, contact sibling should remain away from cancer child for 2 weeks.
- Post-exposure prophylaxis for rabies must include passive prophylaxis for all bite categories and one additional dose of ARV at 90 days.
- Tetanus prophylaxis in wound care must include single Td dose irrespective of past immunization status, and tetanus immunoglobulins in all cases except in clean and minor wounds.
- Post-exposure varicella prophylaxis is must with VZIG, IVIG or high dose acyclovir in exposed children.
- Post-chemotherapy, immunization depends on the previous immunization status and should begin only after 6 months of completion of chemotherapy. While unimmunized or partially immunized children should receive catch-up immunization as usual, fully immunized children before chemotherapy should receive *a single booster dose* of age appropriate DPT, IPV, HBV, Hib, PCV, HAV, TCV, MMR and varicella. In children, who had received only OPV doses in the past, two IPV doses at one month interval are recommended.

Long-term steroid therapy: Efficacy of inactivated vaccines as well as safety and efficacy of live vaccines is doubtful in cases on prolonged corticosteroid therapy and general considerations for immunization in them are as follows:

- Children on low-dose systemic steroids or topical/inhaled steroids may be safely and effectively immunized with all vaccines, as also those on any dose of steroids for < 2 weeks.
- Children on high-dose oral steroids (prednisolone > 2 mg/kg/day or 20 mg/day or equivalent) for more than 2 weeks should not receive live virus vaccines until steroids have been discontinued for one month.
- Children with other immunosuppressant medications, e.g. Rituximab or TNF-α, should not receive live virus vaccines during therapy, except in special circumstances.

Preterms and LBW: Three major concerns regarding immunizations of preterm and LBW infants include high-risk of infections, uncertain immunogenicity due to immature immune system and logistic problems to give a vaccine to very small child. Some basic considerations regarding immunization of these children are as follows:

- BCG and OPV must be administered at birth irrespective of the weight or gestation, after stabilization and before discharge. However, HBV birth dose should be delayed till one month of age in babies <2000 gm at birth due to doubtful immunogenicity, *unless* delivered to an HBsAg positive mother.
- All subsequent vaccines may be given as per chronologic age (even if still in hospital), except RV vaccine, which should be deferred until discharge to prevent the health care-associated spread of virus in nursery.
- Since preterm and low birth weight babies have low muscle mass, smaller and thinner needles must be used in them for intramuscular injections.
- All HCW dealing with these babies should be appropriately immunized.

Sick children: General considerations for immunization in sick children with acute or chronic diseases, are as follows:

- Vaccinations can be safely given during *minor illnesses*, e.g. URTI, mild diarrhea, etc.
- Vaccination may be postponed during *moderate or severe acute illness* to avoid conincidental problems, e.g. febrile seizures wrongly attributed to the vaccine. However parents should be instructed to visit for immunization as soon as the child is better.
- No vaccine is contraindicated in children with *chronic systemic diseases*. In fact, special vaccines may be required in some cases, e.g. HBV in chronic liver disease, pneumococcal and influenza vaccines in cardiopulmonary disease, etc.
- Children with *hemorrhagic disorders*, e.g. haemophilia, may be given injectable vaccines subcutaneously or intramuscularly with a thinner needle and applying

the firm pressure without rubbing over the site for 5–10 minutes. In severe cases, vaccination may be given shortly after administration of clotting factor.

Blood products as well as other antibody products, e.g. immunoglobulins, (e.g. IVIG) may inhibit the immune response to live vaccines for variable period of time. Some considerations for immunization in recipients of blood or antibody products are as follows:

- All except live vaccines can be administered simultaneously, before or after an antibody-containing product without any interval criteria, but at different sites.
- MR/MMR and varicella vaccines should not be given until 6 months after blood product transfusions (3 months after saline washed RBCs), 10 months after IVIG, and 3–4 months after other specific immunoglobulins. Administration of an antibody-containing product within 14 days of MR/MMR or varicella vaccination might affect the vaccine uptake and the dose should be repeated after recommended time interval.
- Other live vaccines, e.g. yellow fever, Rotavirus vaccine, live attenuated influenza vaccine, and zoster vaccines may be given anytime.
- Low dose anti-D globulin to Rh-negative women is not an indication to defer rubella or varicella vaccination.
- HBV, TT/Td and ARV vaccines may be given simultaneously with corresponding immunogobulins but at different sites.

Solid organ transplant (SOT) recipients are immunocompromised even before the transplant due to the underlying disease and continue to be the same after procedure due to immunosuppressive therapy or graft rejection. Important considerations related to immunization for recipients are as follows:

- SOT recipients should complete all age-appropriate immunizations prior to the transplant, at least 2 weeks before the transplant (4 weeks for live vaccines), followed documentation of antibody titers. If required, varicella and MMR vaccines may be given even at 6–11 months of age.
- Post-transplant, live vaccines are contraindicated though catch-up immunization with other vaccines may be started after 6 months. IIV can be given after 1–2 months of transplant and then annually. Antibody titers may be checked after 6 months to decide the need for boosters, e.g. HBV booster.
- Household and health-care contacts of SOT recipients should be immunized with live vaccines, e.g. MMR, varicella etc and influenza to reduce the risk of transmission.

Haematopoietic stem cell transplant (HSCT) recipients are virtually unimmunized due to loss of all memory responses during marrow ablation and need to be re-immunized. Basic considerations in immunization of these cases are as follows:

- Age-appropriate immunization of the donor and recipients should be completed, at least 4 weeks before for live vaccines and 2 weeks before inactivated vaccines.
- Post-HSCT, recipients should be considered as *"never vaccinated"* regardless of pre-HSCT vaccination status and need to be *re-immunized* with all inactivated vaccines, after 6 months of procedure. However, IPV, Hib, PCV and IIV can be given after 3–4 months. Additional doses may be needed for HBV or PCV13.
- Live vaccines should not be administered to HSCT patients with active GVHD or ongoing immunosuppression. MMR and varicella vaccines may be administered after 24 months, if the recipient is presumed to be immunocompetent and 8–11 months after last dose of IVIG.

Splenic dysfunction due to congenital asplenia or secondary to sickle cell disease, splenectomy or radiation therapy render children susceptible for serious infections with encapsulated organisms and important immunization considerations in these cases are as follows:

- No vaccine, including live vaccines, is contraindicated and they should all receive all age-appropriate immunizations, with special emphasis on PCV, Hib, and typhoid vaccines.
- In addition, they should also receive: (a) two doses of MCV at 8 weeks interval after 2 years of age, (b) single dose of Hib vaccine, if not received till 5 years of age, (c) age-appropriate dose/s of PCV, and (d) asingle dose of PPSV after 8 weeks of PCV (and at least 2 weeks before surgery). PPSV must be repeated once after 5 years.
- For *emergency splenectomy*, vaccination should begin at least 2 weeks after the surgery rather than immediately, for better antibody response with: (a) MCV_1, PCV and Hib (if not received earlier), followed after 8 week by (b) MCV_2 and PPSV. PPSV must be repeated once after 5 years.

9.5 IMMUNIZATION PROGRAMS

Operative strategies to achieve adequate immunization keep on changing according to the needs and evaluation assessments. This chapter deals with some important strategies and program to deliver immunization services.

9.5.1 UNIVERSAL IMMUNIZATION PROGRAM

Universal immunization program (UIP), launched on November 19th 1985 to enhance immunization coverage in India, is currently a component of *Reproductive*

Maternal, Newborn, Child and Adolescent Approach (RMNCH+A) since 2013, under National Health Mission.

India has one of the largest immunization program in the world targeting 2.6 crore newborns each year. First country-wide immunization program in India, i.e. *expanded program of immunization* (EPI) was launched in 1978, which was later modified as *universal immunization program* (UIP) to widen the coverage. In 1992, it was incorporated in *Child Survival and Safe Motherhood Program* and then in *Reproductive and Child Health Program* (1997) under *National Rural Health Mission* (2005) and then *National Health Mission* (2013).

Aims: UIP currently aims to provide coverage against twelve vaccine preventable diseases in infants (*tuberculosis, poliomyelitis, diphtheria, pertussis, tetanus, hepatitis B, H. influenzae B, rotavirus, pneumococci, measles* and *rubella)* as well as *Japanese encephalitis* in endemic districts, using National Immunization Schedule (NIS). It also provides for tetanus immunization in pregnant mothers.

Components: Important components of UIP are:

- Universal immunization of infants and pregnant mothers,
- Improved vaccine production and quality control,
- Spread of public awareness,
- Training of health personnel, and
- Surveillance of vaccine preventable diseases.

Strategies: Important strategies adopted by UIP are as follows:

- *For universal immunization:*
  - Routine immunization as per NIS,
  - Intensified immunization programs, e.g. Mission Indradhanush, pulse polio immunization, MR campaign
  - Targeted immunization in high-risk areas, e.g. mop-up rounds.
- *For vaccine production:*
  - Encourage and support private sector participation.
  - Increasing production in public sector.

  India is self-sufficient in production of all UIP vaccines except OPV.
- *For quality control:*
  - Maintenance of adequate cold-chain.
  - Batch-wise testing of vaccines at production/import level and random testing at field level.
  - Adequate supply of refrigerators, vaccination materials, e.g. syringes, etc. and *electricity*.
- *For public awareness:*
  - Information, education and counseling (IEC) activities, using mass-media.
  - Involvement of local community leaders and non-governmental organizations.
- *For regular training:*
  - Periodic training of field workers.
  - Distribution of training material and guidelines.
- *For vaccine surveillance:*
  - Periodic immunization coverage studies.
  - Periodic review of the local disease prevalence.

Evaluation: Reported coverage for all UIP vaccines in India at present is ~76.4% according to NFHS-5 2021 data **(Table 28.3)**, with best coverage for BCG (95.2%) and least for second dose of MR (31.9%). There is also gross disparity between immunization coverage in different states and urban *vs.* rural areas.

While targeted 100% immunization coverage is yet to be achieved, success of this program is reflected in marked decline in morbidity and mortality rates due to vaccine preventable diseases.

9.5.2 MISSION INDRADHANUSH

Mission Indradhanush was launched on 25th December, 2014 with an objective to ensure full (>90%) immunization of children below two years by 2020 and pregnant women by year 2020, specially in low-coverage districts. *Indradhanush* represents seven colors of rainbow—targets to immunize against seven vaccine preventable diseases—*tuberculosis, diphtheria, pertussis, tetanus, polio, hepatitis B and measles,* initially included in the program.

First phase began on 7th April, 2015, the World Health Day, with four week-long monthly rounds of intensified immunization in selected high-priority districts with <50% immunization coverage. Within the districts, the mission focused on high-risk settlements of nomads and migrant labor, forest-dwellers, tribal regions, inaccessible geographical areas and urban slums. Zinc tablets and ORS packets were also freely distributed during these rounds to protect against diarrhea.

Since then, the program has been conducted in different phases, the latest being **Intensified Mission Indradhanush 5.0,** launched in 2023. Unlike previous phases, Mission Indradhanush 5.0 covered whole country (rather than high-priority populations) with three rounds at monthly interval to provide all *due/missed* vaccines under NIS to children below 2 years.

Global alliance for vaccine and immunization (GAVI): GAVI is an international coalition of funding agencies, National Health Programs of various countries and NGOs to independently fund or raise new resources: (a) to improvement of immunization services and coverage in developing countries, (b) to fund research and development activities for newer vaccines, and (c) to promote safe immunization practices. India mainly receives GAVI support for HBV and pentavalent vaccine along with supply of vaccination equipment and injection safety programs.

9.6 COLD CHAIN SYSTEM

Vaccines, being the biological agents, are likely to lose their potency when exposed to higher (or lower) than the recommended environmental temperature. This exposure can occur at the level of manufacture, transport, storage or administration.

Loss of vaccine potency depends not only on the degree of temperature but also on the duration of exposure and type of vaccine. Live vaccines, e.g. OPV and measles are most heat-sensitive and lose their potency rapidly on heat exposure. Inactivated vaccines, specially those containing aluminium adjuvants, e.g. DTwP/DTaP/HBV, HAV, HPV and PCV are usually more heat stable but should never be frozen, as they deteriorate on thawing.

Cold chain is an operational term to define *a system of transporting and storing the vaccines at recommended temperatures from the manufacturers' level till the point of administration*. *Desired temperature zones* for storage and transport of most vaccines is:

For short-term (1–2 months) storage: 2–8°C

For long-term storage: –20°C

In addition, lyophilized vaccines, e.g. BCG, MR/MMR, varicella and rotavirus vaccines are also sensitive to light exposure.

Components: Essential components of cold chain include:

- Supply of *appropriate pieces of equipment* to maintain the desired temperature during transport, storage and immunization sessions,
- Provision of *quick transport* facilities to decrease the risk of exposure to high temperatures,
- *Training of the people*, who organize and manage vaccine distribution,
- Continuous as well as periodic *surveillance* for efficacy of cold-chain maintenance.

Tools (equipment) to maintain adequate cold chain system include **(Table 9.7)**:

- *Walk-in coolers* to store large amounts of vaccines at the state and/or regional centers.
- *Deep freezers* for long-term storage of OPV and MR/MMR vaccine at –20°C.
- *Ice-lined refrigerators (ILR)* are top-open refrigerators, acting as a buffer in case of power failure.
- *Purpose-built or dedicated refrigerator* is essential equipment for the routine storage of vaccines at clinics and small hospitals. In refrigerators, *OPV vaccine should be kept in freezer compartment, BCG, MR/MMR and varicella vaccines on the top-shelf, other vaccines in middle-shelf/s, and diluents in the lower-most shelf* **(Fig. 9.3)**. A dial thermometer should be kept in the upper-shelf to monitor the temperature.

TABLE 9.7: Common cold-chain equipment used under UIP at different storage centers

Site	*For OPV*	*For other vaccines*
Central and state Depots	Walk-in-freezer (–15 to-25°C)	Walk-in-cooler (2–8°C)
District centers	Deep freezer (–15 to-25°C)	ILR (2–8°C)
Primary health center	ILR (2–8°C)	ILR (2–8°C)
Sub-centers	Cold boxes (2–8°C)	Cold boxes (2–8°C)
Immunization sites	Vaccine carrier (2–8°C)	Vaccine carrier (2–8°C)
Private practice	Purpose built Refrigerator* (2–8°C)	Purpose built Refrigerator (2–8°C)

Hold-over time (at 43°C): Deep freezer 2.5 hours, ILR 20 hours, cold box 48–96 hour, vaccine carrier 36 hours

* Avoid domestic refrigerators

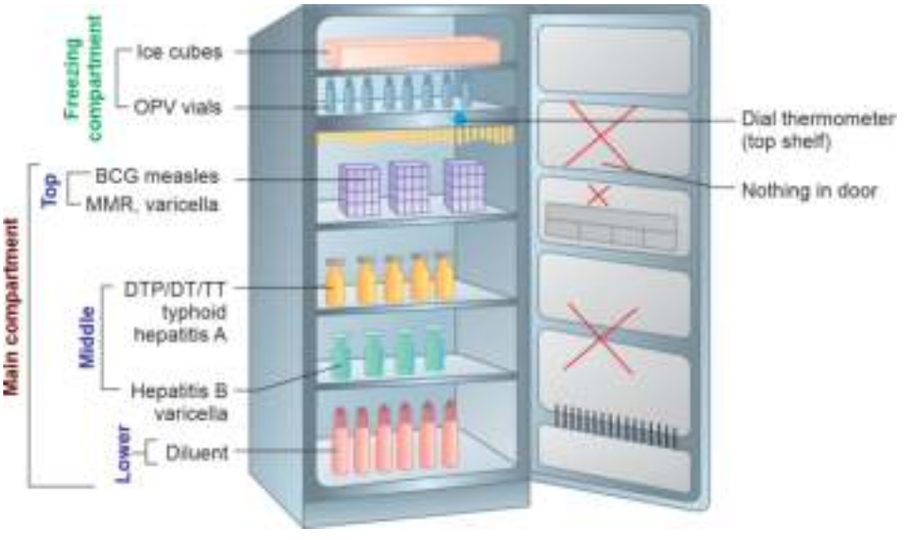

Fig. 9.3: Correct method of vaccine storage in refrigerator.

Fig. 9.4: Vaccine carrier.

Enough ice cubes and vaccine carrier packs should be kept in the freezer compartment to keep the vaccines cool in case of power failure. Nothing should be kept in the door of the refrigerator.

Refrigerators used for vaccine storage, should not be used for any other purpose, e.g. water/drug storage, to avoid unnecessary opening of doors.

Domestic refrigerators should not be used for storage of vaccines due to wild temperature fluctuations during frosting-defrosting cycles and frequent door opening. However if used in absence of alternatives, it should be: (a) frost-free with no heating cycles, (b) have separate door for freezer, (c) accessible only to vaccination staff and not used to store other things, e.g. water, and (d) temperature is maintained at 2–8°C with freezer temperature below –5°F (–15°C).

- *Vaccine carriers or isothermic boxes* are used to carry small amounts of vaccines from refrigerator to the site of immunization session. In these carriers, safe temperature can be maintained for 6–8 hours. Frozen ice packs are used to line the side of the box and a dial thermometer should be kept inside to record the temperature. The vials of DTwP/Td should first be wrapped in plastic sheets before keeping inside, to avoid freezing **(Fig. 9.4)**.

Vaccine van is an insulated van used for bulk transport of vaccines from central or regional depots to district centers. Vaccines should be transported only in cold boxes, which should be loaded in the vaccine van immediately after packing. At destination, these boxes must be unloaded as early as possible and vaccines should be transferred to the ILR immediately.

Monitoring of cold chain is done by: (a) regular check with dial thermometers, (b) vaccine-vial monitors, and (c) random collection of vaccine samples from distribution and field sites for laboratory potency testing. Some other monitoring tools include freeze-indicators, data-loggers and other types of thermometers.

Fig. 9.5: Vaccine vial monitor.

Vaccine Vial Monitor (VVM) is a sticker fixed over many of the heat-sensitive vaccine vials to identify whether the vaccine has been damaged by exposure to heat and should not be used. It includes a lighter square made of a heat-sensitive material inside a darker circle. On exposure to higher ambient temperatures, the color of the square darkens irreversibly. *If the color of square is darker or matching the outer circle, vaccine is probably not potent and should be discarded* **(Fig. 9.5)**.

VVMs are unique to each vaccine and are of four types: VVM 30, VVM 14, VVM 7 and VVM 2, with the number corresponding to the number of days the vaccine remains potent on exposure at +37°C. In combination vaccines, the VVM corresponds to the most heat-sensitive component of the vaccines, e.g. VVM on DPT vial corresponds to the pertussis component of the vaccine.

VVM is not a substitute of expiry date and vaccine may also degrade due to other factors, e.g. light exposure, which is not indicated by VVM.

9.7 ADVERSE EVENTS FOLLOWING IMMUNIZATION (AEFI)

All vaccines are extremely, but not absolutely, safe and adverse reactions are rare but do occur after vaccinations.

Definition: *Adverse event following immunization* (AEFI) is defined as "*an untoward medical occurrence which follows immunization and which does not necessarily have a causal relationship with the usage of the vaccine*." This adverse event may be any unfavorable or unintended sign, an abnormal laboratory finding, a symptom or a disease.

Classification: AEFI are classified according to the probable cause, frequency and severity.

Causality-wise, AEFIs are classified according to probable cause, as follows:

- ***Vaccine-product related reaction,*** due to inherent property of the vaccine product/s, e.g. VAPP following OPV or febrile seizure following DTwP vaccination.
- ***Vaccine-quality defect related reaction,*** due to rare qualitative defect/s in the vaccine or its delivery device provided by manufacturer, e.g. insufficient inactivation of the constituent pathogen or contamination during manufacturing process.
- ***Immunization-errors related reaction*** (programmatic errors), due to inappropriate handling, prescribing or administration, e.g. injection abscess, sciatic nerve injury or toxic-shock syndrome due to contamination of vials.
- ***Immunization-anxiety related reactions,*** during or before the vaccination, e.g. syncope or breath-holding spell.
- ***Coincidental events,*** due to something other than the above factors with a chance temporal association. Considering the sheer number of children immunized, these events are inevitable which can be falsely attributed to immunization.

Frequency-wise AEFI are classified as: *Very common* (>10%), *common* (1–10%), *uncommon* (0.1–1.0%), *rare* (0.01–0.1%) and *very rare* (<0.01%).

Severity-wise these reactions are classified as:

- ***Minor vaccine reactions,*** which are very common and include local reactions, e.g. pain swelling, redness, etc. at the injection site or systemic reactions, e.g. fever, irritability, malaise or others, e.g. rash after measles vaccine. These reactions may be due to the vaccine-product or other excipients.
- ***Severe AEFI*** are of minor medical significance but perceived to be severe in terms of intensity, e.g. high fever.
- ***Serious AEFI*** are potentially life-threatening, which may result in death, significant disability (including birth defects), hospitalization or require intervention to prevent permanent damage, e.g. anaphylaxis, seizures, intussusception, etc. AEFI, seen in clusters should also be considered as serious, due to adverse publicity and consequences on acceptance of immunization program.

Clinically, AEFRs may present immediately or after many days, with:

- ***Local reactions, e.g.*** pain, erythema and induration. These reactions are more common with DTwP and vaccines containing aluminum adjuvants. *Frequency of local reactions tends to increase with subsequent doses.* These reactions may be partly ameliorated by local ice packs application and paracetamol.
- ***Systemic reactions:*** Fever is the most common systemic reaction, more common with DTwP and vaccines containing aluminum-adjuvants. *These reactions tend to decline with increasing number of doses.* Although prophylactic paracetamol may reduce the incidence of post-vaccine febrile reactions, it has been found to blunt immune responses of some vaccines and should be used judiciously. Postvaccine fever rarely last for >48 hours and any fever persisting beyond this time should be evaluated for other causes.
- ***Allergic reactions*** are rare and may present with variable severity, ranging from mild urticaria to life-threatening anaphylaxis. These reactions are rarely due to the vaccine antigen, usually caused by other vaccine constituents, e.g. residual animal protein (egg), stabilizers or preservatives (thiomersol). Since occurrence of anaphylaxis cannot be predicted in most cases vaccines, all vaccines should be observed for 15 minutes and patients with history of serious allergy to any of the vaccine constituents should not receive the vaccine.

Reporting: Any health care provider, whether in public or private sector, who comes across any AEFI, must report it to local health authorities, immediately in case of:

- Serious AEFI leading to death, disability, hospitalization or occur in clusters.
- Signal and events associated with a newly introduced vaccine;
- AEFI, probably due to immunization-error related reactions;
- Any other significant events of unexplained cause within 30 days of immunization.

Causality assessment: All reported AEFIs are investigated by specialists to: (a) ascertain diagnosis and availability of sufficient data for causality assessment, (b) objectively evaluate available facts of the case on the basis of a check-list, (c) assess the strength of association on the basis of an algorithm, and (d) classify the case, as follows:

- ***Consistent*** *causal association* to immunization, with further sub-classification as the reaction being: (A1) vaccine-product related, (A2) vaccine-quality related, (A3) immunization error and (A4) anxiety-related;
- ***Indeterminate,*** with further sub-classification as (B1) consistent temporal relationship but insufficient evidence, and (B2) conflicting qualifying factors;
- ***Inconsistent*** *causal association* to immunization or coincidental, and
- ***Unclassifiable***.

9.8 SAFE IMMUNIZATION PRACTICES

Immunization is a unique medical intervention in the sense that the child is otherwise healthy and any error or compromise on the safety may have serious medical, ethical and legal dimensions apart from negative impact on the acceptability of immunization programs.

This chapter deals with important recommendations and suggestions to make immunization a safe event in practice.

9.8.1 COUNSELING AND VACCINE HESITANCY

All children should be assessed for their immunization status, preferably by reviewing their immunization card at every point of health care contact, even if they are sick or presented for different reasons. Indirect clues, e.g. presence of scar, age and site of previous vaccinations, price paid for the same in private sector, etc. may be used to identify the vaccines received earlier, if required.

A new card should be filled out, if the old immunization card is lost or not available, identifying all the vaccine/s the child needs now, including those missed earlier. Any recommended immunization schedule – NIS or IAP, may be used to customize individual vaccination requirements, with due considerations for contraindications or precautions.

Appropriate communication with parents is the key to let them appreciate the need for a vaccine and should provide information about:

- Potential risk of developing the disease or its complications.
- Efficacy of the vaccine must be informed in realistic terms. No vaccine is 100% effective and failures do occur but even then partial protection is expected to reduce the morbidity and complications.
- Safety of the vaccine must also be explained with risk of potential side effects. However, parent must be explained that benefits of vaccination outweigh the risk of side-effects and most side-effects are minor, transient and easily manageable.
- *Cost of the vaccine* is an important consideration for parents visiting private sector and should be informed in advance along with available alternatives. Parents should also be informed regarding free-of-cost availability of some vaccines under NIS.

Appropriate counseling will go a long way to alleviate parental apprehensions and ensure compliance. However, *a written consent is not necessary before vaccination* (IAP).

Vaccine hesitancy, i.e. the *reluctance or refusal to vaccinate despite the availability* of vaccines has been recognized as one of the leading threats to global health. WHO's Strategic Advisory Group of Experts (SAGE) defines vaccine hesitancy as an individual's behavior, influenced by the 3Cs ***C****onfidence,* i.e. trust or no trust in the vaccine or provider; ***C****omplacency,* i.e. perceived need or value of the vaccine, and ***C****onvenience,* i.e. ease or difficulty of access. It is the duty of HCW to identify the reason/s for vaccine hesitancy in care-givers and allay their concerns.

9.8.2 SAFE IMMUNIZATION PRACTICES

All injections involve breach in the continuity of skin hence, are potentially unsafe, according to a WHO report, ~30% of injections used for vaccinations worldwide are unsafe. A safe injection should not only harm the recipient, but also not expose the provider to avoidable risk or result in a waste that is dangerous to other people. Important recommendations of safe injection practices are as follows:

- ***Hand-washing:*** HCW should wash the hands with soap and water, if visibly dirty or may disinfect with an alcohol-based hand-rub between patients. Gloves are not necessary, though single-use gloves may be used and changed, if soiled. A HCW should avoid giving injections, if suffering from a local infection or cut which may come in contact with injected substance or blood or body fluids.
- ***Examine the vaccine product:*** Each vaccine vial must be examined for the name, expiry date and batch number, date of opening the multi-dose vial and status of vaccine vial monitor if present. Similar scrutiny is also necessary for diluents, if applicable.
- ***Prepare the vaccine:*** While many vaccines are currently available as single-dose pre-filled products, many others need to be drawn from multi-dose vials or reconstituted before use. Following precautions are necessary while preparing a vaccine for administration
  - Vaccine shot must be prepared in a clean designated area where blood or body fluid contamination is unlikely.
  - All vaccines must be prepared fresh and should not be kept as pre-filled syringes in advance.
  - Vials should be checked for cracks and leaks as well as any suspended particles in the contents before use.
  - Swabbing the vial-top with antiseptic or disinfectant is not necessary though vials may be cleaned with a dry single-use antiseptic swab and not by stored wet-cotton balls.
  - Each vaccine must be reconstituted as per manufacturer's recommendations, using *only* the diluents supplied by the manufacturer, if required.
  - Multi-dose vials carry higher risk of contamination and should be used strictly as per *Open-vial Policy.* Under *Open-vial Policy*, open multi-dose vials of some vaccines may be used in subsequent immunization sessions for up to maximum four weeks, provided: (a) expiry date has not passed, (b) vial was stored under appropriate cold-chain conditions, (c) vial septum is visibly clean and has not been submerged in water, (d) aseptic techniques were used to withdraw previous doses, and (e) vaccine vial monitor, if attached, has not reached the discard point.

- Needle used to withdraw the vaccine from this vial should not be left behind in the septum for redrawing, to avoid contamination.
- Whenever possible, vaccine shot must be prepared away from the sight of the child to avoid anxiety.

- ***Positioning the child:*** Unexpected motion at the time of injection may injure the child or cause needle-stick injuries to the HCW. Correct positioning with gentle restraining of the child is important to avoid such accidents.
  - Child is usually more comfortable in presence of mother, who should be permitted to participate in positioning of the child to minimize the anxiety.
  - Choice of the position depends on age of the child and site of administration, while *Cuddling* or *lying-down* position is preferred for infants, older children may be permitted to sit upright in mother's lap or held in the *straddle* position. School children may be immunized sitting upright independently, if cooperative **(Fig. 9.6)**.
  - Forcible restraining is not advisable, though a parent (or assistant) may tuck the child's legs between theirs to secure them or hold the child's free arm.
  - Even though the child is securely positioned and restrained, she/he should be gently informed about the injection.
- ***Route of administration:*** Vaccines are usually administered via intramuscular, subcutaneous or intradermal route **(Fig. 9.7)** as per the manufacturer's instructions or national guidelines, which are not interchangeable and should be strictly followed.
  - *Intramuscular (IM) injections* are given by piercing the skin at 90° with a longer 23–24 gauze needle. All vaccines, containing adjuvants are generally administered IM, due to higher risk of local reactions following superficial injections.
  - *Subcutaneous injections* must be administered by pinching up the skin with provider's fingers and piercing it at 45–60 angle with a shorter 23–25 gauze needle.
  - *Intradermal injections, e.g.* BCG, fIPV or ID-rabies are administered over left shoulder or upper arm using a tuberculin syringe and small 25 gauze needle, by stretching the skin between non-dominant thumb and fingers and piercing it at ~15 with the bevel of needle facing upwards. Only the needle tip should be introduced beneath the skin. A successful intradermal injection is reflected by formation of a small wheel at the site.
- ***Site of vaccination:*** NIS and other schedules generally specify the recommended site and side for each vaccine injection for the sake of uniformity, which should be adhered to unless the change is warranted due to local causes, e.g. infection, etc.
  - IM injections in infants are usually preferred over anterolateral aspect of thigh **(Fig. 9.8)** due to inadequate muscle mass in upper arm. Older children may be given IM vaccines in deltoid region. *No vaccine should be given on gluteal region as the antigen deposited in the fat may not invoke appropriate immune response*.
  - Subcutaneous injections are usually administered over outer aspect of the upper arm, though may be given over thighs in infants.
  - Intradermal injections are given over the shoulder or upper arm, conventionally on left side.
  - Two injections, when need to be given during same visit, must preferably be given on opposite sides. However, more injections can be administered on same site, separated by at least 2.5 cm to avoid overlap of local reactions.
- ***Use of sterile injection equipments:*** WHO no longer recommends the use of standard disposable syringes and needles due to risk of potential re-use. Auto-disable syringes are preferred for immunization purposes in NIS. Some important considerations while using selecting injection instrument are as follows:

Fig. 9.6: Positioning for vaccination: (A) Cuddle position; (B) Bed (lying down); (C) Upright position; (D) Straddle position.

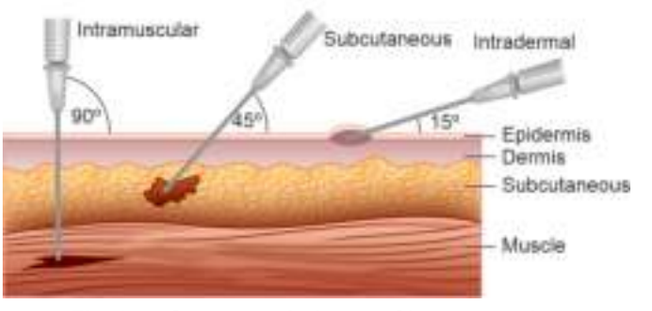

Fig. 9.7: Correct techniques of intramuscular, subcutaneous and intradermal injections.

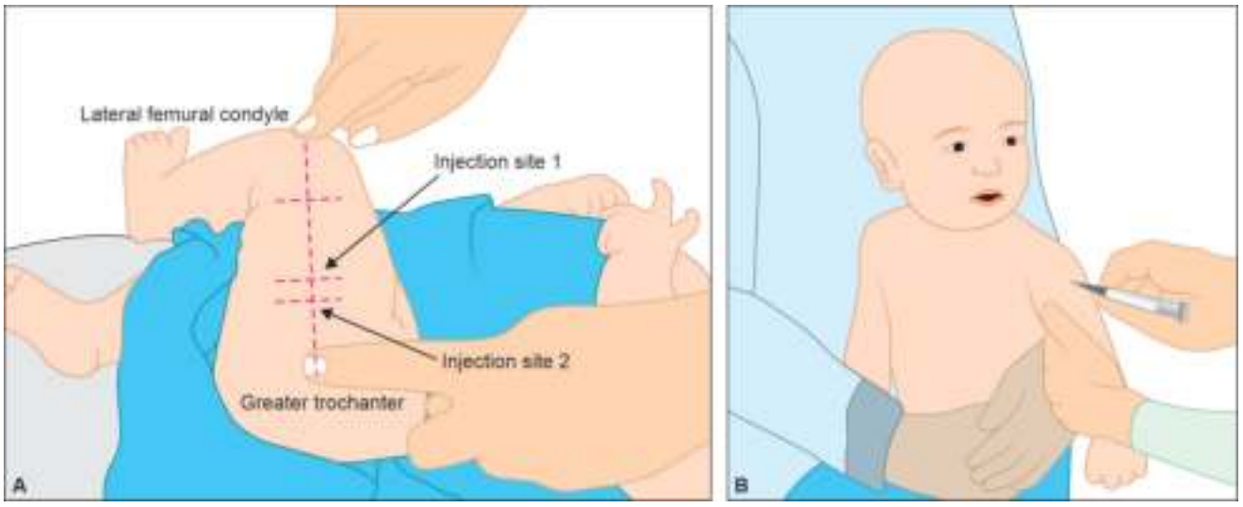

Fig. 9.8: **Correct site of immunization in infants.**
(A) Anterolateral aspect of thigh; (B) Upper arm (Deltoid region)

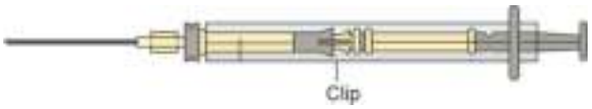

Fig. 9.9: **Autodisable syringe.**

- Package containing syringe and/or needle should be carefully inspected before opening and discarded, if found to be punctured, torn or damaged.
- Changing needles between drawing vaccine into the syringe and injecting it into the child is not necessary, unless twisted or potentially contaminated.
- A longer 23–24 Gauze needle (min 2.5 cm in length) is preferred for IM injections to reach at deeper tissue plain while shorter needles may be used for SC or ID injections.
- While using an auto-disabled syringe **(Fig. 9.9)**, plunger should not be pushed forward before the injection to inject the air in the vial, as it might disable it.

- ***Administering the injection:*** After the child is properly positioned and restrained and the injection is ready, following recommendations must be considered:
  - Selected injection site should be inspected for any local infection, etc. and must be cleaned with a swab, if dirty. Cotton swabs stored wet in a multi-use container should not be used.
  - Vigorous swabbing of the skin with antiseptic before injection is unnecessary and may add to the anxiety. Organisms colonizing the clean injection site are usually non-pathogenic. However, if an antiseptic swab is used, it should be prepared just before use and product-specific skin contact time must be adhered.
  - No antiseptic swabs should be used for local cleaning before administration of live vaccines, e.g. BCG, which may deactivate pathogens.
  - Aspiration, i.e. pulling back on the plunger after insertion of the needle but before pushing the liquid is not advised as no large vessels are present at the recommended sites and the process might be more painful for infants due to movement of needle.
- ***Waste disposal:*** Safe disposal of the injection waste is essential to prevent needle-stick injuries to HCW and re-use of contaminated injection equipments. Following recommendations must be considered for safe waste disposal:
  - Needle should be cut at the point of use only with a electric or mechanical needle-cutter and disposed-off along with part of the syringe nozzle in the puncture-proof sharps container.
  - Remaining part of plastic syringe and vaccine vial must be disposed in the red bag.
  - Empty vaccine vials/ampoules and swabs, etc. may be discarded in yellow bags.
  - *Recapping* of the used needle is a major cause of needle-stick injuries to the provider, and should be avoided. However, if necessary *single-handed scooping-re-sheathing technique* may be used to minimize the risk.
- ***Post-vaccination observation:*** All vaccinated cases must be observed for 15–30 minutes after injection for a major adverse event, e.g. anaphylaxis. All vaccination sites – fixed or outreach, must be equipped to handle anaphylaxis using anaphylaxis kits.

9.8.3 PAIN AND ANXIETY REDUCTION

Injectable vaccines are source of significant pain and anxiety which may be mitigated to some extent by some simple and effective evidence-based strategies as follows:

- HCW should be calm, reassuring and well-trained to deal with young kids. Phrases which raise the anxiety, e.g. *here comes the sting*, or promote distrust, e.g. *it will not hurt or will hurt only for a second*, must be avoided.
- Mother must be allowed to remain present during vaccination to reassure the child and hold him/her in desired position.
- Infants may be breast-fed during or shortly after the vaccination.
- Feeding small volume of sweet liquids, e.g. 1–2 ml Sugar solution before or soon after the injection might help to distract the infant and cope with the discomfort.
- Distraction measures, e.g. toys, video, music, conversation to divert attention away from pain to something more pleasant are often useful.
- Multiple vaccines, if necessary in same session, must be administered in a sequence, starting with oral ones, then less painful ID or SC injections and lastly the more painful IM injections. *WHO recommended sequence of multiple vaccines in same sitting, if required, is as follows – RV > OPV > BCG > Penta V > MR/MMR >JE.*
- Local cooling of the injection site by a topical refrigerant spray immediately before vaccination or application of a topical anesthetic 15–30 minutes before the injection has been proven to reduce the pain though cannot be used for mass immunization sessions due to logistic issues.
- Plunger should not be withdrawn after insertion of the needle to aspirate and check for blood as process may cause pain due to longer contact time and lateral movement of the needle.
- Warming the vaccine by rubbing between palms, vigorous rubbing at the injection site or prophylactic administration of an analgesic before injection is not recommended due to lack of evidence of pain-mitigation effectiveness or potential for altering vaccine effectiveness.
- Oral analgesics, e.g. paracetamol may be used to mitigate pain and/or fever after the vaccination. However, studies in children with previous febrile seizures have not demonstrated antipyretics to be effective in the prevention of febrile seizures after vaccination.

9.9 PASSIVE IMMUNIZATION

Passive immunization against specific infections or in non-specific immunodeficiency states is provided by commercial *immunoglobulins (Ig)* derived from the pooled plasma of multiple adults. These preparations contain a mixture of different *immunoglobulins* fractions, predominantly of IgG class, along with traces of IgM and IgA.

TABLE 9.8: Immunological preparations for passive immunization

Non-specific immunoglobulins
- Intravenous immunoglobulins
- Intramuscular immunoglobulins

Specific (hyperimmune) immunoglobulins
- Tetanus immunoglobulins (TIG)
- Hepatitis B immunoglobulins (HBIG)
- Varicella-zoster immunoglobulins (VZIG)
- Rabies immunoglobulins (RIG)
- Anti-D immunoglobulins

Anti-sera
- Anti-diphtheria serum (ADS)
- Anti-snake venom (ASV)

Therapeutic immunoglobulin preparations are divided into two types: (a) specific or hyperimmune immunoglobulins, and (b) non-specific immunoglobulins.

Specific (hyperimmune) immunoglobulins are prepared from pooled plasma of immunized or *convalescing* adults and contain high titers of specific antibodies against a specific antigen or infection, e.g. tetanus, diphtheria, etc. Being readymade, these antibodies ensure early protection from the specific disease by neutralization of circulating antigen or toxin. However, this protection is limited and temporary, due to quantitatively limited antibodies titers and short-life of immunoglobulins (20–35 day).

Anti-sera are purified concentrates of horse sera, who have been actively immunized with a specific antigen and provide passive immunity to a specific infection, e.g. diphtheria, tetanus and snake bite.

Currently available specific immunoglobulins **(Table 9.8)** are highly-refined biological products of human, which have gradually replaced earlier products of equine origin.

However two anti-sera of equine origin are still in common use due to lack of alternatives including anti-diphtheria serum (ADS) and anti-snake venom (ASV), which carry high-risk of adverse reactions, e.g. anaphylaxis, serum sickness, etc. Indications and dosage of these products are discussed in respective chapters.

Non-specific (normal) immunoglobulins are a polyvalent antibody-rich fraction, obtained from pooled human plasma that contains antibodies against several infections prevalent in general population. These immunoglobulins are available as intravenous (IVIG) as well as intramuscular (IMIG) preparations, though IMIG is rarely used at present due to slow and erratic absorption, proteolytic degradation at injection site and high-risk of adverse events, e.g. anaphylaxis. However, IMIG may still be used for post-exposure prevention of measles and hepatitis A in close contacts, with some benefits.

Intravenous immunoglobulins (IVIG) are the most promising immunomodulatory preparations, prepared

TABLE 9.9: Indications for IVIG

Definite indications:

- Immunodeficiency states
  - *Congenital:* X-linked hypogammaglobulinemia, SCID, WAS
  - *Acquired:* AIDS (prophylaxis for recurrent bacterial infection)
- Autoimmune disorders
  - Idiopathic thrombocytopenic purpura (ITP)
  - Guillain-Barré syndrome
  - Kawasaki disease
  - Chronic demyelinating inflammatory polyneuropathy

Probable uses:

- Neonatal sepsis, specially in preterms
- *Collagen disorders:* Dermatomyositis, SLE
- *Post-transplants:* Prevention of OIs and GVHD
- Autoimmune hemolytic anemia
- *Others:* Myasthenia gravis, Graves' disease, etc.

SCID: Severe combined immunodeficiency; **WAS:** Wiskott-Aldrich syndrome; **GVHD:** Graft versus host disease; **OIs:** Opportunistic infections

from pooled plasma of at least 1000 donors, with specific WHO standards. For example, (a) at least 90% intact IgG with subclasses in normal ratio, (b) free from IgG aggregates and infectious agents, and (c) low IgA content, etc.

Uses: IVIG is used as: (a) replacement therapy in various immunodeficiency states and/or (b) immunomodulatory agent in many clinical disorders **(Table 9.9)**. However, their role in some of these conditions is still experimental.

Mechanism of action: Main immunological properties of IVIG are mediated by:

- Direct neutralization of antigens, toxins and auto-antibodies,
- Structural changes and blockade of Fc receptors of autoantibodies in autoimmune disorders,
- Suppression of the synthesis of cytokines and auto antibodies and
- Other modulations in immunological network.

Adverse reactions with IVIG are rare (<5%) and usually mild, e.g. local flushing, chills and fever, etc., though fatal anaphylactic reactions have been reported in rare cases of selective IgA deficiency.

CHAPTER

10

Infections

Yahswant R Gabhale, Nikita Shah, Mukesh Agrawal

10.1 FEVER IN CHILDREN

Fever, the commonest problem in pediatric practice, is defined as *the rise of body temperature over and above the normal range for age and diurnal variation*. The upper limit of normal temperature is higher in newborns (38°C) and declines gradually with increasing age, till adult level (37.2°C) is achieved by puberty. Body temperature also shows a *circadian or diurnal* rhythm, being highest in afternoon and lowest in early morning. In practice, *fever* is defined as a rectal temperature >38°C (>100.4°F), roughly equivalent to oral temperature of 37.5°C or axillary temperature of 37.2°C fever exceeding 40°C (>104°F) is generally termed as *hyperpyrexia*.

10.1.1 BASIC CONSIDERATIONS

Normal thermoregulation is controlled by a hypothalamic thermostat, i.e. *thermosensitive neurons in pre-optic or anterior hypothalamus,* which maintains the body temperature at optimal levels for normal metabolic activity. These neurons receive *afferent stimuli* form peripheral cutaneous thermoreceptors as well as endogenous sources, e.g. blood temperature; and respond accordingly to conserve/increase heat loss by various *efferent mechanisms*, e.g. cutaneous vasoconstriction/dilatation, sweating/shivering, increased/decreased urine output and behavioral responses, e.g. clothing patterns. Newborns and young infants have wider temperature fluctuations due to ineffective thermogenesis.

Pathogenesis: Fever denotes *resetting of body thermostat at higher temperature* due to variety of factors. For example:

- *Endogenous pyrogens*, produced in response to infections or inflammations, e.g. cytokines interleukins (IF-1β and IL-6), tumor necrosis factor-α (TNF-α), interferon (IFN-β and γ), stimulated leukocytes, etc.
- *Exogenous pyrogens*, e.g. microbes and microbial toxins, which either directly affect thermoregulation (endotoxins), or stimulate release of endogenous pyrogens by immunological reactions.
- *Central causes*, e.g. autonomic disturbances (Riley-Day syndrome), hyperthyroidism, etc.
- *Inadequate heat-loss mechanisms*, e.g. reduced sweating in atropine poisoning *or* ectodermal dysplasia.

Consequences: Fever is an adaptive response to a pyrogenic illness, which may be beneficial as well as detrimental. Elevated body temperature is known to decrease microbial multiplication and increase protective inflammatory response. On the other hand, adverse effects of fever include: (a) febrile seizures or fever-triggered epilepsy, (b) increased oxygen consumption (c) increased CO_2 production, and (d) metabolic acidosis/instability.

Clinically, Childhood fevers may be broadly divided into three categories:

a. Fevers with localizing signs,
b. Fevers without focus or localizing signs (Sec 10.1.2)
c. Prolonged pyrexia *or* pyrexia of unknown origin (Sec 10.1.3)

Fevers with localizing signs: Most acute febrile episodes in childhood are short duration, self-limiting and often associated with localizing signs, e.g. Coryza, cough, diarrhea, jaundice, dysuria, etc. Detailed history and examination is usually enough to arrive at the diagnosis and detailed investigations are unnecessary, except those relevant to the clinical diagnosis. However, sometimes localizing signs may be misleading and patient should be clinically evaluated *in toto* for underlying or associated health problems.

Fever without focus or localizing signs, generally defined as acute fever of <7 days duration, pose a diagnostic dilemma and require detailed evaluation to detect or exclude presence of serious bacterial infections (SBI) or occult bacteremia. Children with fever without focus are at higher risk of o*ccult bacteremia or SBI* if they have: (a) Age < 3 months, (b) immunocompromised state, c) presence of co-morbidities, e.g. severe malnutrition or chronic medical conditions, (c) ill or toxic appearance. Despite the initial impression of a fever without focus,

many of these cases are found to have subtle signs on re-evaluation or develop them during the course of illness, to assist in the diagnosis.

Prolonged fever or pyrexia of unknown origin (PUO) is generally defined as: (a) fever lasting for >14 days, (b) fever documented in the hospital, and (c) no cause identified after one week of routine investigations in the hospital.

Diagnostic considerations in febrile children at the time of presentation include:

- **Age of the child** is a major determinant for the risk for serious bacterial infections or occult bacteremia. Ranging from as high as 30% in newborns to <5% in older infants or toddlers, as follows:
  - A febrile newborn carries substantially high-risk of occult bacteremia (~30%) and serious bacterial infections (~7–10%), e.g. septicemia, meningitis, pneumonia or pyelonephritis, despite being apparently well clinically.
  - Post-neonatal young infants (1–3 months) with fever also have a substantial risk of occult bacteremia (10–15%), though not as high as in newborns. Localizing signs are often absent in these cases despite presence of serious bacterial infections. Many criteria have been developed to identify low-risk cases in this age group, e.g. Rochester criteria **(Table 10.1)** which has a negative predictive value of >98% for serious bacterial infection or bacteremia.
  - Fever in older infants and toddlers (3–36 months) is usually *viral* except in presence of (a) high fever 39°C, (b) leukocytosis 15,000 cells/mm^3 with neutrophilia, (c) elevated inflammatory markers, e.g. CRP, and (d) persistence beyond one week. Most of these cases have localizing signs and risk of occult bacteremia or SBI is < 5% in these cases, in absence of significant clinical abnormalities.
- **Duration of fever:** While short-duration fevers without focus are common and usually benign, persistent of fever beyond a week is a cause of concern and need detailed revaluation and investigations.
- **Periodicity of fever** is an important diagnostic clue in many febrile illnesses, as follows, though the course may be modified by antipyretics:
  - *Continuous fever* with diurnal variation of <0.5°C, e.g. in pneumonia, urinary tract infection, etc.
  - *Remittent fever* with diurnal variation of >1°C but never touching the baseline, e.g. in enteric fever (step-ladder pattern), infective endocarditis, etc.
  - *Intermittent fever* alternating with short afebrile periods, e.g. in malaria, kala-azar, viral fevers. In septicemia, child may never be absolutely afebrile but temperature variations often exceed 5°C.
  - *Relapsing or biphasic fever,* i.e. reappearance of fever after an afebrile period of >2–3 days, e.g. in dengue, leptospirosis, Hodgkin disease (Pel- Epstein fever), etc.
  - *Single isolated spikes* are usually benign, due to intravenous infusions, invasive procedures, drugs and vaccinations.
- **Severity of fever** may be divided into:
  - *Malignant hyperpyrexia* (>41°C), contrary to popular perception, is usually non-infective in origin, e.g. heat-stroke, pontine hemorrhage, drugs/poisonings, hypothalamic dysfunction, neuroleptic syndrome, etc.
  - *Moderate fever* (38–41°C) in most infectious illnesses.
  - *Low-grade fever* (<38°C) in TB, malignancies,viral infections, etc.
  - *Hypothermia* (<35°C) is an important indicator of serious infections in newborns and immunocompromised children.
  - *Significant mismatch between core and skin temperature* (>1°) indicates impending shock.
- **Circadian rhythm,** e.g. evening-rise temperature in tuberculosis or malignancies.
- **Inter-febrile clinical state:** Absence of ill-look between febrile episodes indicates viral etiology or malaria. In bacterial infections, child continues to betoxic or lethargic, even during afebrile phase.
- **Pattern of defervescence:**
  - *Sudden defervescence* (by *crisis*) with profuse sweating, e.g. malaria, roseola infantum.
  - *Gradual defervescence* over 48–72 hours (by *lysis*), e.g. enteric fever or other bacterial infections.
- **Presence of co-existing features:** For example,
  - *Chills and rigors* usually indicate—malaria, urinary tract infection, pneumococcal pneumonia, septicemia, amebic hepatitis, infective endocarditis.
  - *Bradycardia* is common in enteric fever, brucellosis and factitious fevers.
  - *Localizing signs,* e.g. rash (Ch 10.1.3), jaundice (hepatitis), lymphadenitis (viral infections, malignancy), altered sensorium or seizures (CNS infections), respiratory distress (respiratory infections), splenomegaly (malaria, kala-azar), dysuria (urinary tract infections), heart disease (infective endocarditis), osteo-articular pain (osteomyelitis, arthritis, rheumatic disorders), etc.

TABLE 10.1: Rochester criteria for low-risk of serious infection in children 1–3 months age

Apparently well infant with normal examination and

- Total leukocyte count 5000–15000 cells/mm^3 with absolute band cell count <1500 cells/mm^3
- Urine < 10 WBC/HPF
- Stool < 5 WBC/HPF (in presence of diarrhea)

– H/O vaccination, as fever is a common side effect of many vaccines given in this age group though rarely lasts for more than 24–48 hours. In an unwell child, fever should not be attributed to vaccination alone

Management of febrile child depends on the severity of the illness at the time of presentation, possible clinical diagnosis and underlying risk of occult bacteria or serious bacterial infections, apart from symptomatic antipyretic therapy.

Consensus Guidelines on Evaluation and Management of the Febrile Child presenting to the Emergency Department in India (2017) as well as *IAP standard treatment guidelines 2022* suggest that:

- **All febrile newborns** need hospitalization and complete investigative workup which includes complete blood count (CBC), C-reactive protein (CRP), peripheral blood smear (PS) (band form, toxic granules, vacuolization, immature/total ratio), blood and urine culture, urine analysis (UA), lumbar puncture (LP), and chest *X*-ray (CXR) is mandatory. Stool should be examined for pus cell and red blood cell (RBC) only if change in frequency of stool is present. First negative septic screen in an active febrile newborn is not the indication for discharge.

  All ill-appearing newborns should be started on empirical intravenous antibiotics immediately on hospitalization, including ampicillin (100–200 mg/kg/d q8hr) and gentamicin (7.5 mg/kg/d q8hr), after collection of cultures.
- **Young infants (1–3 months),** if apparently active except fever, should be observed in the emergency room, along with CBC, PS and urine analysis and culture (after catheterization) and blood culture in all cases. Chest X-ray is indicated if temperature 39ºC, leucocyte count 20,000/mm^3 or respiratory signs are present. Lumbar puncture is indicated only in sick-looking child.

  All sick-looking children of this age group should be hospitalized and started on empirical intravenous antibiotics immediately on hospitalization, including Ceftriaxone (100 mg/kg/d q12hr) or (75 mg/kg/d q12hr), dose depending on the presence or absence of meningeal involvement.

  Apparently well children of this age group should be managed symptomatically and may be hospitalized for observation or asked to follow-up after 24 hours, for further treatment, if required.
- **Children aged 3 months – 3 years** do not need urgent investigations, if apparently well and have no localizing signs, except urine microscopy, if have fever >24 hours and past history of UTI. However, sick-looking children of this age must be investigated with CBC, PS, urine analysis and culture, blood culture in all cases and chest skiagram and CSF in selected cases. Rapid tests for malaria, dengue and enteric fever may be done in endemic areas.

  While sick-looking children of this age group should be hospitalized and started on empirical intravenous Ceftriaxone, other apparently well children may be managed symptomatically with follow-up after 24 hours, for further treatment, if required.
- **Febrile children >3 years** are unlikely to have serious bacterial infections in absence of thelocalizing signs and need detailed workup only in presence of: (a) prolonged pyrexia, (b) immunocompromised state, (c) co-morbidities, or (d) nosocomial risk factors. Investigations in these cases should directed on clinical suspicion, though rapid tests for malaria, dengue and enteric fever may be done in endemic areas. Treatment is these cases should be directed on clinical grounds.

Antipyretic therapy includes: *(a) hydrotherapy*, i.e. tepid water sponging to bring down high fever, and *(b) pharmacotherapy.* Paracetamol (PO10–15 mg/kg/dose) is the safest antipyretic in children, though others, e.g. Ibuprofen (PO 5–10 mg/kg) or Mefenamic acid (PO 5–7 mg/kg) may be used in selected cases. IV paracetamol may be given in babies with intractable vomiting or altered senosrium as 7.5 mg/kg (<10 kg) or 15 mg/kg in children >10 kg. Nimesulide and Aspirin are not recommended as antipyretics in children due to potential risk of hepatotoxicity and Reye's syndrome, respectively. No antipyretics are necessary in low-grade fevers <38°C.

10.1.2 PYREXIA OF UNKNOWN ORIGIN (PROLONGED PYREXIA)

Pyrexia of unknown origin (PUO) is defined as any fever fulfilling following criteria:

- Fever of >14 days duration,
- Fever documented in the hospital,
- Cause remains unidentified even after one week of routine investigations in the hospital.

Etiology: PUO usually indicates presence of a chronic infection, immunological disorder or malignancy **(Table 10.2)**. Infections account for more than half of these cases and *five* commonest causes in Indian children are: (a) enteric fever, (b) malaria, (c) tuberculosis, (d) urinary tract infection, and (e) infective hepatitis. In ~30%, diagnosis remains an enigma despite best laboratory support. Rheumatic disorders (~10%) and malignancies (~5%) are emerging as important causes of PUO after easier availability of diagnostic tests for common infections.

Diagnostic approach in prolonged pyrexia depends on: (a) epidemiological risk of diseases in local population, (b) review of case history, including prior medications and investigations, (c) re-assessment of clinical examination for missed/new findings and (d) baseline and

TABLE 10.2: Causes of prolonged pyrexia (PUO) in children

Infectious causes	*Non-infectious causes*
1. Bacterial	***1. Immunological***
Enteric fever	Rheumatic fever
Urinary tract infection	Collagen disorders: JRA, SLE
Infective endocarditis	Chronic active hepatitis
Brucellosis	Chronic inflammatory bowel diseases
Deep-seated abscess	
Bone/joint infection	***2. Neoplasms***
2. Viral	Leukemia
Viral hepatitis	Lymphoma
HIV	Solid tumors
Infectious mononucleosis	***3. Neurological***
3. Parasitic	Autonomic disorders*
Malaria	Hypothalamic lesions
Amebic hepatitis	***4. Endocrinal***
4. Miscellaneous	Hyperthyroidism
Leptospirosis	Diabetes insipidus
Rickettsial fevers	***5. Miscellaneous***
Opportunistic Infections	Fictitious fever
	Drug fever

*e.g. Riley-Day syndrome

relevant investigations, as dictated by clinical suspicion **(Table 10.3)**.

Management: Since many cases of PUO are non-infectious in origin, empirical antibiotics are not recommended and may obscure the diagnosis. Treatment is largely supportive and empirical trials, e.g. antitubercular therapy should be avoided.

10.1.3 EXANTHEMATOUS FEVERS (Fever with Rash)

While rashes are seen in many febrile illnesses, term *Exanthematous fevers* is usually reserved for *fevers consistently associated with skin eruptions* during the usual clinical course.

Etiology: Skin lesions in infectious diseases may be due to: (a) direct inoculation, e.g. anthrax, (b) contagious spread from adjacent foci, e.g. herpes, (c) hematogenous spread, e.g. meningococci, (d) toxins, e.g. scarlet fever and (e) immune reactions, e.g. rheumatic fever. Most exanthematous fevers are viral in origin **(Table 10.4)**, commonest being measles and varicella.

Diagnostic evaluation of exanthematous fevers depends on the epidemiological history of similar illnesses in the community, along with: (a) duration and severity of prodromal phase, (b) nature, distribution and duration of rash and (c) other associated features **(Table 10.5)**. Non-infective causes of maculopapular or Vesiculobullous rashes (*see* Ch25.5 and 25.6) should also be excluded.

TABLE 10.3: Laboratory investigations in PUO

- **Baseline** *(in all prolonged pyrexia)*
  - Complete hemogram
  - Peripheral smear for immature cells, parasites
  - Urine analysis
  - X-ray chest and sinuses
  - Tuberculin test
  - Widal test
- **Second-line** *(in all PUO cases)*
  - *Biochemical:* Liver function tests
  - *Microbial:* Blood/urine cultures, AFB
  - *Cytological:* CSF, bone marrow
  - *Serological:*
    - *Infections:* HIV, leptospira, brucella
    - *Others:* ASO, ANA titers
  - *USG abdomen for* deep-seated abscess
  - *Echocardiography for* infective endocarditis
- **Third-line** *(in selected cases)*
  - Whole body CT/MRI
  - Radionuclide scans (bones, abdomen)

TABLE 10.4: Exanthematous fevers in India

- **Viral:**
  - *Common:* Measles, varicella, enterovirus, dengue
  - *Others:* IM, roseola, E. infectiosum, arboviruses
- **Bacterial:**
  - *Common:* Enteric fever, meningococcemia
  - *Uncommon:* Scarlet fever, anthrax
- **Spirochetal:** Leptospirosis
- **Rickettsial:** Typhus, rickettsial pox
- **Mycoplasma:** *M. pneumoniae*
- **Protozoal:** Toxoplasmosis
- **Immunological:** Rh. fever, JRA, Kawasaki disease
- **Drug reactions:** Stevens-Johnson syndrome

IM: Infectious mononucleosis; **JRA:** Juvenile rheumatoid arthritis

10.1.4 HEMORRHAGIC FEVERS (Fever with Petechiae/Purpura)

Fever with petechial/purpuric lesions indicates serious life-threatening infections, often associated with bacteremia, sepsis and meningitis. Common causes of hemorrhagic fevers in Indian children, excluding co-existing bleeding disorders, are as follows:

- *Viral fevers*
  - Dengue (DHS/DSS)
  - *Other arboviruses:* Chikungunya, West-Nile virus, Kyasanur Forest disease
  - Non-polio enteroviral infections
  - Hemorrhagic measles or chickenpox
- *Bacterial infections*
  - Meningococcemia,
  - *Others:* Anthrax, DIC
- *Spirochetal infections:*
  - Leptospirosis

TABLE 10.5: D/D of rash in common exanthematous fevers

Illness	*Rash characteristics*				
	Day[1]	*Type*[2]	*Distribution*[3]	*Duration*[4]	*Important prodromal/coexistent features*
Measles	4–5th	Maculopapular	Hairline > GEN	5–7 d	Fever, conjunctivitis, koplik spots, Post-measles staining on recovery
Rubella	5–7th	Macular flush	Face > GEN	2–3 d	Mild fever, lymphadenopathy
Chickenpox	2nd	Pleomorphic	Centripetal	7–10 d	Transient fever
E. subitum (Roseola)	5th	Discrete macular Rose-colored	Trunk > GEN	1–3 d	High fever for 3–5 days, *Rash appears after fever disappears*
E. infectiosum (Fifth disease)	–	Macular flush *(Slapped-cheek)*	Trunk> GEN	10–14 d	Mild fever Fever, absence of catarrh
Dengue	1–2nd	Macular flush	GEN	2–3 d	Mild fever
Enteroviral illness	1–2nd	Maculopapular	GEN	2–3 d	Fever, circumoral pallor, with flush face, *pastia lines*
Scarlet fever	2nd	Punctate macular *(Goose-flesh)*	Flexural > GEN	5–7 d	Fever with shock/meningitis
Meningococci	1–2nd	Purpuric	GEN	–	Fever, toxic, hepatosplenomegaly
Enteric fever	7th	Maculopapular (Rose-spots)	Truncal	3–5 d	Fever, local eshar, lymphadenopathy
Rickettsial infections	3–5th	Maculopapular	Limbs > GEN	2–4 weeks	Fever, lymphadenopathy, conjunctivitis, strawberry tongue, desquamation of palm/soles
Kawasaki disease	1st week	E. multiforme	Truncal, Groin	1–3 weeks	

GEN: Generalized
[1]usual day of appearance of rash, may vary. A simpler way to remember the day of appearance of rash is to remember a mnemonic – *'Very Sick Patient Must Take Rest' - Varicella* (1 day), *Scarlet fever* (2 days), *Pox i.e.* small *pox* (3 days), *Measles* (4 days), *Typhus* (5 days) and *Rubella* (6 days).
[2]Usual appearance, may vary, special appearance in parentheses
[3]Usual distribution and progression (>) from the site of first appearance
[4]Usual disappearance of primary rash, secondary lesions, e.g. staining (measles), scars (chickenpox), desquamation (scarlet fever, Kawasaki disease) may persist for 2–4 weeks.

- Rickettsial fevers
- *Others:* Purpura fulminans

All fevers with petechial/purpuric rash need hospitalization and close supervision for signs of internal bleeding, e.g. hematemesis, hematuria, etc. Some important hemorrhagic fevers are discussed later in relevant chapters.

10.1.5 FEBRILE NEUTROPENIA (Fever in a Neutropenic Child)

Fever in a neutropenic child is an emergency that needs urgent evaluation and institution of empirical antibiotic therapy, without waiting for a diagnosis.

Febrile neutropenia (FN) is generally defined as:

- Single oral temperature > 38.3°C (101°F)% or > 38°C sustained for > 1 hour,
- Absolute neutrophil count (ANC) < 500/mm^3 or expected to drop below this level in next 24 hours.

Development of fever in a case with neutropenia due to any cause indicates possibility of serious underlying infections, though clinical signs may be masked due to paucity of inflammatory response. Risk of bacterial infection is inversely related to absolute neutrophil count.

Microbiologically, predominant infections in neutropenic children are bacterial, including *Staph. aureus* (~50%), *Pseudomonas* (~20%) and *anaerobic infections* (~15%). While opportunistic viral, (e.g. CMV) and fungal infections are also common in these cases due to co-existing immunological defects, children with *isolated neutropenia* are not excessively prone to these infections.

Clinical presentation of infections in neutropenic children is directly related to its severity:

- *Mild neutropenia* with absolute neurtrophil count >1000/mm^3, is generally well tolerated.
- *Moderate neutropenia* (500–1000 cells/mm^3), may be asymptomatic or presents with mucositis, sinopulmonary infections, fulminant skin/soft tissue infections and enterocolitis.
- *Severe neutropenia* (<500 cell/mm^3) is frequently associated with generalized and potentially fatal infections, e.g. septicemia, pneumonia and visceral abscesses. *Meningitis is unusual* in neutropenic patients.

Disproportionately *less signs of inflammation with minimal pus formation is* an important feature of sepsis in neutropenic cases. Child should be thoroughly examined for source of infection, specially for venous access sites and mucosal surfaces.

Diagnosis of infection in FN depends on microbial cultures from blood and potential sites for entry of infection, e.g. catheters or central lines. Serial neutrophil counts and inflammatory markers, e.g. CRP are necessary to assess the course of disease, along with investigation to search for focus of infection, e.g. chest skiagram, urine analysis, etc. and biochemical investigations for organ dysfunction.

Management aims to recognize infection in early stages and prevent rapid progression from bacteremia to septicemia to septic shock. Important steps include:

- **Risk-assessment:** All cases of FN must be classified as *high-risk* or *low-risk* for serious infections before deciding the line of management **(Table 10.6)**.
- **Management of high-risk FN:** Children with high-risk FN need immediate hospitalization and initiation of empirical antibiotics within 60 minutes, without waiting for reports. Choice of *empirical antibiotic therapy* in them must include a broad-spectrum beta-lactam antibiotic with anti-pseudomonal cover, e.g. *piperacillin-tazobactam* (IV 300 mg/kg/day q8hr) or a fourth-generation cephalosporin, e.g. *cefepime with/without tazobactam* (IV 100 mg/kg/day q12hr) or a carbapenem, e.g. *meropenem* (120 mg/kg/day q8hr). Vancomycin (IV 45–60 mg/kg/day q8hr) must be added in clinically unstable patients with hypotension/shock or in those with (a) mucositis, (b) skin and soft-tissue infection, (c) central lines, (d) locally high MRSA prevalence.

  These cases, specially if on steroids, should also be investigated for invasive fungal disease (IFD) and started on empirical antifungal therapy if fever persists for >96 hours with *liposomal amphotericin B* (IV 3–5 mg/kg/day) or *Caspofungin* (IV 70 mg/m^2 on day 1 followed by 50 mg/m^2/day) empirical antifungal therapy may be stopped after resolution of fever, provided there is no feature suggestive of IFD.

TABLE 10.6: Risk-stratification in febrile neutropenia

	High-risk	*Low-risk*
Duration	>10 days	<10 days
ANC count	<100 cells/mm^3	>500 cells/mm^3
Primary disease	Leukemia/NHL	Solid tumors
Course of disease	Relapse/refractory	No relapse/refractory
Treatment	HSCT	Chemotherapy
Risk factors*	Present	Absent

*Hypotension, Hypoxia, Altered sensorium, Respiratory distress, Mucositis or Abdominal symptoms
HSCT: Hematopoietic stem cell transplant

- **Management of low-risk FN:** Low-risk FN may be treated on OPD basis with oral antibiotics, if patient is accepting well and can be monitored at home. Initial choice of antibiotics in these cases include a fluoroquinolone, e.g. ciprofloxacin (PO 20–30 mg/kg/d q12hr) alone or in combination with amoxicillin-clavulanate (50–80 mg/kg/d q12hr). Same antibiotics may be given parenterally in a small child, vomiting or lack of compliance, after hospitalization.
- **Supportive measures** includes:
  - Barrier nursing, hand hygiene, and strict asepsis.
  - Nutritional support, either enteral with nasogastric tube, or parenteral, as required.
  - Transfusions to maintain hemoglobin >8 g/dl and platelet count >20,000/mm^3.
  - Treatment of primary causes along with recombinant G-CSF therapy in severe/persistent neutropenia (Ch 19.8).
  - Adequate pain relief with opioids should be provided for mucositis, colitis, evolving abscess, or fissures. Paracetamol should be avoided in a FN child until it is clear that the criteria for starting antibiotics are fulfilled.
- **How long to treat?** Antibiotic therapy should continue till the patient is afebrile for at least 48 hours, neutrophil counts rise >500 cells/mm^3 and blood culture is sterile. Persistent of fever alone does not warrant change of antibiotics, which should be changed as per culture reports or in cases developing hemodynamic instability, fresh focus of infection or increase in inflammatory markers.

10.1.6 DRUG FEVER

Drug fever is an uncommon but important cause of prolonged fever, defined as:

- Unexplained pyrexia during the course of specific drug therapy, and
- Normalization of temperature within one week of discontinuation of offending drug.

Clinical indicators: Drug fever is a diagnosis of exclusion, though following characteristics are strongly suggestive:

- Onset of fever within 24–48 hours of starting the offending drug,
- Low-grade persistent fever, rarely exceeding 39°C,
- Frequently, but not essentially, associated features, e.g. rash or eosinophilia,
- Disappearance of fever within 7 days of stopping the suspected drug,
- Reappearance of fever after re-instituting same drug.

Mechanisms: Although frequently idiopathic, possible mechanisms in drug fever include:

- *Presence of exogenous pyrogens* in the preparation, e.g. IV amphotericin.

- *Release of endogenous pyrogens* due to specific drug action, e.g. antibiotics, cytotoxic agents.
- *Inherent pharmacological action* like reduced sweating, e.g. atropine or antihistaminics.
- *Allergic response*, e.g. sulpha-drugs or penicillin.
- *Idiosyncratic reaction* ? genetic predisposition for qualitative intolerance other than immunological mechanisms, e.g. quinine or sulpha drugs.

Management: No treatment is indicated except discontinuation of the suspected drug, though symptomatic therapy may be used if the offending drug cannot be discontinued for medical reasons.

10.2 STAPHYLOCOCCAL INFECTIONS

Staphylococci are broadly classified as coagulase positive (*Staph. aureus*) or coagulase negative (*Staph. epidermidis*), based on their ability to produce a clumping factor (coagulase) to protect themselves against host defense. *Staph. aureus* is a common colonizing pathogen in nasopharynx with carrier rate of 20–30%, transmitted as a droplet infection. All colonized children are not symptomatic and development of disease depends on strain-virulence and host-susceptibility.

High-risk factors for staphylococcal disease include: (a) impaired skin/mucosal barrier, e.g. trauma, surgery, burns, vascular access, shunts, (b) altered nasal flora after viral infections or prolonged antibiotics, and (c) immunodeficiency states.

Pathogenesis: Disease may result due to direct tissue invasion (localized disease) or via toxins produced by different strains, e.g. exfoliative toxins (*staphylococcal scalded skin syndrome*), enterotoxins (*food poisoning*), and TSS-1 (*toxic shock syndrome*).

Clinical spectrum: Staphylococci is the leading cause of superficial skin infections in children, apart from various localized or generalized serious infections **(Table 10.7)**.

Diagnosis rests on the culture from infected lesion. A positive skin/nasopharyngeal culture is of a little significance due to normal colonization.

TABLE 10.7: Clinical spectrum of staphylococcal infections

- **Skin infections**
  - *Focal:* Impetigo, folliculitis, wound infection
  - Staphylococcal scalded skin syndrome
- **Respiratory infections**
  - *Upper*:* Otitis, sinusitis, bacterial tracheitis
  - *Lower:* Pneumonia, empyema, pneumothorax
- **Septicemia**
- **Metastatic lesions:**
  - *Osteoarticular:* osteomyelitis, arthritis
  - *CNS:* Meningitis, brain abscess, epidural abscess
  - *GIT:* Peritonitis, food poisoning
  - *Heart:* Pericarditis, endocarditis
  - *Kidney*:* Renal/perinephric abscess
  - *Muscles:* Tropical myositis and muscle abscesses

*Tonsilopharyngitis and UTI is rare

Treatment includes specific antibiotic therapy and drainage of pus. Antibiotic of choice is a penicillinase-resistant, semisynthetic penicillin, e.g. *cloxacillin* or *amoxycillin-clavulanic acid*, while penicillin-allergic or resistant cases should be treated with *vancomycin* or *imipenem*.

Methicillin-resistant Staph. aureus (MRSA) is an emerging problem in critically sick children, due to presence of a penicillin-binding protein, which is relatively resistant to β-lactam ring of antibiotics. Although methicillin is currently not available, the term 'MRSA' continues to be in use to denote organisms resistant to cloxacillin and other semisynthetic penicillins.

Prevention of staphylococcal infections in hospital requires: (a) strict hand-washing, with/without chlorhexidine, (b) isolation of case or carrier, and (c) rational use of antibiotics.

Toxic-shock syndrome (TSS) is an acute multi-systemic disease due to an exotoxin TSS-1, usually caused by staphylococci phage type-I. Mostly seen in menstruating women due to use of infected tampoons, non-menstrual TSS has been reported following wound infection, nasal packing for epistaxis and invasive staphylococcal disease.

Clinically TSS is characterized by three *major* features: (i) sudden onset of high fever, (ii) severe hypotension/shock and (iii) generalized erythematous rash after 24 hours of the onset of fever.

Important *minor* features include—(a) mucosal lesions, e.g. strawberry tongue, conjunctival congestion, (b) vomiting/diarrhea, (c) severe myalgia, (d) altered sensorium without focal signs, (e) liver/renal abnormalities, and (f) thrombocytopenia.

Diagnosis depends on presence of *all major criteria and/or minimum three minor criteria* (mentioned above), after exclusion of other causes and negative blood culture. *D/D* includes streptococcal TSS and Kawasaki disease.

Treatment includes drainage of infected site, parenteral antibiotic therapy with vancomycin, and supportive treatment for shock and other complications.

Prognosis is poor in untreated cases. Appropriately treated cases recover in 7–10 days, *leaving behind a desquamating lesion, especially over palm and soles*.

Other staphylococcal disorders, staphylococcal scalded skin syndrome (SSSS) are discussed elsewhere (Ch25.6).

Coagulase negative staphylococci (CONS), i.e. *Staph. epidermidis*, is a normal inhabitant of human skin, oropharynx and genital tract. Originally thought to be non-virulent, it is now known to cause serious nosocomial infections in susceptible children.

High-risk factors for CONS infections include: (a) presence of indwelling devices, e.g. shunts, catheters or prosthetic devices, etc., (b) post-operative infections, and (c) immunocompromised states.

Clinical spectrum: CONS infections may be limited to occult bacteremia or present with site-related infections, e.g. CSF-shunt infection (commonest cause), urinary catheter-related UTI, dialysis catheter-related peritonitis or infective endocarditis in cases with prosthetic valves.

Diagnosis rests on blood or shunt/catheter-tip culture, but should be differentiated from normal colonization. A CONS culture is considered as pathogenic if: (a) at least two cultures from same site at different times or different sites at same time are positive, *or* (b) patient is high-risk, i.e. newborn or has an *in situ* catheter.

Treatment: Vancomycin is the drug of choice for CONS, though the efficacy may be enhanced with addition of rifampicin or an aminoglycoside. Removal of suspected source, e.g. catheter is essential.

10.3 STREPTOCOCCAL INFECTIONS

Streptococci are classified according to their hemolytic properties (α, β, γ) *or* carbohydrate components in the cell wall (Group A-H, K-V).

Group A β-hemolytic streptococci (GAβHS) is a common colonizer of oropharynx in normal children (~20%), acquired as droplet infection from infected/colonized persons.

Pathogenesis: After infection, GAβHS attach to oropharyngeal mucosa to produce many *extra-cellular toxins*, (e.g. pyrogenic exotoxin, streptolysin O and S) for systemic manifestations and *digestive enzymes*, (e.g. streptokinase, hyaluronidase, DNAse-B) to facilitate the local spread. GAβHS disease in children represents: (a) local spread, (b) distant spread via bacteremia, (c) toxin-mediated injury, or (d) immunological injury.

High-risk factors for GAβHS infection or colonization include: (a) school-age children, (b) overcrowding, (c) winter season (except by nephritogenic strains, common in summer season).

Clinical spectrum of GAβHS disease spans from localized skin/respiratory disease to systemic disease, e.g. rheumatic fever or acute nephritis **(Table 10.8)**.

TABLE 10.8: Clinical spectrum of GAβHS infections

Direct spread:
- *URTI:* Tonsillopharyngitis, otitis, sinusitis
- *LRTI:* Pneumonia, pleural effusion
- *Skin:* Impetigo, erysipelas, cellulitis, fasciitis
- *Genital:* Vulvovaginitis in pre-pubertal girls

Hematogenous spread: *(metastatic lesions)*
- *CNS:* Meningitis, brain abscess
- *Bones and joints:* Arthritis, osteomyelitis
- *GIT:* Peritonitis, brain abscess

Toxin mediated:
- Scarlet fever
- Streptococcal toxic shock-like syndrome (TSS)

Immunological injury:
- Rheumatic fever
- Acute glomerulonephritis

Diagnosis depends on throat culture in symptomatic case. Positive throat culture in an asymptomatic child is not necessarily pathogenic and reflects colonization. A serological test-elevated *anti-streptolysin O* (ASO) titers (>200 todd units and rising) is commonly used indicator of recent streptococcal infection. Other serological tests include elevated *anti-DNAase B* and *anti-hyaluronidase* titers, which are more specific and *anti-streptozyme* test, which is most sensitive and detects presence of extracellular streptococcal antigens.

Treatment: *Penicillin* is the drug of choice, given orally or parenterally for minimum 10 days. In allergic individuals, erythromycin, clindamycin or first-generation cephalosporins may be used as alternatives.

Prevention: No vaccine is available for clinical use and prophylaxis with long-acting penicillin is recommended only in rheumatic fever.

Scarlet fever, rarely diagnosed in Indian children, is caused by a pyrogenic exotoxin (A, B, C), released by select strains of GAβHS.

Clinically, it is characterized by: (a) sudden onset of high fever and sore-throat, (b) typical *scarlatiniform* rash–a generalized red, punctate exanthem after 24–48 hours of fever that begins from axilla, groin and neck and better felt than visible (*goose-flesh or sand-paper skin texture*), and (c) circumoral pallor, flushed face and *pastia lines* (hyperpigmented creases in ante-cubital fossae). Fever subsides spontaneously after 5–7 days, followed by gradual desquamation of rash.

Poststreptococcal reactive arthritis (PSRA) denotes onset of acute arthritis following an episode of GAβHS pharyngitis, not fulfilling the Jones criteria for rheumatic fever. It is unclear whether this entity represents a distinct syndrome or a variant of rheumatic fever. Unlike rheumatic fever, PSRA may also involve small peripheral joints and axial skeleton, and is typically non-migratory. ASO titres are elevated.

Response to NSAIDs is usually unsatisfactory. Valvular disease is rare but follow-up is recommended for 1–2 years along with secondary penicillin prophylaxis in some cases.

Pediatric autoimmune neuropsychiatric disorders associated with *Streptococcus pyogenes* (PANDAS) denotes a group of neuropsychiatric disorders, e.g. obsessive-compulsive disorder or tics, with a possible relationship with GAβHS infection-induced autoimmune antibodies that cross-react with brain tissue. Causal relationship is not yet proven and penicillin prophylaxis or immune-regulatory therapy to treat exacerbations is not recommended.

Group B streptococci (GBS) is a normal inhabitant of maternal genital tract and gastrointestinal tract, not associated with any major illness *except* in newborns. While GBS is the *commonest cause of early neonatal sepsis/*

meningitis in western countries due to the transvaginal infection during delivery, it is either uncommon or rarely documented in Indian newborns. Penicillin with an aminoglycoside is the drug of choice in these cases.

α-hemolytic streptococci, (e.g. *S. viridans*) is a part of normal skin and oropharyngeal flora. While rarely pathogenic in normal children, it is the commonest cause of infective endocarditis in cases with heart disease. Drug of choice is ampicillin with an aminoglycoside agent.

Group D streptococci, now re-classified as 'Enterococci' (*E. faecalis* and others), are common inhabitants of oropharynx and gastrointestinal tract. These organisms, previously considered as nonpathogenic, are emerging as important *nosocomial pathogens* in wound infections, catheter-related sepsis, urinary tract infections and infective endocarditis. Penicillin is generally *not effective* and drug of choice is ampicillin with an aminoglycoside *or* vancomycin.

Vancomycin-resistant enterococci (VRE), an emerging problem in recent years, may be treated with linezolid or other newer antibiotics, e.g. daptomycin or tigecycline. Timely removal of urinary and vascular catheters and debridement of necrotic tissue are important strategies to prevent enterococcal infections.

10.4 PNEUMOCOCCAL INFECTIONS

Streptococcus pneumoniae is a common colonizing organism of upper respiratory tract, present in encapsulated and noncapsulated forms. Only capsulated forms are pathogenic and classified according to their type-specific capsular polysaccharide. Human disease is usually caused by serotypes 4, 6, 9, 14, 19 and 23.

Pathogenesis: Pneumococcal colonization is common in under-five children, institutionalized cases and during winter season, via droplet infection from a case/carrier. Although host-defence mechanisms, e.g. mucociliary clearance and local phagocytosis limit the infection to colonized site, it may spread in susceptible host to neighboring tissues (localized disease) or via bacteremia to distant tissues (invasive disease).

High-risk factors for pneumococcal disease include: (a) impaired mucociliary clearance due to viral infections, passive smoking and airway allergy, or (b) immunodeficiency states, *specially with impaired splenic function*, e.g. sickle cell disease, asplenia, splenectomy, etc.

Clinical spectrum spans from local upper respiratory tract disease to invasive disease, e.g. meningitis, pneumonia, etc. **(Table 10.9)**. *Pneumococci is the leading cause of community-acquired pneumonia, otitis media and meningitis in 1–5 years age group.*

Diagnosis rests on culture from the site of infection or blood. Nasal/pharyngeal culture isolation is of little significance, due to frequent colonization.

TABLE 10.9: Clinical spectrum of pneumococcal infections

Direct spread:
- *URTI:* Otitis media, sinusitis, pharyngitis, croup
- *LRTI:* Pneumonia, pleural effusion

Hematogenous spread:
- *CNS:* Meningitis, epidural abscess, brain abscess
- *Bones and joints:* Arthritis, osteomyelitis
- *Cardiac:* Pericarditis, myocarditis
- *GIT:* Peritonitis

Immunological mechanisms
- Hemolytic-uremic syndrome
- Disseminated Intravascular Coagulation (DIC)

Treatment: *Penicillin* is the drug of choice in susceptible cases, while resistant or allergic cases must be treated with cefotaxime or ceftriaxone with/without vancomycin. Rifampicin (PO 20 mg/kg BD) may be added in severe, non-responsive cases.

Prevention of pneumococcal disease involves universal immunization of all children with polyvalent conjugated vaccine (PCV). NIS recommended three doses of PCV_{10} in all infants at the age of 6 weeks, 14 weeks and 9 months. IAP recommends three primary doses of $PCV_{10/13}$ at 6,10 and 14 weeks followed by a booster dose at 12–15 months of age (See Ch 9.2.1).

Additionally, all high-risk cases with (a) splenic dysfunction, e.g. asplenia, splenectomy or sickle cell disease, (b) nephrotic syndrome, (c) CSF leaks, (d) HIV/AIDS, and (e) chronic cardiopulmonary disease, etc. should also receive 23-valent polysaccharide vaccines (PPSV) after two years of age or before surgery (splenectomy, cochlear implant), etc. PPSV is not adequately immunogenic below 2 years of age and need to be repeated after 3–5 years.

Penicillin prophylaxis with 3-weekly IM benzathine penicillin or daily PO penicillin is also recommended in splenectomized children against pneumococcal infections, for at least 2 years after surgery.

10.5 DIPHTHERIA

Diphtheria is a life-threatening but vaccine preventable disease of childhood, characterized by acute severe inflammation of upper respiratory epithelium with membrane formation and marked toxemia. Incidence has declined in recent years, due to expanding immunization.

However, India still contributes to more than half of the cases of diphtheria globally and recent years have seen its resurgence in some geographical regions.

Epidemiology: Diphtheria is caused by three toxigenic strains (*gravis, intermedius and mitis)* of *C. diphtheria* (Klebs-Löffler bacillus)-gram positive non-invasive bacilli, almost exclusively found at respiratory mucous membranes of clinical cases or asymptomatic carriers.

Infection is usually transmitted as droplet infection or via contaminated fomites/dust, though direct contact with infected secretions is a rare source of infection.

Infectivity period lasts for ~2–4 weeks from the onset of disease, except in chronic carriers (>1 month). A case or carrier is considered as non-infective, only when at least two throat cultures at 24-hour interval are negative.

Diphtheria is most common in preschool children (<5 years), during autumn and winter season and unvaccinated children living in overcrowded environment.

Pathogenesis: Major virulence of the organism lies in its ability to produce an *exotoxin*, responsible for local necrosis and systemic complications. On entry, *C. diphtheriae* proliferates superficially at the site of inoculation (usually respiratory epithelium) to produce dense necrotic material consisting of organisms, epithelial cells, fibrin, leukocytes and erythrocytes and an adherent *grayish-white pseudomembrane that bleeds on attempted removal*.

Clinical features: After *incubation period* of 2–5 days, these cases present with

- ***Constitutional symptoms***, e.g. acute onset of moderate fever, typical toxic look and altered mental state, e.g. confusion or irritability. Circulatory collapse is not uncommon.
- ***Local respiratory tract symptoms,*** depending on the site of lesion, as follows:
  - *Pharyngotonsillar diphtheria*, the commonest type, presents with sore throat, dysphagia, submandibular swelling (*bull-neck*) and a grayish-white dirty membrane on soft palate, tonsils and pharyngeal wall that bleeds on removal **(Fig. 10.1)**.
  - *Laryngotracheal diphtheria*, the most serious type, presents with acute hoarseness of voice, croupy cough, stridor and progressive respiratory distress due to airway obstruction by membrane and tissue edema.
  - *Nasal diphtheria*, the mildest form, is characterized by serosanguineous or blood-mixed nasal discharge with membrane formation and shallow ulcers at nasal mucosa and external nares.
- ***Non-respiratory disease*** is uncommon, presenting as *cutaneous diphtheria* (punched-out, tender ulcers with membrane), *conjunctival diphtheria* (purulent/ulcerative conjunctivitis), *aural diphtheria* (otitis externa) and *genital diphtheria* (purulent or ulcerative vulvovaginitis).

Complications may be due to: (a) airway obstruction by membrane or edema, (b) aspiration of infected material, (c) exotoxin production, and (d) abnormal immune response, e.g. Guillain-Barré syndrome **(Table 10.10)**.

Airway obstruction is the immediate cause of mortality in most cases of diphtheria, though important late complications include:

- *Toxic myocarditis*, usually during 2nd week of illness presenting with tachycardia, muffled heart sounds, CCF and arrhythmia. Seen in 10–25% cases, it is responsible for ~ 50–60% of late deaths in diphtheria.
- *Cranial nerve palsies* usually present as *palatal palsy* in 2nd-3rd weeks with nasal twang, regurgitation of feeds and aspiration, or *occular palsies* in 3rd–5th weeks with loss of accommodation (earliest sign), blurred vision and squint.
- *Post-diphtheritic peripheral neuropathy* may be sensory, motor or combined, involves one or more limbs and usually develop in 2nd–3rd weeks.
- *Guillain-Barré syndrome* is a rare late complication after 6–8 weeks and indicates immunological insult.

Diagnosis of diphtheria depends on:

- *Clinical* presence of tough dirty-white membrane in throat that bleeds on removal,
- *Direct microscopy* of throat/nasal swabs with *Albert's stain* to demonstrate the characteristic club-shaped

Fig. 10.1: **Diphtheria (oropharyngeal membrane).**

TABLE 10.10: Complications of diphtheria

Respiratory:
- Airway obstruction > respiratory failure
- Secondary bacterial pneumonia
- Atelectasis
- *Late:* Bronchiectasis, lung abscess

Cardiac:
- Toxic myocarditis and CCF
- Endocarditis (extremely rare)

Neuropathies:
- *Cranial:* Palatal or ocular palsy
- *Peripheral:* Monoparesis
- Guillain-Barré syndrome

Renal:
- Proteinuria (secondary nephrotic syndrome)
- Acute renal failure

Others: Septicemia, hepatitis, arthritis

bacilli with metachromatic staining, arranged in a *chinese-letter pattern.* Fluorescent antibody staining is more sensitive for this purpose.

- *Throat/nasal swab culture* on Loffler or tellurite media to confirm the diagnosis and differentiate from *diphtheroids*—non-pathogenic oropharyngeal commensals.
- A rapid ELISA test, PCR test or modified Elk test may be used to detect presence of diphtheria toxin.
- *Ancillary investigations*, e.g. ECG, urine examination, etc. help to exclude complications.

D/D depends on the site of lesion:

- *D/D nasal diphtheria*: Other causes of serosanguineous or blood-mixed discharge, e.g. (a) viral rhinitis, (b) foreign body and (c) snuffles (congenital syphilis).
- *D/D pharyngotonsillar diphtheria*: Other causes of throat membrane, e.g. (a) streptococcal membranous tonsillitis, (b) viral membranous tonsillitis, e.g. infectious mononucleosis, (c) oropharyngeal candidiasis, (d) post tonsillectomy membrane.
- *D/D laryngeal diphtheria*: Other causes of acute croup and stridor (*see* **Table 16.8)**.

Management: Considering high mortality, morbidity and infectivity, all suspected cases of diphtheria need hospitalization. Important steps in management include:

- ***Strict isolation*** till at least two consecutive nose/throat swabs at 24-hour interval are negative.
- ***Specific anti-toxin therapy*** to neutralize free circulating toxin, given as early as possible.

  Currently, only equine diphtheria antitoxin (ADS) is available. Doses are empirical, depending on the site of membrane and duration of illness, i.e. 40,000-60,000 *IU for nasopharyngeal lesions, 20,000–40,000 IU for pharyngeal or laryngeal lesions of <48 hours and 80,000–1,20,000 IU for severe airway obstruction or longer illness.* It is given as slow IV infusion over 30–60 minutes after a subcutaneous test dose (0.02 ml) to detect hypersensitivity.
- ***Antibiotic therapy*** to stop further toxin production and eliminate organisms. Drug of choice is *Crystalline penicillin* (IV 1–1.5 lac U/kg/d q6hr) or Erythromycin (PO 40–50 mg/kg/d q6hr), given for 14 days or till two successive cultures are negative. However, antibiotic therapy is not a substitute for antitoxin therapy.
- ***Management of complications:*** Immediate tracheostomy is indicated in severe respiratory distress. Even in mild cases, hospitalization with complete bed rest is indicated for 2 weeks—to monitor for late complications, to reduce risk of myocarditis and to prevent spread of infection.

Prevention: Diphtheria is preventable by:

- ***Active immunization*** of all children with three primary doses at 6, 10 and 14 weeks of age and two boosters at 18 months and 5 years, followed by Td every 10 years from 10 years onwards (*see* Ch 9.2.1). IAP also recommends a single dose of Tdap vaccine after 7 years, followed by Td at 17–18 years.
- ***Isolation and treatment*** of symptomatic cases as well as asymptomatic carriers. All carriers must be treated with PO Erythromycin (40–50 mg/kg/d q6hr) for 10–14 days or till two throat-cultures are negative. ADS is not required in asymptomatic cases, even if culture is positive.
- ***Management of close contacts:*** While all close contacts should be cultured from nasopharynx to detect asymptomatic carriers, chemoprophylaxis with PO Erythromycin (40–50 mg/kg/day for 7–10 days) or a single IM Benzathine Penicillin 6 Lac IU (12 Lac IU above 30 kg) is necessary in all close contacts.

All immunized contacts should also be given a booster dose of DPT/DT, if the last dose was received >2 years ago. Unimmunized contacts must be started on primary immunization schedule.

10.6 WHOOPING COUGH

Whooping cough (pertussis) is a highly contagious respiratory infection due to *Bordetella pertussis,* characterized by recurrent bouts of severe paroxysmal cough and typical *whoop* at the end of it. Incidence of pertussis has significantly declined in recent years due to widespread immunization.

Epidemiology: *B. Pertussis*-a gram negative coccobacilli, is present in nasopharyngeal secretions of clinical or subclinical infected case and spreads via droplets. *Infectivity period* spans from 1 week post-exposure to 3 weeks after onset of paroxysmal stage, with maximum infectivity in catarrhal phase.

W. cough is primarily a disease of infants and preschool children < 5 years, including newborns due to absence of maternal antibodies. Immunity after natural infection or immunization wanes after 3–5 years, responsible for increasing number of cases being seen in previously immunized older children and adolescents. Maximum cases occur in late winter/early spring season.

Pathogenesis: It is a *non-invasive* infection, with localized multiplication of organisms in respiratory epithelium with marked inflammation, necrosis and secondary infection. A specific *pertussis toxin* and other bioactive substances, produced by *B. pertussis,* contribute to pathology and development of immunity.

Clinical manifestations: Incubation period is 7–14 days. W. cough is a lengthy disease (also termed 100-day cough) with three stages:

- ***Catarrhal stage*** (2 weeks) begins as a non-specific upper respiratory infection with mild fever, coryza, conjunctival congestion and cough, which is initially dry, intermittent and irritating, mainly in nights.
- ***Paroxysmal stage*** (2–4 weeks), characterized by recurrent bouts of cough with typical sequence of events – each bout begins with sudden onset of

explosive cough, often precipitated by trivial stimuli, e.g. sucking, cold-exposure, etc. During the bout, the child is anxious, appears choked with suffused face and frequent protrusion of tongue. At the end of bout, the hallmark *whoop*—an inspiratory crowing sound, is produced by air rushing-in during inspiration, through partially closed glottis. Most episodes usually terminate with vomiting and production of small, thick-tenacious sputum. Child appears exhausted and sweats profusely.

Frequency and severity of paroxysm increase gradually over next few weeks, till convalescence.

- ***Convalescent stage*** (2–4 weeks) is associated with decreasing frequency and severity of cough bouts, return of appetite and general well-being.

Clinical examination may reveal complications of explosive cough, e.g. conjunctival hemorrhage or tongue lacerations, but no significant lung findings.

Complications may develop due to forceful coughing, secondary infections and reduced dietary intake, as child is scared of feed-precipitated bouts **(Table 10.11)**.

Diagnosis must be suspected in any unimmunized preschool child with prolonged cough (>14 days) and at least one of the following features: *(a) paroxysmal nature, (b) typical whoop* and/or *(c) post-tussive vomiting*. Absolute *lymphocytosis* is common and supports the diagnosis. Further confirmation is possible with:

- *Rapid diagnostic tests*, e.g. direct fluorescent antibody test in nasopharyngeal secretions or laryngeal swab. Serological tests, e.g. ELISA to detect major pertussis antibodies are sensitive, but not in early stages.
- *Culture* on *Bordet-Gengou media* either from naso-pharyngeal swab *or preferably* by direct inoculation (asking the baby to cough directly on culture-plate) is the *gold standard* for diagnosis, though yield is maximum in catarrhal stage.
- *PCR test* in nasopharyngeal secretions. Cultures or PCR tests are often negative in partly-immunized cases or in late paroxysmal stage.

D/D includes other causes of whoop or paroxysmal cough, e.g. (a) other infections, e.g. *B. parapertussis*, mycoplasma, chlamydia, adenoviral infections, (b) airway foreign body, (c) tubercular lymph nodes, compressing trachea/bronchi, etc.

TABLE 10.11: Complications of W. cough

- **Respiratory**
  Early : Pneumonia, atelectasis, pneumothorax
  Late : Bronchiectasis, reactivation of TB
  Others : Otitis media, subcutaneous emphysema
- **Neurological**
  Early : Hypoxic seizures, intracranial hemorrhage
  Late : Motor deficits, aphasia, blindness, deafness
- **Hemorrhagic**: Subconjunctival hemorrhage, epistaxis
- **Gastrointestinal**: Rectal prolapse, hernia
- **Malnutrition**, due to vomiting and ↓ intake

Treatment: Pertussis is self-limiting, with a limited role of antimicrobial therapy, unless instituted in very early stage. All infants < 6 months or older children with complications, must be hospitalized.

Management aims to limit the number of paroxysms, maintain the nutrition and general health, and treat complications, by:

- ***Isolation*** for at least 5 days after starting erythromycin therapy,
- ***Prevention of attacks*** by nursing in quiet comforting environment, avoidance of large feeds and exposure to cold draught,
- ***Management of acute attack*:** Though reassurance is usually enough to relieve anxiety, prolonged attack may need airway maintenance, oxygen or ventilatory support. Nebulized salbutamol may be effective in controlling the attack.
- ***Antibiotic therapy*** with Azithromycin (PO 10 mg/kg/day q24hr × 5 days) or other macrolides are effective only if given in early catarrhal stage. It shortens the natural course, reduces severity as well as infectivity and prevents secondary infection.

  Other agents, e.g. steroids, salbutamol, hyper-immune pertussis immunoglobulin, etc. are of no proven value.
- ***Supportive treatment*** to ensure adequate hydration, nutrition and treatment of complications.

Prevention depends on:

- ***Routine immunization*** with whole-cell killed vaccine (DTwP) or acellular pertussis vaccine (DTaP) at 6th, 10th and 14th weeks of life with booster at 18 months and 5 years (see Ch 9.2.1)
- ***Isolation of the index case***, specially from high-risk contacts, e.g. newborns.
- ***Prompt treatment of contacts:*** Since pertussis is highly contagious with secondary attack rate of 60–70%, all unimmunized household contacts <7 years of age should receive PO Azithromycin for 5 days or erythromycin for 14 days, along with immediate pertussis vaccination including those who received their 3rd primary dose before 6 months or booster dose before 3 years.

10.7 ENTERIC FEVER

Enteric fever, systemic infection due to Salmonella organisms, is a leading cause of prolonged pyrexia in children. While the term *enteric fever* includes both *typhoid* (*S. typhi*) and paratyphoid fever (*S. paratyphi* A, B and C), in practice it is used interchangeably with typhoid fever. Paratyphoid infections are less common, less severe and difficult to differentiate from typhoid.

Enteric fever is an endemic illness in India with occasional outbreaks and annual incidence of ~1% in population <17 years of age.

Epidemiology: *S. typhi* is a gram-negative, mainly intracellular organism, having 3 major antigens (O, H, Vi) and over 80 phage types. *Phage typing* is necessary to trace the source of epidemic.

Reservoir of infection is a case or carrier, who excretes the bacilli in urine or stools.

Modes of transmission is *fecooral,* due to contamination of food/water, either directly by hands of infected food handlers or indirectly via flies. Raw vegetables grown in sewage farms or washed with contaminated water are common sources of infection. Eggs with cracked shells may get contaminated during storage/transport. Transplacental and intrapartum infection due to fecal contamination of amniotic fluid in carrier mothers is known.

Risk factors: Enteric fever is more common in school-age and adolescents (5–19 years) and in males. It is rare during first two years of life due to less risk of exposure. Children with natural infection or immunization are *relatively* protected for 3 years. Peak incidence is during rainy season (July to September), due to higher risk of water contamination and fly population. Sewage-contaminated water supply, open air defecation and poor hygiene are other important risk factors.

Pathogenesis: On ingestion, Salmonella attach to microvilli of ileal brush borders and invade intestinal epithelium through Peyer's patches, to reach and proliferate in mesenteric lymph nodes (*local lymphoid hyperplasia*). From here, they enter blood stream via thoracic duct leading to asymptomatic *primary bacteremia* and seedling of reticuloendothelial tissues, e.g. liver, spleen, bone marrow, for further proliferation. After an incubation period of 7–14 days, *secondary bacteremia* develops from these sites, marking the onset of fever as well as infection of other tissues including gallbladder-*the most important reservoir of infection, responsible for carrier state.*

Pathology: Important pathological changes in enteric fever include:

- *Typical typhoid ulcers*-shallow oval ulcers along the axis of intestines, due to hyperplasia of Peyer's patches and slough of overlying epithelium,
- *Lymphoid hyperplasia* in mesenteric nodes, liver and spleen with mononuclear infiltration.
- *Metastatic micro-abscesses* in deeper tissues, due to secondary bacteremia.

Clinical manifestations: After incubation period of ~10–14 days, enteric fever presents with: (a) typical *remittent fever with step-ladder pattern* (gradual rise in first week), though many cases have continuous fever, (b) constitutional symptoms, e.g. malaise, anorexia, myalgia, headache, and (c) GIT symptoms, e.g. abdominal pain, constipation or diarrhea. Important clinical signs include:

- Ill or toxic general appearance,
- Relative bradycardia,
- Dry and coated tongue,
- Tympanic abdomen with mild to moderate hepato-splenomegaly, and
- Typhoid rash (*rose spots*)—discrete macular blanching lesions over trunk on 7^{th}–10^{th} day, rarely visible in dark-skinned Indians.

Clinical manifestations are usually mild in younger children (<5 year) and paratyphoid fever.

Complications: Although fever and physical findings may resolve spontaneously in 2–4 weeks, complications are common in untreated cases, usually during 2nd–3^{rd} weeks of illness **(Table 10.12)**. Mortality is <1% in treated cases.

Diagnosis should be considered in any case with: (a) prolonged fever without localizing signs, and (b) toxic appearance with coated tongue and tympanic abdomen. Confirmation requires:

- *Bacterial cultures:* Blood cultures are positive in 60–80% cases during first week, but positivity declines in later weeks. Multiple cultures, with volume not less than 5 ml on different days, are preferable as typhoid bacteremia is low-grade and intermittent. Bone marrow culture is more sensitive (85–90% positivity), even after antimicrobial therapy. Stool and urine cultures turn positive by 3^{rd}–4^{th} weeks and help in diagnosis of carrier state.
- *Serological tests:* Classical *Widal test* measures titers of agglutinin antibodies against O and H antigens and turns positive only after 5–7 days of fever. Generally, anti-O titers of >1:160 *or* rising anti-H titers on second test after a week, are considered as suggestive (but not diagnostic) of enteric fever. Single anti-H titers may be false-positive due to *anamnestic response* to other fevers, e.g. malaria and rickettsial infections. Anti-O titers do not differentiate between typhoid and paratyphoid infection.

  Rapid serodiagnosis tests, e.g. *Typhidot* to measure IgM antibodies against outer membrane protein of

TABLE 10.12: Complications of enteric fever

- **Gastrointestinal:**
  - Intestinal bleeding (1–10%)
  - Perforation, peritonitis
- **Hepatobiliary:** Hepatitis, cholecystitis
- **Respiratory:** Pneumonia, bronchitis
- **Neurological:**
  - Encephalitis, meningitis, psychosis
  - Acute cerebellar ataxia,
  - Peripheral neuritis, Guillain-Barré syndrome (rare)
- **Skeletal:** Osteomyelitis, arthritis
- **Deep tissue abscesses** in liver, spleen, etc.
- **Blood:** Aplastic anemia, thrombocytopenia
- **Miscellaneous:**
  - Parotitis
  - *Rare:* Myocarditis, acute nephritis

organism using ELISA technique have a sensitivity and specificity of ~80%.

- Direct detection of *S. typhi* specific antigens in serum using *monoclonal antibodies* is possible but not routinely available.
- *PCR testing* is expensive but most specific and sensitive diagnostic method for early diagnosis, even in cases with very low bacteremia.
- *Other investigations* are largely supportive, to detect complications or exclude other causes of prolonged pyrexia and include: (a) *hemogram* (leucopenia with relative lymphocytosis), (b) *platelet counts* (thrombocytopenia), (c) stool examination for occult blood to exclude GIT bleeding, (d) *chest X-ray* to exclude pneumonia or tuberculosis (e) *standing X-ray abdomen* to exclude perforation, and (f) *USG abdomen* to exclude peritonitis, cholecystitis and metastatic abscesses in children with prolonged illness.

Management aims to: (a) eradicate infection as well as carrier state, (b) provide nutritional support and symptomatic relief, and (c) diagnose and treat complications promptly.

Hospitalization is indicated in cases with acute toxemia, poor intake or suspected complications. Important treatment modalities include:

- ***Antimicrobial therapy*:** Conventional antibiotics, e.g. chloramphenicol, ampicillin or cotrimoxazole are rarely used at present due to widespread resistance. Quinolones are the drugs of choice for treatment of enteric fever in adults, but not uniformly approved in children. Current IAP recommendation (2022) are as follows:
  - For *uncomplicated enteric fever*, PO Cefixime (20 mg/kg/day q12hr 7–14 days) is the preferred choice, the alternative being PO Azithromycin (20 mg/kg/day q24hr 7–14 days).
  - For *complicated or severe disease*, IV Ceftriaxone (100 mg/kg/day q12hr) or Cefotaxime (150–200 mg/kg/day q12hr) is the preferred choice, to be given for 10–14 days. Alternatives include IV Aztreonam (50–100 mg/kg/day q12hr) or Azithromycin (20 mg/kg/day q12hr) for 7 days, in cases of penicillin allergy or poor response.
- ***Supportive treatment*** includes: (i) bed rest, (ii) soft diet, (iii) fluid and electrolyte therapy, and (iv) general nursing care, especially for oral hygiene. *Steroids* (PO/IV for 2–3 days) may be used in cases with severe toxemia, shock or mental obtundation, though prolonged steroid therapy increases the risk of intestinal perforation.
- ***Treatment of relapse:*** Relapses are common after partial treatment, usually within two weeks of stopping antibiotics. Each relapse should be treated as a fresh case, but for longer duration.
- ***Eradication of carrier state:*** Persistent excretion of Salmonella in stool/urine after defervescence defines a '*carrier state*', which includes convalescent carriers (<3 months) and chronic carriers (>3 months). Carrier state is less common in children (1–5%) than adults.

Reservoir of infection in carriers is *gallbladder* and treatment includes: (a) *medical therapy* with PO ampicillin or amoxicillin for 2–4 weeks till at least two stool cultures are negative, and (b) *surgery*, i.e. cholecystectomy in chronic carriers (>1 year) refractory to repeated antibiotics therapy for 4–6 weeks, to remove the reservoir of infection

Prevention against enteric fever includes—(a) general sanitation and supply of safe drinking water, (b) personal and food hygiene awareness, (c) immunization, and (d) detection, treatment and follow-up of carriers. Stool/urine cultures are indicated in all cases after 3–4 months of recovery to exclude carrier state.

Currently, two types of typhoid vaccines are available: (a) Vi polysaccharide vaccine and (b) conjugate vaccine. Polysaccharide vaccines are less effective, cannot be used < 2 years and need boosters every 3 years.

While Typhoid vaccination is not included in universal immunization program, IAP recommends a single dose of typhoid conjugate vaccine (TCV) at the age 6–9 months, with catch-up immunization upto 18 years (Ch 9.2.2).

Non-typhoidal salmonellosis due to other *Salmonella* species, e.g. *S. enteritidis, S. choleraesuis, S. typhimurium, S. newport*, etc., is usually acquired by use of contaminated animal products, e.g. eggs *or* raw vegetables/water.

Clinically these cases present as: (a) *acute gastroenteritis* (food poisoning) with crampy abdominal pain after ~ 24 hours of consumption, *or* (b) *extraintestinal disease*, e.g. osteomyelitis, arthritis or meningitis, which is more common in newborns, severe malnutrition, sickle cell anemia, malignancy and immunodeficiency states.

Diagnosis rests on culture and phage typing, though serological tests, e.g. latex agglutination test or immunofluorescence test are available for early diagnosis.

Treatment of Salmonella gastroenteritis is symptomatic, *without antibiotics*, which may prolong carrier state. Extraintestinal disease should be treated like enteric fever, but more intensively, via parenteral route only.

10.8 SHIGELLOSIS

Shigellosis is the commonest cause of bacillary dysentery in children, characterized by: (a) typical small volume, bloody-mucoid stools with extreme frequency, (b) high fever with toxic appearance and (c) risk of systemic complications.

TABLE 10.13: Complications of Shigellosis

- Dehydration, dyselectrolytemia
- Hypoglycemia
- Septicemia and DIC
- Seizures, encephalopathy*
- Renal failure, hemolytic uremic syndrome
- Hemolytic anemia, thrombocytopenia
- *Local:* Rectal prolapse, toxic megacolon
- *Others***:* Arthritis, Reiter syndrome, hepatitis, myocarditis

**Ekeri syndrome*: Hyperpyrexia, toxic appearance, seizures, coma and death, without significant sepsis/dehydration
***? autoimmune ?? toxin-mediated

Epidemiology: Shigellosis is caused by one of the four species—*S. dysenteriae* (commonest), *S. flexneri, S. boydii* and *S. sonnei*. Contaminated food and water is the commonest source of infection, though person-to-person transmission through infected food handlers is common.

High-risk factors: It is most common in pre-school age group (except in breastfed infants due to protective antibodies in breast milk) and institutionalized children, e.g. orphanages and daycare centers. While most cases are endemic in India, intermittent outbreaks are common in rainy season.

Pathogenesis: Shigella requires very low inoculum to produce clinical disease, mainly caused by invasion of colonic epithelium (invasive disease). However, some strains of *S. dysenteriae* produce a powerful exotoxin—*Shiga toxin* and/or an endotoxin *(ShET1).*

Pathological lesions are characterized by intense mucosal inflammation and formation of multiple ulcers, mainly in *distal colon*. Development of secretory IgA and type-specific serum antibodies leads to spontaneous recovery after 7–10 days in uncomplicated cases. Chronic diarrhea is rare.

Clinical manifestations develop after a short incubation period of 1–3 days, with:

- Acute watery diarrhea, which rapidly evolves into typical small-volume blood and mucus mixed stools with high frequency (15–20/day), urgency, painful defecation (strangury) and colicky abdominal pain.
- High fever, toxic appearance and other constitutional symptoms.
- Extraintestinal manifestations and complications in ~ 30–40% cases **(Table 10.13)**.

Diagnosis is supported by presence of leukocytes (usually >50–100/hpf) and blood in stools and peripheral leukocytosis with band cells. Confirmation requires stool culture (or rectal-swab cultures) on selective media, e.g. xylose-lysine deoxycholate (XLD) and Salmonella-Shigella agar. However, negative culture does not exclude shigellosis. Molecular PCR tests are available but rarely used.

TABLE 10.14: Common causes of dysentery

- *Bacterial:*
  - Shigella
  - *E. coli* (enteroinvasive serotypes)
  - *C.difficile* (pseudomembranous enterocolitis)
  - *Others: C. jejuni, Y. enterocolitica*, Salmonella
- *Protozoal: E. histolytica*
- *CIBDs:* Ulcerative colitis, Crohn's disease

CIBD: Chronic inflammatory bowel diseases

D/D of shigellosis includes other causes of infective dysentery and acute attack of chronic inflammatory bowel diseases, e.g. ulcerative colitis **(Table 10.14)**.

Management includes: (a) fluid and electrolyte correction, (b) antibiotic therapy, and (c) symptomatic measures.

Antibiotics of choice for shigellosis are Ciprofloxacin (PO 20–30 mg/kg/day q12hr) or Cefixime (PO 8 mg/kg/day q12hr) for 5 days, while IV Ceftriaxone (50 mg/kg/day OD) may be used in small infants or seriously sick patients. Azithromycin is a second-line antibiotic in non-responders.

Studies have also shown beneficial effects of single dose vitamin A (200000 IU) and zinc supplements (PO 20 mg 14 days) in recovery from shigellosis, apart from high-protein, high-caloric diet.

Most cases recover within 5–7 days and mortality is uncommon except in severe malnourished children or those with complications, e.g. severe dyselectrolytemia, DIC, renal failure and encephalopathy.

Prevention depends on: (a) prolonged breastfeeding, (b) personal hygiene, e.g. hand-washing after defecation/before food handling and (c) proper water/sewage treatment. No vaccine is available at present.

IMNCI recommends diagnosis of *dysentery* in any child age 2 months-5 years with blood in stools, who should be treated with Cefixime (PO 10 mg/kg/day q12hr) for 5 days and Tab Zinc 20 mg once a day (half tab in infants 2–6 months), with follow-up after 2 days.

10.9 *H. INFLUENZAE* B DISEASE

Haemophilus influenzae b *(Hib)* infections are commonest cause of meningitis and pneumonia in young children (6 months–3 years) of developing countries, though the incidence seems to be substantially reduced due to widespread immunization.

Epidemiology: *H. influenzae*, a gram-negative coccobacilli, exists in capsulated or uncapsulated forms, with 6 serotypes (a–f). Invasive disease is caused by *capsulated serotype b*, while other serotypes or uncapsulated organisms may cause localized airway disease or invasive disease in immunocompromised host.

High-risk factors: There is a striking age distribution of invasive Hib disease, with >90% cases seen within first 5 years of life. In older children, it is more likely in immunocompromised children specially with *splenic dysfunction*, e.g. sickle cell disease, asplenia and splenectomy.

Pathogenesis: Hib organisms colonize respiratory flora via droplet infections-colonization rate being directly related to age. As colonized individuals develop natural immunity in due course of time, uncolonized infants and young infants are more susceptible for Hib disease at the time of first infection. Infection may spread locally *or* via hematogenous route to distant sites (invasive disease).

Clinical spectrum of Hib disease varies from *localized disease*, e.g. otitis or sinusitis to *invasive disease,* i.e. meningitis, pneumonia or septicemia **(Table 10.15)**.

Diagnosis depends on the culture and serotyping of organism, which requires prompt transport and inoculation as the organism is very fastidious.

A latex agglutination test to detect antibodies against capsular polysaccharide antigen, i.e. polysaccharide reactive proteins (PRP) in CSF or other secretions is very useful for early diagnosis, especially in partially-treated cases.

Treatment depends on the severity of disease. While PO Amoxycillin or Co-amoxclav for 7–10 days is usually adequate for localized disease, intensive parenteral therapy with a third-generation cephalosporin, i.e. *Ceftriaxone* is essential in invasive disease.

Prevention of Hib disease involves:

- ***Routine Hib immunization*** with a conjugated polysaccharide vaccine, given at 6,10 and 14 weeks as a combination pentavalent vaccine in NIS, without any booster dose. However, IAP recommends three primary doses as in NIS, along with a booster dose at 12–18 months. Catch-immunization is not recommended beyond 5 years of age, except in *high-risk cases*. (Ch 9.2.1)
- ***Post-exposure chemoprophylaxis*** with *Rifampicin* (10–20 mg/kg OD for 4 days) is indicated in close contacts of confirmed cases, who are unimmunized and <5 years of age.

TABLE 10.15: Clinical spectrum of Hib disease

Localized disease:
- Otitis media
- Sinusitis
- Acute epiglottis
- *Others:* Orbital cellulitis, conjunctivitis

Invasive disease:
- Meningitis
- Pneumonia
- Bacteremia
- *Others:* Arthritis, pericarditis, peritonitis

10.10 MENINGOCOCCAL INFECTIONS

Meningococcal infections usually occur in small outbreaks, presenting as *localized* meningococcal meningitis or *systemic* meningococcemia.

Epidemiology: According to antigenic differences in capsular polysaccharide, *Neisseria meningitides* are divided into 13 serotypes. Of these, six (A, B, C, W, X and Y) account for virtually all cases of meningococcal disease. Group A infections are more common in India.

High-risk factors: Meningococcal disease is more common in young infants (3–24 months). Newborn <3 months are protected by transplacental maternal antibodies. Older children are also relatively protected by antibodies acquired during previous colonization, though those with complement-deficiency states, e.g. nephrotic syndrome, hepatic failure and autoimmune disorders, are more susceptible for these infections.

Pathogenesis: Meningococcal infection is a highly contagious droplet infection with nasopharyngeal colonization rate as high as ~100% during outbreaks. Post-colonization, infection may remain asymptomatic (colonization) or disseminate hematogenously (invasive disease), to produce meningococcemia and secondary involvement of meninges, skin, adrenals and other organs.

Pathologically, invasive disease is characterized by acute inflammatory reaction (meningitis), vasculitis (rash) and tissue hemorrhages, especially in adrenals (*Waterhouse-Friderichsen syndrome*), due to a DIC-like state.

Clinical spectrum of disease varies from mild fever and occult bacteremia to a shock-like state and death. Common presentations include:

- ***Acute meningococcemia***, begins as a flu-like illness with fever, sore-throat, headache, myalgia and pathognomonic *purpuric skin rash*, but may progress rapidly to septic shock, hypotension, DIC, adrenal hemorrhage (*Waterhouse-Friderichsen syndrome*) and multi-organ failure. Meningitis may or may not be present.
- ***Acute meningitis*** is most common manifestation, with/without skin lesions or signs of meningococcemia.
- ***Non-CNS focal disease***, e.g. pericarditis, pneumonia or arthritis is rare.
- ***Chronic meningococcemia*** is rare, with prolonged intermittent fever and rash, arthralgia and headache during fever, lasting for 6–8 weeks.

Complications of meningococcemia include: (a) metastatic infections, e.g. pneumonia or arthritis (b) adrenal hemorrhage, (c) cutaneous vasculitis, leading to skin gangrene and (d) late complications, e.g. immune complex arthritis or cutaneous vasculitis, after 6–9 months.

Diagnosis rests on isolation of organism from blood, CSF or skin lesion. A positive throat culture is not diagnostic and may reflect only the carrier state. Early diagnostic tests, e.g. latex agglutination test, are useful but not as replacement of the culture. Molecular PCR tests are available with high sensitivity and specificity.

Treatment: IV Ceftriaxone 100 mg/kg/day q12–24 hr for 5–7 days is preferred at present over conventional high-dose Penicillin therapy (2–3 Lac U/kg/d q4–6 hr) due to dosage convenience and eradication of nasopharyngeal carrier state. Allergic cases may be treated with ciprofloxacin or meropenem.

Prevention includes:

- ***Post-exposure chemoprophylaxis:*** All close-contacts should receive Rifampicin (PO 10 mg/kg BD for 2 days) or a single dose of ciprofloxacin or ceftriaxone. Since penicillin does not eradicate nasopharyngeal carriage, even index case should receive chemoprophylaxis, if treated by penicillin and not ceftriaxone before discharge.
- ***Pre-exposure immunization*** with a quadrivalent conjugate vaccine (MCV) is recommended only in high-risk cases or during outbreaks as follows: (a) high-risk cases with two doses at 8 weeks interval, followed by a booster dose every 5 years, (b) during outbreaks, a single dose to close-contacts above 3 months of age, (c) single dose to laboratory or health care workers at risk of exposure with booster every 5 years, if required, (d) for international travels (Ch 9.2.2)

  Polysaccharide vaccines (MPSV) are also available but should be used only in high-risk children >2 years if MCV is not available, given as a single dose followed by revaccination every 3–5 years. During outbreaks too, a single dose of PPSV may be given in children > 2 years or two doses at 3 months interval in younger children 3–24 months of age (Ch 9.2.2).

10.11 CHOLERA

Cholera is an ancient killer disease, with many pandemics recorded in different parts of the world with very high mortality. In India. Disease is currently endemic throughout the country, with intermittent focal outbreaks.

Epidemiology: Cholera is caused by different strains of *vibrio cholerae 01*, a gram-negative motile, slightly curved rods with polar flagellum.

V. cholerae 01 has two major biotypes—*classical and El Tor vibrio*, subdivided into many serotypes (serovars) according to somatic antigens—mainly the *ogawa*, *inaba* and *hikojima* strains.

Current infections in India are mainly caused by El Tor biotype and ogawa serotypes. Last two decades have seen emergence of a new virulent strain *V. cholerae 0139* from Chennai, responsible for the many outbreaks in India and south Asia.

Source of infection is an asymptomatic carrier or a case, and infection is transmitted *feco-orally* after ingestion of contaminated water or food. *Period of infectivity* is 7–10 days for a case, though chronic carrier state may continue for >10 years.

Cholera affects all age groups with highest attack rate and more severe disease in children. Most outbreaks begin in summer or rainy season, with two important risk factors—poor sanitary conditions and large congregations of people, e.g. in fairs, *kumbhs*, etc.

Etiopathogenesis: *V. Cholera, o*n reaching the small intestine, proliferate and colonize the duodenum/jejunum to produce various enterotoxins. Two important enterotoxins include:

a. A cholera toxin, which activates adenylate cyclase to raise cyclic AMP levels in intestinal mucosa, with decreased sodium and chloride absorption as well as increased chloride secretion.
b. A *zonula occludens* toxin *(zot),* which alters the intercellular tight junctions to increase intestinal mucosal permeability and leakage of water and electrolytes into lumen.

Clinical manifestations depend on the type of strain, dose of organisms and age of the patient. El Tor infections are frequently asymptomatic (>95%) as compared to classical Vibrio (<20%).

A typical case present after an incubation period of 6 hours – 5 days, with 3 stages:

a. *Stage of evacuation* characterized by abrupt onset of profuse, painless, watery diarrhea *(rice-water stools)* with fishy odor and vomiting.
b. *Stage of collapse* due to extensive fluid and electrolyte loss with severe dehydration, shock, hypothermia, renal failure and acidosis. Patient develops intense thirst and muscular cramps due to dyselectrolytemia, and gradually becomes disoriented or stuporus. Purging can continue for as long as one week, unless untreated patients die due to dehydration and acidosis.
c. *Stage of recovery* in survivors begins with decreased frequency, better consistency, appearance of color (bile) in stools and improved hydration.

However, classical presentation is seen in only 10–15% cases while other children present with milder non-specific diarrhea and recover within 1–3 days.

Diagnosis should be suspected in any case from endemic region, presenting with profuse diarrhea and/or rice-water stools. Confirmation requires:

- *Direct stool microscopy (hanging-drop preparation)* under dark-field illumination for motile Vibrio, which appear like many *shooting stars in the dark sky*. Motility ceases on mixing with polyvalent anti-Vibrio

sera. Stools should be collected before antimicrobial therapy on a transport media, e.g. *Venkatraman-Ramakrishnan media* or alkaline-peptone water and transported to the laboratory immediately for direct motility examination and culture.

- *Stool cultures* are necessary for confirmation, bio-typing, sero-typing and phage-typing of infections for epidemiological purpose. Cultures are done on bile-salt agar media, e.g. *thiosulfate citrate bile sucrose* (TCBS), after initial enrichment in peptone-water tellurite media.
- *Serological tests* are not useful except for epidemiological studies and molecular identification with PCR-DNA probes is possible but rarely used.

Management: Prompt management is essential to reduce mortality, prevent further transmission and control the outbreak and includes:

- ***Fluid and electrolyte therapy:*** Over 90% cases of cholera can be managed with ORS alone, which should be started as early as possible and given *ad libitum* with minimum 75 ml/kg during first 24 hours *plus* 50–100 ml after each stool. IV fluid therapy with Ringer lactate is required in cases with: (a) severe dehydration and shock, (b) persistent vomiting, and (c) altered sensorium (*see* Ch 7.7 for fluid therapy).
- ***Antimicrobial therapy:*** Antibiotics shorten the course of illness and reduce the risk of transmission. Drugs of choice, in order of preference, are PO *Tetracycline* 50 mg/kg/day q6hr or PO *Erythromycin* 50 mg/kg/day q6hr, both for 3 days. Single dose PO *Ciprofloxacin* 20 mg/kg or *Azithromycin* 20 mg/kg are equally effective.
- ***Continuous monitoring*** for intake/output of fluids, hydration status and electrolyte disturbances.
- ***Adequate parenteral nutrition*** in critically sick children, though oral feeds should be started as soon as possible.
- ***Treatment of complications***, e.g. (a) circulatory shock, (b) electrolyte disturbances, e.g. *hypokalemia* due to excessive stool loss or *hypocalcemic tetany* due to persistent vomiting, (c) acidosis, (d) hypoglycemia, (e) neurological depression due to hypovolemia and hypoxia, and (f) pulmonary edema due to fluid overload.

Prevention: Control of cholera outbreak is a major public health exercise, involving:

- *Immediate notification* to the authorities,
- *Early detection* of cases and asymptomatic carriers by contact-stool examinations and door-to-door survey in affected locality,
- *Public health measures* to improve sanitary conditions and excreta disposal,
- *Proper disposal/disinfection* of infectious biomedical waste,
- *Vaccination is* recommended only in special circumstances, e.g. residents and travellers of highly endemic regions and high-risk settings for outbreaks, e.g. *kumbh*. It should not be used as outbreak control measure.

  Two types of whole-cell killed oral cholera vaccines are available, of which only a bivalent vaccine (Shanchol) containing *V. cholerae* 01 (classic and El Tor) and *V. cholerae* 0139 serotypes is licensed in India, to be given orally as two doses at two weeks interval, only beyond two years of age.

10.12 BRUCELLOSIS

Brucellosis, caused by *B. melitensis* in India is a zoonotic disease of cattle, with humans infected by ingestion of contaminated animal products, e.g. unpasturized milk. It is a major public health problem in adults specially cattle-handlers, but rare in children.

Clinical manifestations begin after 3–4 weeks of incubation period, with a triad of: (a) prolonged fever, (b) arthralgia, and (c) hepatosplenomegaly. Constitutional features, e.g. GIT upset, sore throat, headache/lethargy and rash may be present. Invasive brucellosis, e.g. osteomyelitis, meningitis or endocarditis is extremely rare in children.

Diagnosis rests on clinical suspicion in prolonged pyrexia with *rising serological titers*, i.e. serum agglutination test on acute and convalescent sera. It is confirmed by culture or PCR.

Treatment: Doxycycline (PO 2–4 mg/kg/day q24hr) with Streptomycin (IM 15–30 mg/kg/day q24hr) or Rifampicin (PO 15–20 mg/kg/day q24hr) is the drug of choice for older children, while younger ones may be treated by cotrimoxazole with rifampicin, for 6 weeks. Invasive brucellosis requires at least 4–6 months therapy with three drugs-doxycycline, streptomycin and rifampicin.

10.13 CHILDHOOD TUBERCULOSIS

Tuberculosis (TB) continues to be major public health problem in India and recent years have witnessed resurgence of disease due to spread of HIV infection and emergence of multi-drug resistance. However, India is committed to eliminate tuberculosis by the year 2025, ahead of WHO-target for global TB elimination by 2030.

Magnitude of problem: Natural course of tuberculosis may be divided into two stages:

a. Primary infection that may or may not progress to disease state and
b. Active disease, due to spread of primary infection, re-activation of latent primary infection *or* re-infection in later life.

Accordingly, the magnitude of problem is ascertained by the frequency of either *infection* or *disease.* Recent TB report 2023 suggests estimated prevalence of disease in India as 312 per lakh population, including 5.6% children below 14 years of age. However, ~30–40% children by this age are Tuberculin-positive, suggesting a large pool of latent infections. Year 2022 has reported ~13% rise in newly detected cases *vs* previous year, perhaps due to delayed medical attention in COVID years and increase in the case detection/notification under National Tuberculosis Elimination Programme (NTEP).

Epidemiology: *Mycobacterium tuberculosis*—an obligate aerobe, is characterized by hallmark *acid-fastness,* i.e. capability to resist decolorization by acid or alcohol on staining. Presence of a lipid-rich cell wall resists intracellular killing and hence, the organism may survive for many years intracellularly within phagocytes and macrophages, even after extracellular destruction.

Genus *Mycobacterium* includes two broad groups—(a) *Typical mycobacteria*, e.g. *M. tuberculosis, M. bovis,* etc. and (b) *Atypical mycobacteria*. While atypical mycobacteria can also produce similar disease specially in immunocompromised hosts, the term *tuberculosis* is reserved for disease caused by typical mycobacteria, of which *M. bovis* is rare in India.

Atypical mycobacteria are classified as: (i) photochromogens, e.g. *M. kansasii*, (ii) scotochromogens, e.g. *M. scrofulaceum*, (iii) nonphotochromogens, e.g. *M. intracellulare*, and (iv) rapid growers, e.g. *M. fortuitum*.

Primary infection is most common in early childhood with important risk factors being malnutrition, low socioeconomic status and absence of BCG vaccination.

Overcrowding and history of contact in the household are two most important environmental factors for natural infection.

Source of infection is usually an adult sputum-positive household contact. While effective therapy reduces the infectivity of index case by 90% within 48 hours, intermittent discharge of organisms in sputum may continue for 3 months (or longer in drug-resistant cases). Pediatric cases are seldom infective, unless having endobronchial or cavitatory lesions.

Mode of transmission is usually a *direct* person-to person droplet infection, or rarely via *indirect* contact with contaminated fomites. Newborns of infected mother may be infected via transplacental infection or after aspiration of infected amniotic fluid at birth.

Portal of entry: Lung is the commonest portal of entry in acquired infections, including in newborns due to aspiration of amniotic fluid at birth. However, congenital transplacental infection may be first lodged in liver.

Pathogenesis (Natural history) of infection depends on previous exposure and presence of cell-mediated immunity (CMI). In most cases of childhood infections, when infection is often primary and CMI is absent, infection progresses in following manner:

- ***Formation of primary complex:*** After airborne entry, bacilli are primarily lodged in *peripheral subpleural alveoli around the right interlobar fissure* (due to sluggish air current in this region) and multiply in alveolar spaces and ducts. About 20% cases have more than one primary lesion. In transplacentally infected infants, primary lesion forms in liver with similar course.

  First protective response to infection is nonspecific local inflammatory reaction to attract macrophages, which attempt to ingest and destroy invading pathogens. However, presence of unique sulfatides molecules in mycobacterial cell wall inhibits phagocytic activity and many organisms escape intracellular destruction and in fact, multiply intracellularly.

  During this period of uninhibited growth, bacilli either remain concentrated in parenchymal lesion (*Ghon lesion*-a pulmonary granuloma of ~1 cm size with central necrosis and surrounding mononuclear infiltration, epitheloid cells and giant cell formation) *or* carried to regional lymph nodes via local lymphatics. The term *primary complex* includes: (i) parenchymal (Ghon) lesion, (ii) draining lymphatics, and (iii) regional lymph node infection.

  Till adequate and specific immune response develops in next 8–12 weeks (as discussed below), local lesion progresses relentlessly with intense tissue reaction. During this period, intermittent bacteremia is common with hematogenous seedling of distant organs (*extrapulmonary tuberculosis*).
- ***Immunological response:*** Four different types of specific immunological responses develop in next 8–12 weeks, which determine the further course of disease:
  - *Specific macrophage-mediated response:* After initial non-specific macrophage response, small population of lymphocytes with capability to recognize specific mycobacterial antigens proliferate and secrete lymphokines and other inflammatory mediators, to enhance the bactericidal activity of activated macrophages and trigger humoral/cellular response.
  - *Humoral response:* Although tubercular infection provokes a robust antibody response, humoral immunity plays negligible role to protect from progression of disease.
  - *Cell-mediated immunity* (CMI), i.e. T-cell mediated immune response is the most important protective response to arrest primary lesion. Development of adequate CMI leads to healing of primary complex, while inadequate CMI permits unhindered progression. Persistence of adequate CMI is essential to keep healed lesions in check, as intracellular pathogen often survive in these lesions and may

be reactivated during immunocompromised states, e.g. malnutrition, diseases, e.g. measles, whooping cough, HIV, etc. and steroid or cytotoxic therapy.
  - *Delayed tuberculin hypersensitivity* (DTH) is a potentially harmful response that arrests the mycobacterial growth but provokes intense tissue reaction and destruction due to release of bacterial breakdown products and inflammatory mediators like TNF- , hydrolytic or proteolytic enzymes, oxidation intermediates, etc. DTH is also responsible for tuberculin positivity and other hypersensitivity manifestations **(Table 10.16)**.
- ***Fate of primary complex*** after initial 6–10 weeks **(Table 10.17)**, depends on the balance between protective CMI and destructive DTH in the host:
  - In >90% cases, development of adequately CMI heals primary lesion with calcification.
  - In cases with inadequate CMI, (e.g. in malnutrition), healing is incomplete with progression of disease (*see* below, *spread of primary lesion)*. Even in partially healed lesions, viable organisms may persist for many years.
  - In cases with excess DTH (with/without adequate CMI), local reaction is so intense as to cause excessive tissue destruction and cavity formation. Uncommon in primary infection, it is the major pathological mechanism of *adult or reactivation TB*.
  - ***Spread of primary lesion:*** In children with poor CMI and/or high DTH, primary lesion may progress locally (*progressive primary complex*), invade neighbouring bronchi (*endobronchial disease*) or vessels (miliary disease) **(Fig. 10.2)**. Regional mediastinal/hilar nodes may also enlarge to compress the bronchi or rupture into them.
    - *Progressive primary complex* is the least severe form of disease, characterized by slowly progressive concentric lesion (coin lesion) or segmental bronchopneumonia.
    - *Endobronchial rupture* of parenchymal or nodal lesion leads to the discharge of infective material into bronchial lumen, with following consequences: (a) diffuse spread to lung, i.e. *bronchopneumonia*, or (b) complete block of bronchus, i.e. *collapse* of distal lung, or (c) partial block of bronchus to act as a ball-valve mechanism, i.e. *emphysema* in distal lung.
    - *Hematogenous spread* may occur during early bacteremia at the time of primary infection or late bacteremia, due to invasion of vessels traversing infected lung tissue. Further course depend on the number of organisms leaked into blood stream. Sudden and heavy bacteremia may produce more serious *miliary tuberculosis*, while intermittent mild bacteremia may be silent or present later with *disseminated or extrapulmonary tuberculosis*.

      Invasion of extrapulmonary organs leads to formation of *satellite tubercular lesions* (granulomas) in different tissues, sometimes termed as *Rich's focus* in brain, *Simond's focus* in spleen and liver, *Sheehan's focus* in adrenals, etc. Most of these lesions remain silent for long time or progress slowly over 3–5 years to manifest as extrapulmonary TB.
    - *Lymphatic spread* via continuous channels from mediastinal nodes to cervical or abdominal nodes as well as direct spread of pulmonary/pleural lesion to ribs or spine, are other important modes of spread for tubercular disease.
- ***Re-activation/Re-infection tuberculosis*** is primarily seen in adolescents/adults and follows a different course than primary infection **(Table 10.18)**. Local response in these cases is modified by presence of prior DTH, leading to intense tissue reaction with cavitation. Reactivation/reinfection pulmonary lesions often develop in apical (*Puhl's lesion*) or infraclavicular region (*Assman's focus*).

TABLE 10.16: Hypersensitivity manifestations in TB

- Tuberculin positivity
- Phylectenular conjunctivitis
- Erythema nodosum
- Aseptic (Lincoln's) meningitis
- Pleural effusion

TABLE 10.17: Possible fates of primary infection

- **Complete healing with/without calcification**
- **Local progression**
  - Progressive primary complex
  - Segmental/lobar pneumonia
  - Pleural effusion
- **Endobronchial spread**
  - Consolidation
  - Collapse
  - Emphysema or pneumothorax
- **Hematogenous spread**
  - Acute miliary TB
  - Protracted disseminated TB
  - Localized extra-pulmonary TB
- **Lymphatic spread**
  - Cervical lymphadenopathy
  - Abdominal lymphadenopathy
- **Reactivation in later life**
  - Fibrocaseous tuberculosis (adult type)

Clinical spectrum of tuberculosis is extremely wide, depending on the type and extent of lesion and includes:

Primary complex is basically a radiological diagnosis and most cases are asymptomatic except mild constitutional symptoms, e.g. low-grade fever and anorexia. Mild dry

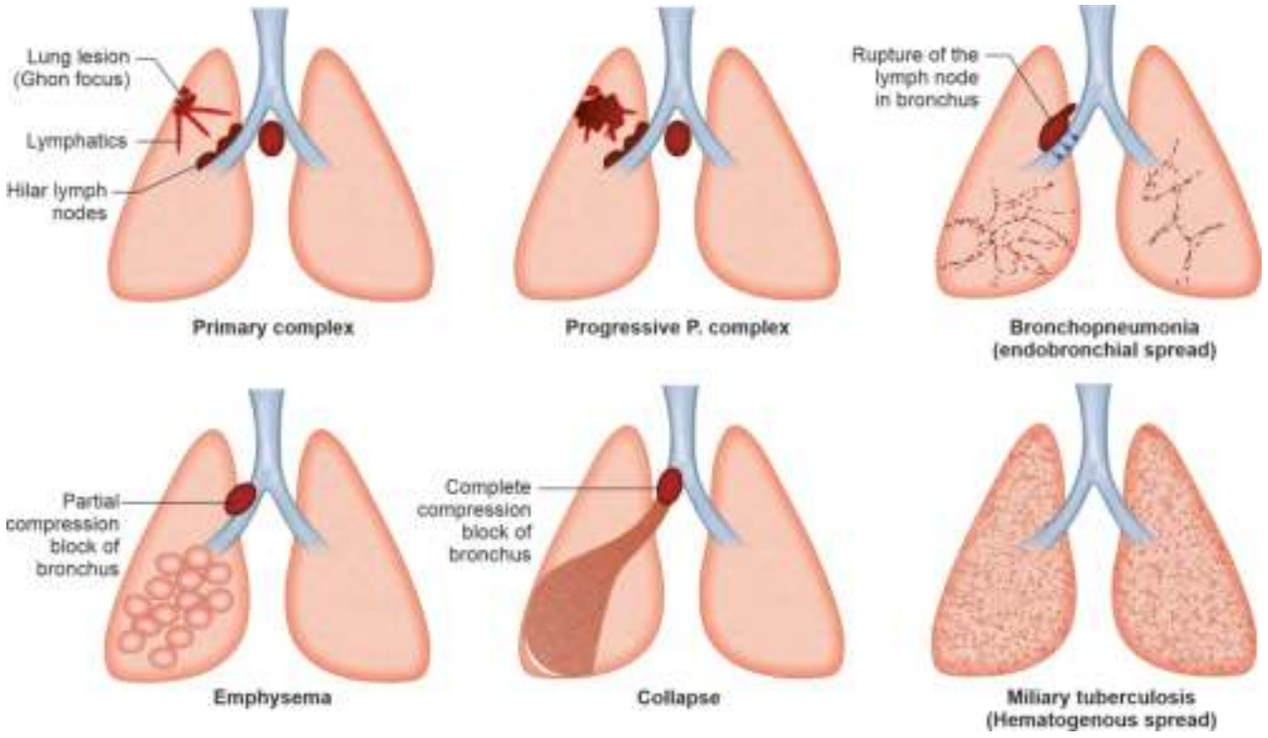

Fig. 10.2: **Various types of pulmonary tubercular lesions in children.**

TABLE 10.18: Primary vs Reactivation TB

Differences	***Primary***	***Reactivation****
Common age	<5 years	>7–8 years
Source of infection	Exogenous	Endogenous
CMI	Absent	Usually low
DHT	Absent	Present
Lung focus	Sub-pleural	Apical
Mode of healing	Calcification	Fibrosis
Mediastinal nodes	Enlarged	Minimal
Bacillary load	Low	High
Infectivity	Rare	Common
Hematogenic spread	Common	Rare

**or* re-infection

cough may be present due to compression of airways by enlarged mediastinal nodes.

Pulmonary tuberculosis, other than primary complex, presents with:

- Constitutional symptoms, e.g. mild evening-rise fever, anorexia, weight loss, night sweats, etc.
- Respiratory symptoms, e.g. dry/wet cough, respiratory distress, wheezing or stridor. Chest pain indicates pleural involvement.
- Signs of local disease, depending on the type of lesion.

In NTEP, *pulmonary tuberculosis (PTB)* refers to:

- Any confirmed or clinically diagnosed case of TB involving lung parenchyma or tracheobronchial tree, including intrathoracic lymphadenopathy (mediastinal or hilar), without radiological abnormalities in the lung.
- *Miliary TB* (discussed later) is classified as PTB due to lesions in the lungs.
- *PTB with extrapulmonary disease* (discussed later) is also classified as PTB.
- *Extensive pulmonary tuberculosis* refers to severe pulmonary bilateral cavitatory disease or extensive parenchymal damage on chest X-ray.

Miliary tuberculosis is the most serious manifestation (mortality >50%), usually presenting within first year of primary infection with acute onset of:

- High fever with severe toxemia
- Moderate/severe dyspnea, disproportionately more than lung signs, e.g. crepts/ronchi
- Signs of distant lesions, e.g. hepatosplenomegaly, meningitis (30%), etc.

Diagnosis of miliary tuberculosis rests on characteristic X-ray, i.e. diffuse fine (<2–3 mm) miliary mottling (*snowstorm appearance*) and/or extrapulmonary disease. D/D of similar X-ray findings includes *Pneumocystis carinii* pneumonia, tropical eosinophilia, Loeffler syndrome, pulmonary hemosiderosis and fungal infections of lung.

Disseminated tuberculosis refers to relatively more insidious form of hematogenous or lymphatic spread of infection, characterized by symptomatic or asymptomatic involvement of at least *two non-contiguous sites, i.e. either pulmonary and one extrapulmonary or two extrapulmonary*

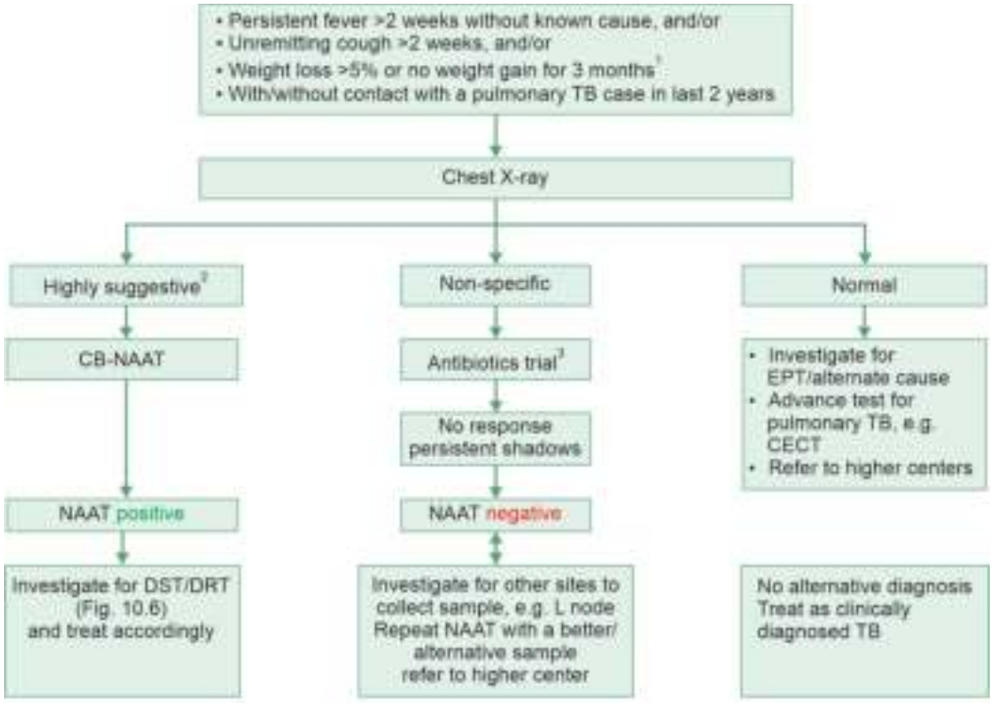

Fig. 10.3: Diagnostic algorithm for pulmonary tuberculosis in children.

NAAT: Nucleic acid amplification test

sites. Most cases manifest after 3–5 years of primary infection due to slow evolution of extrapulmonary lesions.

Extrapulmonary tuberculosis (EPT) may be due to: (i) *hematogenous* spread during bacteremia, (ii) *lymphatic* spread via connecting channels, e.g. cervical/abdominal lymphadenopathy, or (iii) *direct spread* to adjacent tissues, e.g. rib or spine. While EPT may involve any organ, important lesions include: (a) *early* EPT with CNS or GIT disease, and (b) *late* EPT after 4–5 years with osteoarticular, genitourinary or skin disease. Common forms of EPT in children, e.g. lymphadenitis, meningitis, osteoarticular or abdominal disease have been discussed in respective chapters.

In NTEP, EPTB refers to:

- Any bacteriologically confirmed or clinically diagnosed case of TB involving organs other than the lungs, including pleura, peripheral lymph nodes, abdomen, genitourinary tract, skin, joints and meninges.
- *Severe EPTB* refers to neurotuberculosis in all age groups and other forms of EPT in children <15 years (except peripheral or mediastinal lymphadenopathy without signs of compression).

Diagnosis: Detection of *M. tuberculosis* on direct smear or culture from infected body fluids/tissues, e.g. sputum, CSF, etc. is the *gold standard* for diagnosis, though yield is poor in children due to difficulties in specimen collection and paucibacillary nature of disease.

TABLE 10.19: Diagnostic tools in tuberculosis

Supportive	*Confirmatory*
• **TT/IGRA** • **Radiodiagnosis** X-rays USG, CT/MRI • **Biochemistry** Exudative body fluids ADA/TSA levels • **Histopathology** Aspiration cytology Tissue biopsy	• **Bacterial diagnosis** Direct smear (Ziehl-Neelsen stain) Solid culture: LJ Media Liquid culture: BACTEC, MGIT • **Molecular diagnosis** CB-NAAT (x-pert Mb) Line probe assay (LPA)

TT: Tuberculin test, **IGRA:** Interferon Gamma Adenosine deaminase (ADA) and tuberculostearic acid (TSA)

NTEP 2022 has proposed a diagnostic algorithm for diagnosis of PTB in children **(Fig. 10.3)** as well as for some other types of EPTB. Diagnosis in microbiologically negative cases must be made cautiously, supported by clinical or epidemiological indicators as well as indirect investigations **(Table 10.19)**.

- **Clinical suspicion** is the key for early diagnosis of TB, based on: (a) history of contact with sputum-positive case, (b) absence of BCG vaccination, (c) presence of malnutrition, (d) poor socioeconomic status with overcrowding, and (e) suggestive clinical picture.

TABLE 10.20: Common radiological features in TB

Mediastinal lymph nodes with ill-defined lung shadow
- Primary complex
- Progressive P. complex (large lung shadow)

Localized homogenous opacities
- Consolidation (large segmental, trachea central)
- Collapse (trachea > same side)
- Cavity (round/coin lesion, air/fluid level +)
- P. effusion (trachea > opp. side, obliterated CP angle)

Non-homogenous opacities
- Bronchopneumonia (large, irregularly distributed)
- Miliary (tiny, bilateral, uniformly distributed)
- Bronchiectasis (segmental honey-Coomb lesion)

Hyperleucent lesions
- Pneumothorax (trachea > opposite side, no BVM)
- Emphysema (trachea normal, BVM +)

BVM: Bronchovesicular markings

According to NTEP 2022 guidelines, Children with presence of any one of the following three clinical indicators are considered as ***Presumptive Pediatric Tuberculosis***, with/without history of contact in preceding 2 years:
- Persistent fever for > 2 weeks without a known cause
- Persistent cough for > 2 weeks, and/or
- Weight loss of >5% or no weight gain for >3 months, despite adequate nutrition and no apparent cause.

- **Radiological diagnosis:** Chest X-ray is the base-line investigation in children with presumptive PTB, **(Table 10.20)** interpreted as follows:
  - *Chest X-rays highly suggestive of the PTB* include those with: (a) miliary pattern, (b) hilar or paratracheal lymphadenopathy with/without parenchymal involvement, and/or (c) fibrocavitary lesions **(Fig. 10.4)**. All presumptive cases with these radiological patterns are considered as probable cases and should be subjected to bacteriological confirmation. Even if microbiologically negative, these children may be treated as ***clinically-diagnosed tuberculosis,*** after exclusion of alternative causes. Specificity of diagnosis increases with positive TST or history of contact in preceding two years.
  - *Chest X-rays with other lesions*, e.g. consolidation, non-homogenous shadows or bronchopneumonia, etc. are considered as non-specific **(Fig. 10.4)**. They must receive a 7-days course of antibiotics before repeat skiagram. Cases without improvement on repeat X-ray should be tested bacteriologically and if negative, need further evaluation to exclude other causes.
  - *Normal chest X-ray* practically rules out the pulmonary disease and child must be assessed for EPT *or* alternate causes *or* referred to higher center for further assessment.

  Other imaging investigations, e.g. USG, CT/MRI and bone scans are useful to delineate the extent of pulmonary or extrapulmonary disease.

- **Bacteriological diagnosis** is the gold standard for diagnosis with choice of specimen depending on the site of tubercular lesion. As sputum collection is difficult in young children: (a) early morning *gastric aspirate* after overnight fasting, (b) *induced sputum* after 3% saline nebulization and chest percussion, or (c) *bronchoalveolar lavage* is advised. Bacteriological diagnosis depends on:
  - ***Direct smear exam*** for AFB in sputum or other body fluids by conventional *Ziehl-Neelsen* staining **(Table 10.21)** or more sensitive fluorescent *fluorochrome* staining may also be used for rough quantitative assessment of bacillary load (1+, 2+, 3+). Smears are frequently false negative in children due to paucibacillary disease, specially if bacillary load is <10,000 bacilli/ml. Yield may be enhanced by centrifugation of specimen. Presence of AFB on smear is highly suggestive but cannot differentiate *M. tuberculosis* from other acid-fast organisms.
  - ***Bacteriological cultures*** are more sensitive with detection threshold of ~10 bacilli/ml. Cultures also allow species-identification and drug sensitivity testing (DST).
    - *Conventional* cultures using solid *Löwenstein-Jensen* media take longer time, i.e. about 3–6 weeks for isolation of organisms and another 2–4 weeks for DST and hence, have been gradually replaced by.
    - Rapid liquid-culture methods, e.g. automated radiometric culture assay (BACTEC) or myco-bacterial growth indicator tube (MGIT) systems, which allow isolation of organisms in 1–3 weeks and DST in further 3–5 days.
    - *Mycobacterial growth indicator tubes (MGIT)* is a rapid culture technique in which culture tubes have oxygen-sensitive fluorescent compound at the bottom. Initially, large amount of dissolved oxygen in media quenches emissions from the compound. Later, actively respiring mycobacteria consume the oxygen and allow the fluorescence to be detected by automated instruments.

- **Molecular diagnosis** is as reliable as bacteriological diagnosis, involving detection of mycobacterial DNA using cartridge-based nucleic acid amplification tests (CBNAAT) or Line probe assays (LPA).
  - ***Cartridge-based nucleic acid amplification test*** or CBNAAT (Xpert-RIF or Truenat) is the first test of choice for confirmation of diagnosis under NTEP guidelines due to rapid results (1–3 days) and ability to detect very low bacterial load, with sensitivity and specificity of >95% in smear-positive and 40–70% in smear-negative cases.

  However, CBNAAT cannot differentiate living from dead organisms in treated cases and contamination of samples by blood or pus may lead

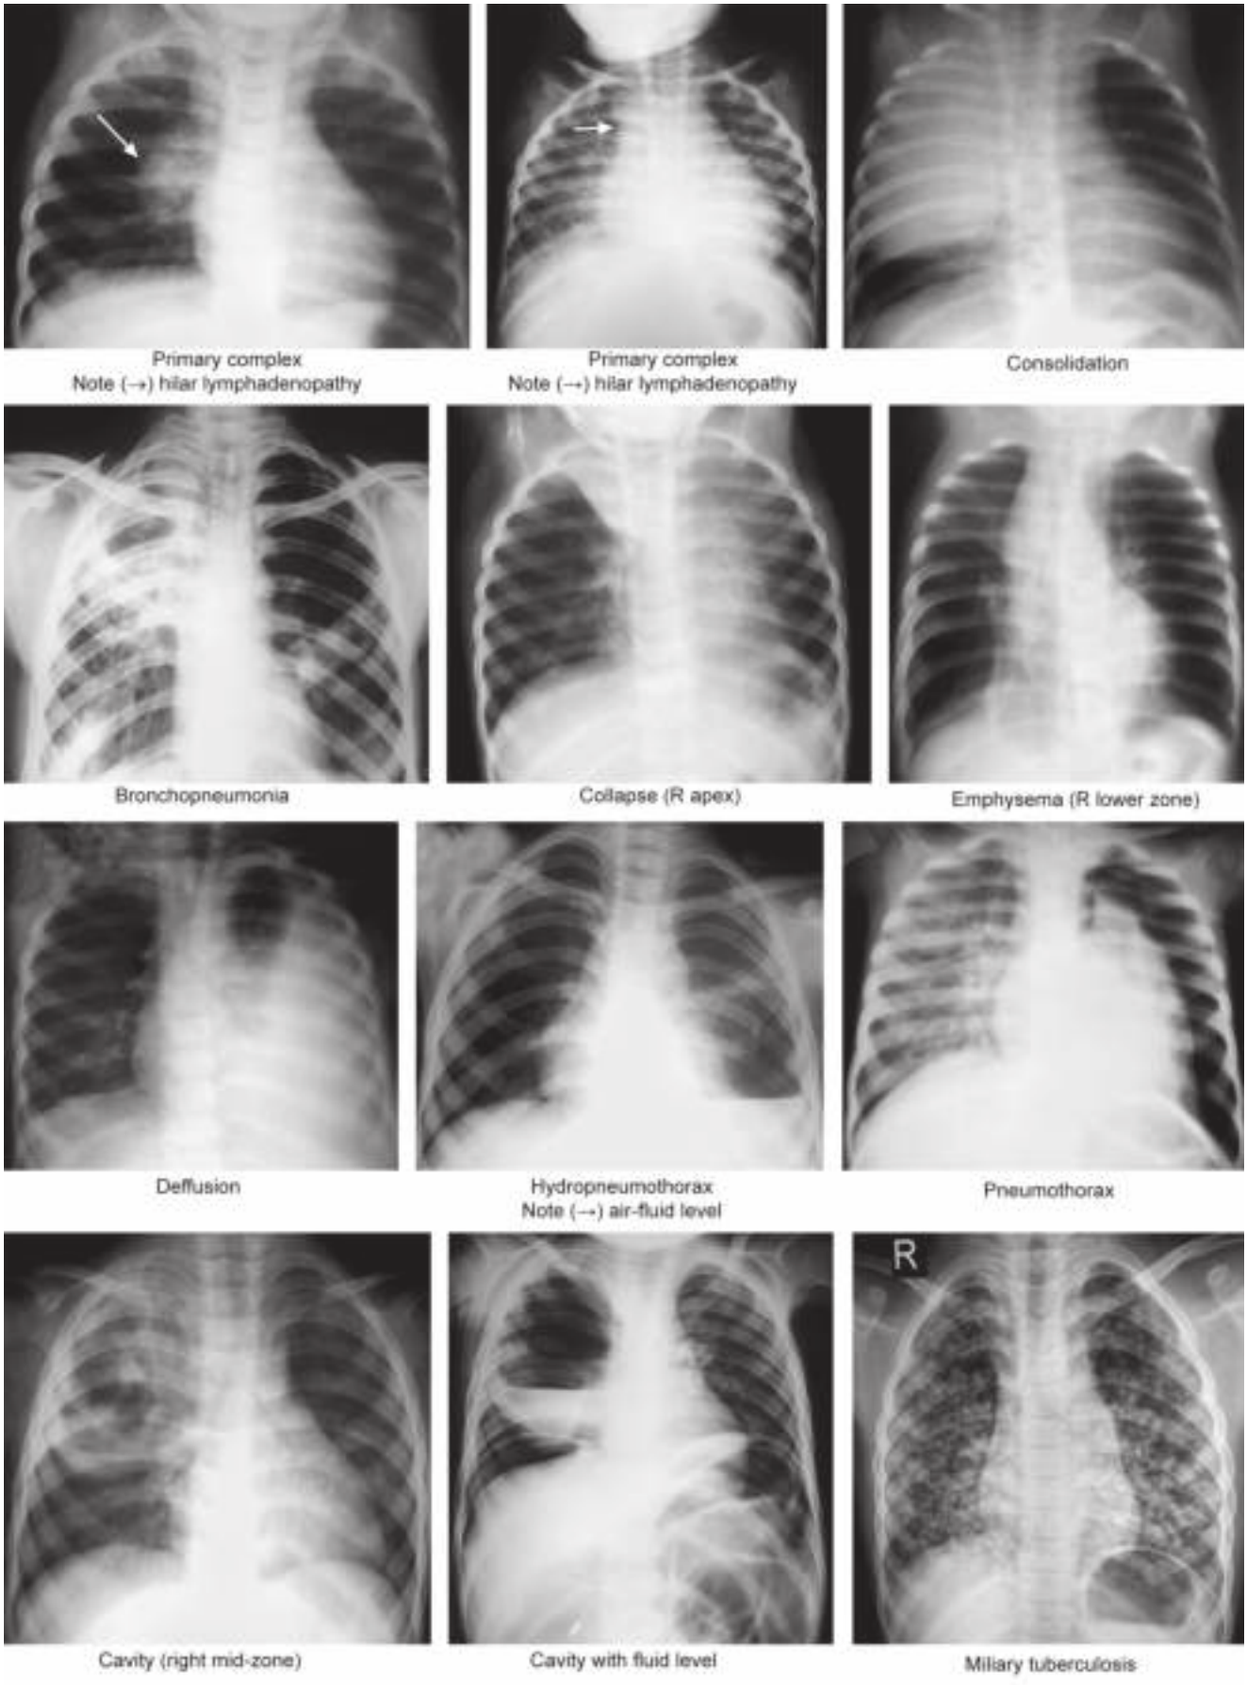

Fig. 10.4: **Common X-ray findings in pulmonary tuberculosis.**

TABLE 10.21: Ziehl-Neelsen staining for AFB - method

- Dry the slide (15–30 minutes) and fix over a flame
- Cover with carbolfuchsin and heat till vapours rise
- Leave for 5 minutes, then rinse in running water
- Stain with 25% sulfuric acid (2–4 minutes), then rinse
- Stain with 0.1% methylene blue (30 seconds), then rinse
- Examine under high power and oil immersion

to false-positive or false-negative results. CBNAAT also detects the presence of Rifampicin resistance (RR-TB), which is often used as a proxy for multi-drug resistance disease (MDR-TB).

– ***Line probe assay (LPA)*** are molecular tests to detect MTb complex and rapid diagnosis of Rifampicin and INH resistance by *first-line LPA* (LPA-FL) and resistance to fluoroquinolones and other second-line drugs by *second-line LPA* (LPA-SL). LPA needs many DNA copies (>10,000 per ml) for detection and can be used only on smear-positive or culture isolates with processing time of ~72 hours each for both LPA-FL and LPA-SL.

In NTEP, LPA-FL is indicated in all cases of confirmed tuberculosis and LPA-SL in cases of RR-TB or or INH resistance.

- **Histopathological diagnosis** is commonly used to confirm the diagnosis of EPT, using fine needle aspiration cytology (FNAC) or biopsy of the suspected lesion, showing presence of *chronic inflammatory infiltration, giant cells and caseation.* These specimens should also be used for microbial diagnosis and drug sensitivity/resistance testing.
- **Tuberculin sensitivity test (TST)** is a simple, widely used test to detect latent tuberculosis based on the presence of delayed type of hypersensitivity (DTH) against tuberculosis—an indicator of prior natural infection or BCG vaccination.

Tuberculin is a protein suspension of *M. tuberculosis*, available as purified protein derivative (PPD), with antigen load denoted as test units or TU (1 TU = 0.00002 mg PPD). Considering variable potencies of PPD derived from different strains, WHO recommend use of a standardized PPD-S, derived from *RT-23 strain* and stabilized with an additive *Tween 80. In India, 2 TU of PPD-S is recommended for TST.*

Mantoux test (MT) is the commonly used method for TST (others include *heaf test* or *tine test),* done and interpreted as follows:

– 0.1 ml of PPD-S (2 U) is administered intradermally using a TT syringe on volar aspect of forearm to raise a wheal of ~5–8 mm at the site of injection. This wheel subsides in 15–30 minutes and no reaction is visible locally for next 6–8 hours. In presence of DTH either due to previous natural infection or BCG vaccination, a local induration appear after 6–8 hours and peaks at 48–72 hours, associated with erythema.

Fig. 10.5: Tuberculin (Mantoux) test.

– Size of this induration (not erythema) should be read after 48–72 hours (up to 7 days), by a ball-point method, in *transverse direction* **(Fig. 10.5)**.

– An induration of 10 mm is considered as positive (5 mm in HIV infected), suggestive of *previous natural infection*. BCG is unlikely to produce an induration of >5 mm.

– *Diagnostic errors* in TST include:

▪ *False negative TST* in: (1) severe disease, e.g. military tuberculosis or tubercular meningitis, (2) severe malnutrition, (3) infection-induced anergy-up to 3 months after pertussis or measles, (4) immunocompromised states, e.g. HIV, (5) recent infection, as TT conversion takes 2–3 months after infection, (6) technical errors, e.g. inactive tuberculin, subcutaneous injection, etc.

▪ *False positivity* is rare, due to: (1) use of higher PPD strength for testing, (2) presence of non-tubercular mycobacterial infections, e.g. atypical mycobacteria or leprosy, and (3) secondary infection at the site.

– TST *alone should not be used for diagnosis of tuberculosis but only to support the diagnosis of: (a)* latent TB, (b) bacteriologically negative cases. It is also used to – (c) test the success of BCG vaccination, (d) identify the need for BCG vaccination in older TST-ve children, and (e) measure the prevalence of infection in the community.

– A new C-TB test to detect tuberculin skin sensitivity is in pipeline, which is not affected by prior BCG vaccination.

- **Interferon gamma release assay (IGRA),** commercially available as *TB quantiFERON gold®* or *TB Spot®* is an *in vitro* test to detect interferon (IFN)-gamma production by mononuclear cells in response to *M. tuberculosis* antigens. Like TST, positive IGRA test also indicates presence of TB infection but does not confirm the presence of disease. IGRA is expensive but unlike TT, does not require repeat visit for test reading or cross-react with BCG vaccination.
- **Biochemical investigations** are not diagnostic but may be used differentiate tubercular from pyogenic

etiology in EPT, e.g. CSF, ascites or pleural/pericardial effusions.

Tubercular exudate is characterized by: (a) straw-colour appearance, (b) cobweb formation on standing due to high fibrinogen content, (c) predominant lymphocytic leukocytosis, and (d) lesser elevation of proteins than in pyogenic exudate.

Other useful biochemical markers include presence of elevated *adenosine deaminase (ADA)* and *tuberculostearic acid (TSA) levels* in exudates—produced by degradation of lymphocytes and tubercular bacilli respectively.

- **Serodiagnosis** of tuberculosis involves detection of specific TB antigens (A60) or antibodies (IgM/IgG) in body fluids, though none of them differentiates infection from active disease and have *no role* in diagnosis of tuberculosis.

In NTEP 2022,

- ***Confirmed TB*** refers to a bacteriologically confirmed case on smear microscopy, culture or WHO recommended rapid diagnosis test, e.g. XpertMTB/RIF.
- ***Clinically diagnosed TB*** refers to a case, which is not bacteriologically confirmed but has been diagnosed as having active TB by a medical practitioner, who has decided to give full course of TB treatment. It includes cases dignosed on the basis of X-rays, suggestive history and extra-pulmonary disease without laboratory confirmation.
- ***Probable TB*** refers to at least one sign or symptom (unexplained fever, cough, weight loss) with chest X-ray consistent with tuberculosis ***and*** one of the following: (a) response to TB therapy, and/or (b) documented exposure and/or immunological evidence of TB infection.

Management of tuberculosis depends on the type and severity of the disease, DST and patient characteristics. For the sake of clarity, it has been discussed in following sections:

a. Anti-tubercular drugs
b. Anti-tubercular regimens
c. Supportive and symptomatic therapy
d. Monitoring and follow-up

A. Antitubercular drugs may be broadly divided into:

- ***First-line drugs*** are highly effective and least toxic, used in the majority of cases and include four drugs – Isoniazid (H), Rifampicin (R), Pyrazinamide (P), Ethambutol (E). Streptomycin is no longer used as first-line drug **(Table 10.22)**.
- ***Second-line drugs*** are less effective and more toxic, used only in cases with resistance to one or more first-line drugs. These drugs are classified in three groups, based on their efficacy and experience in treatment of drug-resistant cases **(Table 10.23)**. While all three drugs from Group A and one or two drugs may be included in second-line regimen, Group C drugs should be added only if Group A/B drugs cannot be used due to resistance or intolerance.

  Bedaquiline is the heart of second-line anti-tubercular regimen at present, except that it is not licensed for used in children below 5 years.

TABLE 10.22: First-line antitubercular drugs

Drug	*Dose (Range)* (mg/kg)*	*Side effects*
Isoniazid (H)	10 mg (7–15 mg)	Peripheral neuritis, hepatitis, psychosis
Rifampicin (R)	15 mg (10–20 mg)	Hepatitis, flu-like illness
Pyrazinamide (Z)	35 mg (30–40 mg)	Hepatitis, gout
Ethambutol (E)	20 mg (15–25 mg)	Optic neuritis

Maximum dose:* H 300 mg, R 600 mg, Z 2000 mg, E 1500 mg
All drugs given orally as single dose on empty stomach.

TABLE 10.23: Second-line antitubercular drugs

Group A *(Add All 3)*	Levofloxacin/Moxifloxacin (Lfx/Mfx) Bedaquiline (Bdq) Linezolid (Lzd)
Group B *(Add one or both)*	Clofazimine (Cfz) Cycloserine (Cs) or Terizidone (Trd)
Group C *(Add to complete the regimen and When Group A/B drugs Cannot Be Used)*	Ethambutol (E) Delamanid (Dlm) Pyrazinamide (Z) Imipenem-cilastatin (Ipm-Cls) *or* Meropenem (Mpm) Amikacin OR Streptomycin (Am/S) Ethionamide OR Prothionamide (Eto/Pto) p-aminosalicylic acid (PAS)

B. Antitubercular regimens: Multi-drug therapy is the cornerstone of anti-tubercular therapy, based on following considerations:

- Each case has different types of bacillary populations in the same lesion, including extracellular or intracellular organisms and slow-growing or rapidly-growing organisms. Some drugs act better on some bacillary sub-populations than others. H and R act best on fast-growing bacilli, Z on intracellular organisms and R on extracellular slow-growing bacilli.
- An effective drug regimen should use a mix of these drugs to attack all sub-populations of organisms. Ethambutol, though bacteriostatic drug with poor efficacy, is largely included in these regimens to prevent development of resistance to other drugs.
- An effective drug regimen should only include the drugs for which phenotypic sensitivity has been demonstrated on cultures *or* the resistance has not been detected on molecular testing. Indian data has shown maximum resistance to H (13%) followed by R (7%) and rarely to second-line other drugs (2–3%).

- An effective drug regimen should not contain less than four drugs at a time. In fact, drug-resistant cases usually need more than 5–6 drugs due to relatively less efficacy of second-line drugs.
- Since the emergence of drug-resistant mutations is higher in early stages of treatment due to higher bacillary load, antitubercular regiments are usually biphasic – including an:
  - *Intensive phase* (IP) to rapidly decrease the bacillary load, reduce infectivity and prevent deterioration and death, and a
  - *Continuation phase* (CP) to eliminate residual bacilli and reduce the risk of treatment failure and relapse. As fewer bacilli are left after IP, continuation phase usually needs fewer drugs.
- Since the dividing time of TB bacilli is ~21 hours, all drugs should be administered once a day, with no role of intermittent chemotherapy, unlike practiced earlier.

Universal Drug Resistance/Sensitivity Testing: NTEP 2022 recommends selection of appropriate drug regimen based on DST/DRT profile of cases, irrespective of previous treatment status (unlike previous protocols). All cases should be offered universal testing as per following algorithm **(Fig. 10.6)**:

- Two appropriate body fluid/tissue specimens should be collected from every patient and sent to laboratory in a cold chain – one for the CBNAAT and another for culture and sensitivity (preferably MGIT). EPTB samples should not be collected in formalin.
- Based on CBNAAT report, cases are divided into MTB detected (confirmed) or not detected (negative/presumptive). Confirmed TB cases are also further divided into – Rifampicin sensitive (RS-TB) or Rifampicin-resistant (RR-TB). If RR is detected with a very low level in a patient with low clinical suspicion, it should be confirmed on a repeat sample.
- All cases of RS-TB should be started on first-line regimen (discussed later) and tested by LPA-FL to confirm R-sensitivity and detect H-resistance. In case of LPA-FL showing:
  - H-sensitivity, continue with first-line ATT.
  - H-resistance, first-line ATT must be revised to H-mono/poly regimen, (discussed later) along with asking for LPA-SL.
  - Discordance with CBNAAT report in terms of R-sensitivity, CBNAAT should be repeated from another good sample.
- All cases of RR-TB should be subjected to LPA-SL to detect resistance to fluoroquinolones (Flq) and second-line injectable (SLI) drugs.
- Treatment should be initiated on the basis of LPA results, which may need to be modified later according to DST on liquid culture (LC-DST).

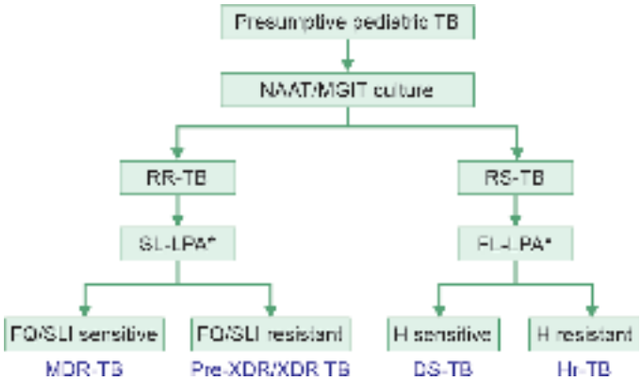

Fig. 10.6: Diagnostic algorithm for suspected drug resistant tuberculosis in children

*For discordance for RR between NAAT and FL-LPA, repeat NAAT at LPA laboratory

**Repeat NAAT in cases of RR-TB in a treatment-naive case

FL-LPA: First line-line probe assay, **SL-LPA:** Second line-line probe assay, for other abbreviations, *see text*

Drug Resistant Tuberculosis (Nomenclature): For the treatment purpose, all tuberculosis cases are classified on the basis of drug-resistance pattern, as follows:

- *Mono-resistant* (MR-TB), with resistant to one first-line drug only.
- *Isoniazid-resistant* (Hr-TB), with resistance to INH but susceptibility to RMP.
- *Poly-drug resistant* (PDR-TB), with resistance to more than one first-line drugs, other than both H and R.
- *Rifampicin resistant* (RR-TB), with resistance to R, with/without other drugs.
- *Multidrug-resistant* MDR-TB). With resistance to both H and R, with/without resistance to other drugs. *All cases of RR-TB are considered as H-resistant as well unless proved otherwise, hence, should be treated as MDR-TB.*
- *Pre-extensively drug-resistant TB* (Pre-XDR-TB), including MDR/RR-TB with resistance to fluoroquinolones (levoflox or moxiflox).
- *Extensively drug-resistant TB* (XDR-TB), including MDR/RR-TB with resistance to fluoroquinolone and at least one additional second-line drug from Group A, i.e. Bedaquiline and/or Linezolid.

Treatment Regimen: NTEP-2022 recommends following Regimens for Childhood TB, depending on DST/DRT **(Table 10.24)**:

- **First-line regimen** for All RS-TB (without H-resistance) including four drugs for 2 month of intensive phase and three drugs for 4 months for continuation phase **(2HRZE + 4 HRE)** with following considerations:
  - Continuation phase is extended to 10 months in cases of neurotuberculosis or spinal tuberculosis, with total duration of 12 months. (Intensive phase is not extended)

TABLE 10.24: TB treatment regimen as per DST/DRT

1. RS-TB with No H resistance	
All cases	2 HRZE +4HRE*
2. RS-TB with H mono/poly resistance	
All cases	(6**) Lfx R E Z (No intensive/maintenance phase)
3. RR/MDR TB (No FQ Resistance) (Non-extensive/Non-Diseminated PTB, Non-severe EPTB)	
Age >5 yrs/15 kg	**IP** (4–6 mo) Lfx, Cfz, Z, E, H^h, Eto, Bdq (6 mo) **CP** (5 mo) Lfx, Cfz, Z , E
Age < 5 yrs/15 kg (Shorter oral regimen)	**IP** (4–6 mo) Mfx^h, Km/Am, Cfz, Z, E, H^h, E **CP** (5 mo) Mfx^h, Cfz, Z , E
4. RR/MDR TB, but No FQ Resistance (Extensive/Disseminated PTB, severe EPTB)	
Age > 5 yrs/15 kg (Longer oral regimen)	(18–20) Lfx, Lzd, Cfz, Cs, Bdq (6 mo or more) (Replace Bdq with Dlm in children 6–17 years)
Age < 5 yrs/15 kg	Replace Bdq with any group C drugs
5. Pre-XDR TB with FQ Resistance	
Customized treatment with expert consultation	
6. XDR TB with Resistance to FQ + one more group A drug	
Customized treatment with expert consultation	

*Extent continuation phase to 10 months for Neuro/Spinal TB
**Extend to 9 months for extensive disease, uncontrolled co-morbidity, ExPT or any change in regimen due to resistance/intolerance. Extend to 12 months for Spinal and Neuro TB.
Ak: Amikacin; **Bdq:** Bedaquiline; **Cfz:** Clofazimine; **Cs:** Cycloserine; **Dlm:** Delanamid; **Eto:** Ethionamide; **FQ:** Fluoroquinlone **Hh:** High dose INH; **Km:** Kanamycin; **Lfx:** Levofloxacin; **MDR:** Multidrug-resistant; **Mfx:** Moxifloxacin; **IP:** Intensive phase; **CP:** Continuation phase

  - First-line regimen is also used for all: (a) cases with clinically-diagnosed TB or (b) cases who have been treated in the past even with history of treatment failure, default or recurrence, provided they are RS-TB at present.
  - Fixed-drug combinations (FDCs) are available under NTEP for first-line regimen and preferred due to simplified treatment and no risk of missing one or more of combination drugs.
- **H-resistant TB,** with/without resistance to other first-line drugs, should be treated with a monophasic regimen of four drugs **(6 LfxRZE)** for six months, i.e.: (a) replacing INH with Levofloxacin, and (b) no continuation phase.
- **RR-/MDR-TB** without resistance to second-line drugs should be treated with different regimens including second-line drugs depending on the severity of disease and age of the child **(Table 10.24)**. These regimens with higher pill burden and toxicity profile need longer duration of treatment. In case of intolerance to component drugs in second-line regimen, management has to modified in consultation with experts to decide the replacement sequence.
- **Pre-XDR/XDR TB** must be managed with tailor-made regimens in consultation with experts, replacing resistant drugs with group C drugs.

Probable or clinically diagnosed MDR-TB, with risk factors, e.g.: (a) close contact with a person having MDR-TB, treatment failure, death on treatment, (b) prior treatment with second-line drugs, and (c) no response to first-line regimen after excluding other cause of non-response, must also be managed in consultation with experts. In these cases, drug regimen is usually decided based on the drug sensitivity pattern of the likely source-case, if possible.

C. Supportive therapy includes adequate nutrition, management of co-morbidities, symptomatic treatment and treatment of complications, e.g. hydrocephalus, electrolyte imbalance, etc. Some specific issues in supportive management are as follows:

- ***Pyridoxine:*** Isoniazid interferes competitively with pyridoxine metabolism and may result in peripheral neuropathy. NTEP recommends pyridoxine supplementation (10 mg/day) to all children on INH-containing regimen.
- ***Steroids*** help in selected cases by reducing of excessive inflammatory damage and exudation, and facilitating intracellular penetration of drugs. Prednisolone (PO 2 mg/kg/day q8hr) is used for 2–4 weeks followed by gradual tapering only in: (a) tubercular meningitis, (b) military tuberculosis, (c) extensive endobronchial tuberculosis, (d) pericarditis, (e) large pleural effusion with distress and (f) immune reconstitution inflammatory syndrome (IRIS).
- ***Surgery*** may be indicated in large tubercular lesions to remove residual lesions after completion of antitubercular therapy, e.g. in lymphadenitis, segmental/lobar lung lesions or extrapulmonary tuberculosis.

D. Monitoring and follow-up: All children on ATT should be closely monitored for disease response, compliance and treatment, including clinical and laboratory follow-up. Clinical follow-up is advised even after completion of treatment for 2 years.

Clinical follow-up must focus on: (a) changes in clinical symptoms and signs, (b) physical examination, including weight record, (c) side-effects of medications, (d) adherence to treatment.

Laboratory investigations are needed only if indicated clinically, except repeat microbiological testing of respiratory secretions at the end of IP and CP, if possible. Liver function test are not routinely required without evidence of hepatopathy. Follow-up chest radiographs should be performed only at the end of therapy or earlier if no clinical improvement. Some important issues on follow-up are as follows:

- **Treatment interruptions** in the first-line regimen up to four weeks are managed by resuming the therapy, though missed doses of IP should be completed before starting CP and missed doses of CP should be completed by extending the duration of therapy.

However, in cases with longer interruption (>4 weeks), patient must be re-investigated for resistance profile, as in fresh case.

- **No-response or deterioration during follow-up**: All cases who do not respond satisfactorily or deteriorate on ATT are not due to drug resistance. Common causes of treatment failure include: (a) incorrect diagnosis in a clinically diagnosed case, (b) lack of adherence to therapy, (c) incorrect drugs or dosages, (d) inability to retain drugs, e.g. vomiting after medications, (e) comorbidities, and (f) paradoxical upgrading reactions, apart from drug resistance. All cases with poor response should be evaluated for these cases.
- **Paradoxical upgrading reactions (PUR)** refers to enlargement of existing lesions or unexpected appearance of new lesions during apparently adequate antitubercular therapy. These reactions usually develop after 3–12 weeks of the initiation of therapy and lasts for ~2 months before spontaneous resolution. PUR represent improvement of local immunity and accumulation of inflammatory exudates at previously small or invisible lesion and may present with new lesions or increase in size of existing lesions, e.g. lymph nodes, pulmonary infiltrates, pleural effusion, tuberculoma, etc. Lack of systemic symptoms suggests paradoxical reaction, though diagnosis should never be made without excluding DR-TB.
- **Drug-induced liver injury (DLI)** may develop in ~5% cases on first-line regimen, usually within first month of starting treatment due to three hepatotoxic drugs–INH, RMP and PZA. While routine liver function tests are not necessary, all suspected cases must be investigated for liver functions.

DLI is diagnosed in presence of any one of the following:

- >5 times elevation in AST/ALT values in asymptomatic patient,
- > 3 times elevation in AST/ALT values with > times elevation in bilirubin levels or
- Symptomatic patient.

Management of DLI includes withholding the offending drugs, e.g. RMP and PZA, and repeat LFT after a week. Withdrawn drugs are restarted in gradually increasing doses if AST/ALT drops < 2 times, in order of R followed by Z with AST/ALT monitoring every 3 days.

However, "*Hepatosafe*" therapy with alternative drugs is indicated in seriously sick patients with DLI, e.g. meningitis or military disease, using minimum three drugs – Streptomycin, Fluoroquinolone and Cycloserine.

In case of the recurrence of DLI, alternative treatment options with prolongation of treatment must be considered.

Prevention: Apart from public health measures to control airborne infections, important preventive measures to control TB in children include:

- Early detection and treatment of infectious cases,
- Airborne infection control practices,
- Contact screening and TB preventive therapy (TPT), and
- BCG vaccination.

TB preventive therapy (TPT) is indicated using single drug-INH PO 10 mg/kg/day (7–15 mg/kg/day range) in children <10 years and 5 mg/kg/day in older children (> 10 years) for 6 months, *after ruling out the active disease*, to all:

- All household contacts < 5 years of age of a bacteriologically confirmed PTB within past 3 months, irrespective of BCG or nutritional status,
- All household contacts > 5 years of age of a bacteriologically confirmed PTB, irrespective of the age, *if they are* positive on TT/IGRA.
- All HIV-infected children >1 year of age irrespective of the degree of immunosuppression, antiretroviral treatment or previous TB treatment.
- All HIV-infected infants <1 years of age, in contact with a pulmonary tuberculosis case.
- Babies born to mother diagnosed with tuberculosis during pregnancy.
- Other risk-groups individuals, e.g. those on immunosuppressive therapy, dialysis, planned for transplant, if they are positive on TT/IGRA.

TPT in contacts of MDR-TB, after exclusion of active disease depends on the sensitivity profile of contact case as follows:

- Contacts of RR-TB but FQ sensitive patients should receive TPI with Levofloxacin for 6 months (PO 15–20 mg/kg/day to max 75/mg/day).
- Contact of H-resistant R sensitive cases should receive RMP PO 15 mg/kg/day for 6 months (20 mg/kg/d above 10 years).

Congenital Tuberculosis

Congenital TB is not uncommon in Indian children though female sterility due to maternal genitourinary tuberculosis prevents many cases.

Mode of infection in these cases is either: (a) *transplacental infection* after placental lesion in mother (primary focus in liver), (b) *aspiration of infected aminotic fluid* (primary focus in lungs).

Clinically, congenital TB may be asymptomatic or presents as neonatal septicemia during 2nd–3rd weeks of life with fever, respiratory distress, hepatosplenomegaly, lymphadenopathy and meningitis (in 20–30%).

Diagnosis depends on maternal history of tuberculosis, placental examination for tubercles, clinical suspicion, neonatal chest X-ray and rarely, demonstration of AFB/

NAAT from gastric aspirate or bronchial lavage. TT is negative at birth in infected cases (but becomes positive by 2–3 months).

Management depends on clinical or radiological evidence of disease in the newborn. *Separation from mother and avoidance of breastfeeding to prevent postnatal infection is not recommended, even in sputum positive mothers.* NTEP/IAP recommends that:

- All babies born to tubercular mother should be breastfed, though mother should practice cough-etiquettes.
- All babies should receive BCG vaccinated at birth, without prior TST.
- Babies with normal chest X-ray at birth should receive TPT with single drug INH PO 10 mg/kg/day for 6 months with/without Pyridoxine, if mother is having RS-TB. TPT is not recommended if mother is having RR/MDR-TB.
- Babies with abnormal chest X-rays at birth, should be treated as per DST/DRT.
- Simultaneous treatment of mothers must be ensured.

Prevention of congenital TB largely depends on early diagnosis and treatment of disease in pregnant women. Streptomycin, due to risk of vestibular damage in newborn, is contraindicated during pregnancy.

National Tuberculosis Elimination Programme (NTEP)

National Tuberculosis Elimination Programme (NTEP) is the current version of Revised National Tuberculosis Control Programme (RNTCP, 1995), to fulfill the vision of *National Strategic Plan (NSP)*, i.e. to achieve "TB-free India" by the year 2025 (Five years ahead to global target in 2030).

Elimination refers to (a) achieve 80% reduction in disease burden, i.e. incidence and prevalence of disease <44 and <65/lakh population respectively, and (b) 90% reduction in mortality, i.e. <3/lakh population.

Objectives: NSP rests on four pillars of interventions- ***DETECT, TREAT, PREVENT, BUILD***. Accordingly, NTEP aims to:

- Achieve 90% notification rates
- Achieve 90% success rates for new cases and 85% for re-treatment cases
- To improve successful outcome of treatment of DR-TB cases
- To achieve decreased morbidity and mortality of HIV-associated TB
- To improve outcomes of TB care in private sector.

Operationally, NTEP is a centrally sponsored program under National Health Mission, managed by Central TB division, Ministry of Health and Family Welfare.

Activities: Some novel aspects of NTEP include:

- Screening of all cases with presumed TB disease, using standard screening **(Fig. 10.3)**
- Confirmation of diagnosis using standard algorithms and necessary investigations.
- Universal drug-resistance and sensitivity testing for all confirmed cases **(Fig. 10.6)**
- Standard treatment regimens, depending on resistance/ sensitivity profile **(Table 10.24)**
- Provisions for nutritional support and direct benefit transfer, to ensure compliance and manage co-morbidities.
- Use of Nikshya (NI- Nil, Kshya- TB) app – a web based information management system to ensure quality surveillance and monitoring.

10.14 LEPROSY

Leprosy (Hansen disease) is a chronic infectious disease, caused by *Mycobacterium leprae*. It mainly affects the peripheral nerves and skin, though upper respiratory tract, eyes, testes and other organs may also be involved.

While India achieved the target of leprosy elimination at National level in Dec 2005 with prevalence rate of < 1/10000 population, it still accounts for over half of the new leprosy cases in the world. About 7% of them are children <15 years of age. While there have been few reports of some resurgence in selected regions during 2021–22, National Health Mission aims to eradicate leprosy from India by 2027.

Epidemiology: *M. leprae* is an intracellular as well as extracellular acid-fast bacillus, present predominantly inhuman host.

Source of infection is usually a multibacillary open case, harbouring millions of organisms in nasal mucosa. Paucibacillary cases are intermittently infectious during exacerbations.

Mode of infection: Organisms are usually transmitted to susceptible host as droplet infection. Other modes of transmission, e.g. direct skin-to-skin contact, contaminated fomites, breast milk and via insect vectors, are extremely rare.

High-risk factors: Prolonged close contact with an index case is necessary for transmission. Infection in children is usually acquired from a family contact. *Other risk factors* include overcrowding, high humidity, social stigma preventing early diagnosis and immune status of the child.

Etiopathogenesis: All infected cases do not develop the disease and cell-mediated immunity (CMI) plays an important role in course of the disease. While in persons with high CMI, organisms are destroyed immediately on entry; progressive disease is produced in hosts with no or a little CMI. Most cases with moderate immunity develop a localized disease, e.g. *tuberculoid* or *indeterminate leprosy*, with acute exacerbations during periods of immunosuppression.

M. leprae multiplies very slowly, with long *incubation period* of ~ 3–5 years for lepromatous leprosy, though it is shorter in tuberculoid form.

Clinical spectrum spans from mildest indeterminate disease to most severe lepromatous leprosy (*see* classification below), with one or more of following cardinal features:

- *Skin lesions*, i.e. hypopigmented patches with/without loss of sensations. Loss of normal histamine induced flare response over hypopigmented patch is an early indicator of peripheral nerve damage, before detectable anesthesia.
- *Neurological lesions*, i.e. tender thickening of peripheral nerve trunks on palpation or nerve abscess formations with secondary anesthesia or parasthesia (tingling, crawling or pricking sensations). These lesions are best palpable over ulnar nerve behind the greater epicondyle or lateral popliteal nerve behind the lateral malleolus.
- *Secondary trophic changes*, e.g. neuropathic ulcers and deformities rarely appear in childhood and include facial deformities (nasal septal perforation, ear-lobule deformities, corneal ulcers) or limb deformities (wrist-drop, foot-drop, acral-ulcers, absorption of digits). Typical *leonine facies* with loss of eyebrows is uncommon in childhood.

Classification: According to *Indian classification*, leprosy is classified into five major types: (i) indeterminate, (ii) tuberculoid, (iii) borderline, (iv) lepromatous, and (v) neuritic disease. *WHO classify* leprosy as: (a) paucibacillary, single lesion, (b) paucibacillary (2–5 patches) and (c) multibacillary (6 patches).

- ***Indeterminate type*** is the earliest and least severe form, characterized by: (a) one or two flat hypopigmented macules, measuring 2–4 cm in size, with ill-defined margins, (b) nil or minimal loss of sensations over lesions, (c) negative smear and lepromin test. Most of these cases heal spontaneously, though 25–50% may progress to more severe forms.
- ***Tuberculoid leprosy*** is the commonest (50–60%) type in children, characterized by: (a) one or two large, raised erythematous papules or plaques (>10 cm) with well-defined margins, (b) definite loss of sensations over skin lesions, (c) thickening of regional nerve trunk, with/without formation of tender nerve abscesses, (d) negative smear but positive lepromin test and (e) granulomatous lesions (tuberculoid foci) on skin biopsy. Untreated cases remain stable for long time with intermittent exacerbations and increasing size.
- ***Borderline leprosy*** is a relatively ill-defined and unstable state, with frequent changes between tuberculoid (after treatment) or lepromatous (during immunosuppression) forms. Clinical features vary between two extremes of spectrum.
- ***Lepromatous leprosy,*** is most severe but rarest (<10%) type, with: (a) innumerable, confluent and *symmetrical* skin lesions, which begin as vague macules but turn papulo-nodular in late stages, (b) nil or minimal loss of sensations over lesions, (c) diffuse and often symmetrical sensory polyneuropathy, (d) positive smear but negative lepromin test, and (e) presence of vacuolated macrophages filled with *M. leprae* (*foam cells*) on skin/nerve biopsy.

  Untreated lepromatous cases may progress to develop trophic ulcers and deformities over years, while treated cases respond very slowly over 2–5 years with frequent recurrences. A combination of skin lesions (diffuse thickening of skin) and neuritic lesions (with loss of eyebrows and distortion of ear lobes) is responsible for typical *Leonine facies* in adults.
- ***Pure neuritic leprosy*** is very rare, characterized by tender thickening of multiple nerve trunks with sensory, motor and trophic changes in supplied area, leading to deformities and neuropathic ulcers, *without skin* lesions.

Diagnosis of leprosy in children depends on:

- ***Pathognomonic signs***, i.e. (a) hypopigmented lesion with loss of sensation, and (b) neural thickening and tenderness. Diagnosis of paucibacillary disease usually rests on clinical grounds only.
- ***Bacteriological confirmation*** **ons** Ziehl-Neelson staining of smears from skin lesions (*slit and scrape smear*) and nasopharynx. At least 6 slides should be prepared from each site and at least 200 fields should be examined before declaring the smear as negative.

  Bacterial index is calculated to assess the response to therapy after examining 7 smears-4 from skin lesions, one from nasal swab and 2 from ear lobes. Each smear is graded as per WHO criteria as negative, 1+, 2+ and 3+, followed by averaging of results to calculate bacterial index. Cases with bacterial index <2 are designated as paucibacillary while others as multibacillary lesions.
- ***Histopathological confirmation*** by skin or nerve biopsy to demonstrate granulomatous lesions is rarely required.
- ***Lepromin test*** measures the presence of CMI against *M. leprae*, using a refined antigen preparation, i.e. *Lepromin*. After intradermal injection of 0.1 ml of lepromin on forearm, reaction is read after 48 hours and after 21 days. *Early (Fernandez) reaction*, i.e. redness and induration of >10 mm after 48 hours, indicates previous infection by lepra bacilli. *Late (classical mitsuda) reaction* is taken as positive in presence of a nodule of > 5 mm on 21st day. Lepromin test is not diagnostic for leprosy but helps to classify the disease-strongly positive in tuberculoid leprosy and strongly negative in lepromatous variety.
- ***Serological tests,*** e.g. fluorescent leprosy antibody absorption tests (FLA-ABS test), RIA and ELISA are useful to detect subclinical infections, with high sensitivity and specificity.

TABLE 10.25: Anti-leprosy therapy in children (National Leprosy Eradication Programme)

Age	*> 10 years*	*< 10 years*
Multibacillary disease (3 drugs for 12 months)		
Rifampicin (monthly)	450 mg	10 mg/kg
Dapsone (daily)	50 mg	2 mg/kg
Clofazimine (monthly)	150 mg	6 mg/kg
Clofazimine (alternate day)	50 mg	1 mg/kg
Paucibacillary disease (2 drugs for 6 months)		
Rifampicin (monthly)	450 mg	10 mg/kg
Dapsone (daily)	50 mg	2 mg/kg

*Based on WHO schedules, which also includes single-dose therapy for single-lesion disease (Rifampcin 600 mg, Ofloxacin 400 mg and Minocycline 100 mg). However, it may be less effective than 6 months regimen.

- ***Molecular diagnosis*** with PCR testing is possible but rarely needed.

Management of leprosy includes:

- ***Specific antimicrobial therapy:*** Due to emergence of drug-resistance, current anti-leprosy therapy is essentially a *multi-drug therapy*, using three drugs-*bacteriostatic* dapsone and clofazimine and *bacteriocidal* rifampicin, in different regimens according to bacillary load **(Table 10.25)**. Therapy should continue for minimum 12 months in multibacillary and 6 months in paucibacillary disease or till smears are negative.
- ***Post-treatment surveillance:*** All cases should be followed clinically and bacteriologically, every year for minimum 2 years (paucibacillary) or 5 years (multibacillary disease), for relapses.
- ***Supportive therapy*** with: (a) prevention and treatment of trophic ulcers and deformities including reconstructive surgery, (b) vocational and social rehabilitation, (c) psychological support and (d) control of lepra reactions, discussed later.

Prevention: Reduction of infectious population by complete treatment is the mainstay of leprosy prevention in children. In an individual child with close family contact, following measures may be useful:

- *Chemoprophylaxis* with Dapsone (PO 1–4 mg/kg/week) for minimum 3 years or till index cases turns bacteriologically negative, has shown ~35–53% protection rate. Recently, long-acting *acedapsone* given intramuscularly every 10 weeks for 210 days, has shown ~ 78% protection.
- *Vaccine is not* available, though BCG is expected to provide ~30% protection against leprosy.

Lepra reactions, i.e. acute clinical exacerbation, usually after initiation of therapy are common (50%), and reflect sudden change in host's parasite immunological balance. Mainly two types of reactions are seen:

- *Type I (Reversal) reactions* are common in borderline leprosy, with acute swelling and tenderness over existing cutaneous and neural lesions, often leading to irreversible nerve injury with foot-drop, claw-hand, etc. These may be treated with PO prednisolone 1 mg/kg/d till response, followed by alternate day therapy to prevent relapse.
- *Type II (Erythema nodosum leprosum) reactions* occur in lepromatous leprosy, presenting with high fever, migratory polyarthralgia and tender erythema nodosum. These reactions may be treated with steroids, thalidomide or clofazimine.

National Leprosy Eradication Programme

National Leprosy Eradication Programme (1983) is the revised version of previous National Leprosy Control Programme (1955) that aims to eradicate leprosy from India by early case detection, multidrug chemotherapy, and disability prevention. Leprosy screening has been now integrated with Rashtriya Bal Swasthya Karyakram (RBSK) and Rashtriya Kishor Swasthya Karyakram (RKSK) for screening of children. National Health Mission aims to eradicate leprosy by 2027.

10.15 TETANUS

Tetanus is an acute life-threatening illness, characterized by painful muscular spasms and stiffness continues to be a significant cause of morbidity and mortality in children despite the availability of a safe and high effective vaccine for many decades.

However, *Tetanus neonatorum*, the severest form of tetanus in newborns has been eliminated from India since 15th May 2015.

Epidemiology: *C. tetani* is gram-positive *anaerobe*, present as spores in stools of various herbivores animals. These spores survive for many years in fecal-contaminated soil and cannot be killed by boiling, but easily by autoclave.

Tetanus spores from soil enter the body via: (a) contaminated wounds, usually a penetrating or crush injury, (b) perforated ear canal in otitis media (*otogenic tetanus*), (c) unsterilized needles/surgical instruments, and animal bites. Neonatal infection due to cord-cutting by unsterile blade/scissors is now extremely rare.

Pathogenesis: At the site of entry, the spores germinate, proliferate and produce a powerful exotoxin, i.e. *tetanospasmin*. Being strongly neurotropic, this toxin binds at neuromuscular junction and traverses along the axonal sheaths towards the spinal cord. In cord, it blocks the release of neurotransmitters in inhibitory spinal interneurons, leading to simultaneous agonist-antagonist muscular action, i.e. typical muscular spasms. The role of Tetanolysin – another exotoxin released in tetanus is unclear, perhaps contributing to produce anaerobic environment by damaging surrounding tissues.

Clinical manifestations range from localized or provoked *trismus* to generalized, severe, frequent and spontaneous muscle *spasms*. A typical case presents after *incubation period* of 5–15 days with three overlapping stages, as follows:

a. ***Stage of trismus*** (lock-jaw) is characterized by painful spasm of masseters with difficulty in opening the mouth, chewing and swallowing. For few days, it may be the sole manifestation or associated with signs of muscular rigidity, e.g. (i) *risus sardonicus*-a typical fixed-smiling face due to spasm of facial muscles, (ii) *abdominal rigidity*, and (iii) *opisthotonus*-spasm of back muscles with dorsally-curved posture **(Fig. 10.7)**.
b. ***Latent period*** is the time-lag between onset of trismus and appearance of spasms, usually not more than 2–3 days. Duration of latent period is inversely related to the severity of disease.
c. ***Stage of spasms*** is characterized by: (i) *reflex spasms*—sudden, painful tetanic contractions of voluntary muscles with hyperextension of limbs and back on slightest provocation, e.g. sound, touch, light or even wind movements, (ii) *spontaneous or unprovoked spasms* in severe disease, and (iii) *laryngeal spasms*—commonest cause of death in these children. Moderate fever and signs of autonomic imbalance, e.g. tachycardia and hypertension, are present in some cases.

As a rule, the sensorium remains normal even in severe or terminal cases of tetanus, unless clouded by hypoxia due to respiratory failure or other co-existing disease.

Other presentations include:

- ***Localized tetanus***—the mildest form with painful muscular rigidity and spasm around the site of injury, e.g. trismus in otogenic tetanus.
- ***Cephalic tetanus***—the rarest variant, with cranial nerve palsies, trismus, risus sardonicus, lid-retraction and spastic paralysis of tongue and pharynx, but *without* generalized muscular rigidity.
- ***Neonatal tetanus*** usually presented from 3rd 14th day, with refusal to accept breastfeeds, gradually progressing to full-blown picture over few hours.

Complications result from: (a) mechanical injury due to violent muscle spasms, (b) airway obstruction due to laryngeal spasms, (c) autonomic disturbances, and (d) therapeutic procedures **(Table 10.26)**.

Diagnosis is mainly clinical, based on: (i) history of injury or otitis media, (ii) unimmunized status, and (iii) typical clinical features, e.g. trismus, spasms, etc.

Spatula test, i.e. clenching of teeth on insertion of a spatula into the patient's mouth, is useful to demonstrate mild trismus in doubtful cases, though should be avoided in an obvious case due to risk of oral mucosal injury.

While rarely required, diagnosis may be confirmed on wound cultures for *C. tetani*, positive in <40% cases.

Investigations are also indicated to: (a) identify concomitant infection at the site of entry, e.g. wound/ear-swab cultures, (b) detect serious complications and (c) exclude other causes of muscle spasms.

D/D includes: (a) *rabies* (history of dog bite, hydrophobia), (b) *strychnine poisoning* (extremely rare), (c) *meningitis* (abnormal sensorium/CSF), (d) *tetany* (carpopedal spasms), (e) *phenothiazine dyskinesia* (history of drug exposure, transient course) and (f) *pseudotrismus* due to painful conditions, e.g. dental or parapharyngeal abscess.

Treatment of tetanus aims to: (a) neutralize circulating exotoxin by antitoxin, (b) prevent further toxin production by local wound care and antibiotic therapy, (c) prevent muscular spasms, and (d) treatment of complications.

All cases need to be hospitalized irrespective of severity. Important steps in management are:

a. ***Nursing environment:*** The child should be nursed in a dark-quite room with minimum stimulation, as even slight light/sound may stimulate painful spasms.
b. ***Wound care*** with cleaning and debridement of dead tissue to prevent anaerobic conditions that favour clostridial growth. Though cultures are usually negative for clostridia, wound/aural cultures should be collected to identify secondary infections.

Fig. 10.7: Tetanus: (A) Trismus; (B) Ophisthotonus.

TABLE 10.26: Complications of tetanus

Mechanical injuries:
- Tongue or lip injuries
- Compression fractures bones, e.g. spine
- Muscle fractures and/or rhabdomyolysis

Airway obstruction due to laryngeal spasms
- Sudden choking and death
- Aspiration pneumonia

Autonomic disturbances
- *CVS:* Hypertension/hypotension, arrhythmia
- *GIT:* Paralytic ileus, acute gastric dilatation

Iatrogenic complications
- *Over-sedation:* Apnea or respiratory failure
- *Nursing-related:* Bed-sores, aspiration

c. ***Passive immunization*** with human tetanus immunoglobulin (TIG), as soon as possible to prevent fixation of exotoxin at peripheral neuromuscular junctions. Optimal dose of TIG is not established, ranging 3000–6000 IU, given intramuscularly. Intrathecal TIG is no longer recommended.

d. ***Antibiotics*** to arrest further growth of clostridia and production of antitoxin, as well as to prevent secondary infections. Metronidazole (IV 30 mg/kg/d q6hr) is the preferred choice than conventional penicillin, which is a GABA-antagonist like tetanus toxin and can accentuate spasms.

e. ***Active immunization*** with a single dose of TT/Td (0.5 ml deep IM) is indicated in all cases on admission to initiate active antibody formation, irrespective of previous immunization status.

f. ***Sedation*** is cornerstone of symptomatic therapy in tetanus, to prevent and control the spasms. Level of sedation has to be adjusted according to severity of disease. Mild cases without spasms may be treated with single drug, i.e. diazepam, given orally via intragastric tube or per-rectally. However, severe cases require either high-dose monotherapy (oral or IV diazepam) *or* multi-drug sedation (additional drugs, e.g. phenobarbitone and/or chlorpromazine).

A general practice is to start with a single drug-diazepam IV (0.1–0.2 mg/kg every 3–6 hr) and gradually increase the dose, till spasms are controlled or safe-limit is reached. *In controlled cases*, IV therapy may be substituted with oral preparation via intragastric tube. *In uncontrolled cases*, additional drugs may be added gradually in increasing doses. Some basic rules of sedation therapy are:

- Parenteral sedation is risky than oral therapy and should be used only for initial control or in severe cases.
- Drug-doses should be increased gradually, but never to exceed safe-limits.
- IV bolus of sedatives should be given very slowly, to avoid sudden respiratory depression.
- When multiple drugs are used, simultaneous administration should be avoided. Schedule must be tailored to provide round-the-clock sedation.
- Sedation is gradually tapered after the patient is spasm-free for minimum seven days.
- Occasional breakthrough spasms in a controlled case are not uncommon, which may be treated with additional doses of IV diazepam (0.2–0.5 mg/kg).

IV magnesium sulphate has been used as an adjunctive drug to reduce the doses of benzodiazepines with added benefit of controlling autonomic symptoms. Magnesium is a pre-synaptic neuromuscular blocker, which blocks the release of catecholamines from nerves and reduces receptor responsiveness to released catecholamines. Hypotension and respiratory depression are major adverse effects of magnesium therapy.

g. ***Muscle relaxants***, e.g. *pancuronium* or *anesthesia* with ventilatory support may be required in refractory cases to maximize sedation. Other muscle relaxants, e.g. baclofen, if required, should also be used only in intensive care settings.

h. ***Supportive care*** includes: (i) Adequate nutrition via nasogastric tube or IV, (ii) airway maintenance with frequent suction and/or tracheostomy, (iii) breathing support with oxygen/assisted ventilation, (iv) back, bowel and bladder care and (v) management of complications. Percutaneous gastrostomy may be used for feeding to minimize the risk of aspiration.

Outcome: Overall mortality is post-neonatal tetanus is 15–20%, usually due to laryngospasm or aspiration.

Outcome is poor in—(a) younger children, (b) shorter incubation period (<7 days), (c) shorter latent period (<48 hours), (d) higher frequency and duration of spasms, (e) presence of autonomic disturbances, (f) concomitant complications, e.g. aspiration and airway obstruction and (g) quality of nursing care and sedative therapy. *Patel and Jog criteria* may be used to assess the severity of tetanus **(Table 10.27)**.

In survivors, long-term sequelae, e.g. cerebral palsy, mental retardation and behavioral problems, are not uncommon due to hypoxic brain damage during spasms.

Prevention of tetanus includes:

- *Active immunization* with three doses of primary immunization at 6, 10 and 14 weeks and boosters at 18 months and 5 years (DTwP or DTaP), followed by Td at 10 years of age and subsequently at every 10 years (TT). IAP recommends a single dose of Tdap at or after 7 years of age, followed by Td every 10 years (Ch 9.2.1). Antenatal immunization of mothers with two doses of Td at 4 weeks interval, starting in early

Respiratory rate > 40/min	2
Severity score:	
< 3 (mild), 3–10 (moderate), > 10 (severe)	

pregnancy (single dose in subsequent pregnancies) is vital to prevent neonatal tetanus.

- *Prevention of spore-entry* by immediate wound care, treatment of otitis media, trained obstetrical care, etc. Safe delivery practices include cord-cutting by sterile blade with no subsequent contaminated dressings.
- *Passive prophylaxis* with tetanus immunoglobulin (TIG) is indicated in: (a) potentially infected severe wounds with incomplete or unknown previous immunization status, (IM 5000 IU) within 3 days of injury, and (b) babies born to unimmunized mothers (IV 250–500 IU), within 6 hours of birth. Anti-tetanus serum of equine origin (ATS) is no longer recommended due to serious side effects.
- *Post-injury TT immunization* schedule depends on previous immunization status **(Table 10.28)**; using any age-appropriate tetanus containing vaccine (DPT/Tdap/Td/TT).

Other important clostridial infections in children are as follows:

Pseudomembranous colitis (PMC): It is an acute dysentery-like illness, due to overgrowth of pathogenic *C. difficile* or *C. perfringes* in gut.

Pathogenesis: Preceding antibiotics therapy (specially ampicillin) is most important risk factor for PMC, which damages normal gut flora to facilitate clostridial growth. Pathogenicity of these strains is mediated by production of two toxins—toxin A (enterotoxic) and B (cytotoxic).

Clinically, most cases present with mild self-limiting diarrhea, but a typical case presents with bloody dysentery and passage of pseudomembranes (mucosal sloughs) in stools. Constitutional features, e.g. fever, abdominal cramps and vomiting are common.

Diagnosis must be suspected in a case of diarrhea or abdominal pain, who is on antibiotics *or* has received them in last 2 months. Confirmation requires: (a) detection of *C. difficile* toxin in stools by immunoassay, *or* (b) colonoscopy to visualize pseudomembranous plaques.

Treatment includes: (a) discontinuation of suspected antibiotics, (b) fluid and electrolyte correction, and (c) specific therapy with metronidazole (PO 20–40 mg/kg/d q6hr) or vancomycin (IV 40 mg/kg/d q6hr) for 7–10 days. *Vancomycin is the only antibiotic, not known to cause PMC*. Although most cases respond well, recurrence is common.

TABLE 10.28: Post-injury immunization for TT**

Immunization Status	*TIG*	*TT*
Fully immunized		
Minor injury	No	TT/Td if >10 years lapsed
Major Injury	No	TT/Td if >5 years lapsed
Unimmunized/Partially immunized		
Minor injury	No	DTwP/DTaP/TdaP/Td*
Major injury	Yes	DTwP/DTaP/TdaP/Td*

*Followed by remaining doses for catch-up immunization

Botulism is a rare but potentially fatal disease with acute flaccid paralysis, due to a *neurotoxin,* produced by some strains of *C. botulinum*.

Pathogenesis: Spores of *C. botulinum* are ubiquitously present in soil, which may germinate *in vivo* (wounds) or *in vitro* (foods), under anaerobic conditions to produce a highly potent neurotoxin. According to the mode of infection, botulism may be divided into 3 distinct types:

a. *Infant botulism* due to ingestion of contaminated honey (as pre-lacteal feed) is often fatal, unless recognized and treated promptly.
b. *Food-borne botulism* due to ingestion of pre-formed toxin, present in spore-contaminated foods, e.g. home-canned or low-acid foods (sauces). Heating for 5 minutes destroys the pre-formed toxin.
c. *Wound botulism* due to *in vivo* germination of spores, multiplication of organisms and toxin production in infected wounds with dead tissue, e.g. crush injuries. Toxin spreads hematogenously to reach synaptic sites and block neuromuscular transmission.

Clinical presentation: Incubation period is shorter in food-borne or infant botulism, due to pre-formed toxins (18–36 hours), as compared to wound botulism (4–10 days).

Acute symmetrical descending flaccid paralysis is the cardinal feature of botulism, beginning with oculobulbar involvement, e.g. diplopia, ptosis, dysphagia, dysarthria and dysphonia and rapidly progressing downward to involve all muscles, including respiratory paralysis. In infants, weak cry and reduced spontaneous movements may be the first manifestation. Sensorium is normal, except in terminal cases due to hypoxia.

Other important features resemble atropine poisoning (anti-parasympathetic activity) with dry mouth, constipation and absence of sweating.

Outcome is poor in severe cases with death due to respiratory failure. Mild cases recover completely.

Diagnosis is suggested by: (a) *typical clinical picture*, i.e. descending flaccid paralysis with normal sensorium, and (b) *characteristic EMG findings*—brief, small, abundant motor-unit action potential in infants *or* potentiation of evoked muscle potential at high frequency in older children.

Confirmation requires: (a) *detection of toxin* in serum, wound site or feces, *or* (b) positive *wound culture.*

Management includes: (a) *supportive* therapy including ventilatory assistance, (b) *debridement* of dead tissue in contaminated wounds, (c) *anti-toxin infusion* (equine/

human, not freely available), and (d) *antibiotics* (in wound-botulism only) to control bacterial proliferation and further toxin production.

Aminoglycosides, which have neuromuscular toxicity, are contraindicated. *Antibiotics are not recommended for food-borne or infant botulism,* except to cover secondary infections.

Gas gangrene is rapidly progressive infection of soft tissue due to *C. perfringens*, with severe edema, necrosis, crepitations and a characteristic sweet odor in serosanguineous discharge. Pain is typically disproportionate to appearance of wound and systemic complications, e.g. shock and renal failure, develop rapidly.

Early debridement of wound with excision of necrotic tissue, IV antibiotic therapy with high-dose penicillin *or* clindamycin, and hyperbaric therapy (controversial role) may be life saving, but prognosis is poor.

10.16 NON-CLOSTRIDIAL ANAEROBIC INFECTIONS

Anaerobic infections may be classified according to their microbial characteristics **(Table 10.29)** or oxygen tolerance, i.e. *obligate* and *facultative* anaerobes. Of these, clostridial infections have already been discussed in previous Ch 10.15.

Non-clostridial anaerobes are common colonizers of human flora and disease is usually caused by proliferation of endogenous flora in anaerobic conditions. Clinical disease due to these infections is often non-specific and remains localized to colonized sites, e.g. GIT, respiratory tract, ears, sinuses, etc.

High-risk factors for non-clostridial anaerobic infections include: (a) crush injuries with devitalized areas and reduced oxygen tension, (b) co-existing aerobic infection to utilizes oxygen, and (c) defective mucosal clearance, e.g. poor hygiene, aspiration and unconscious child.

Clinical spectrum of non-clostridial anaerobic infections is extremely wide, **(Table 10.30)**, though some unique presentations are as follows:

- ***Vincent angina*** *(trench mouth)* is an acute, fulminant, necrotizing infection of oral cavity, characterized by painful ulcers, mucosal swelling, foul breath and pseudomembrane formation.
- ***Ludwig angina*** is life-threatening cellulitis of sub-lingual and sub-mandibular spaces, characterized by sudden onset of tender neck swelling (*bull-neck*) and respiratory difficulty due to airway compression.
- ***Noma neonatorum*** **(cancrum oris)** is a rare serious anaerobic infection in newborns and severely malnourished infants; characterized by acute, rapidly progressive gangrene of buccal mucosa that rapidly progress to form perforating cheek ulcer. Secondary Pseudomonas infection is common. Diagnosis is clinical and therapy includes intensive antibiotic therapy. Reconstructive plastic surgery may be needed in survivors.

Diagnosis of anaerobic infections depends on clinical suspicion and proper cultures. Anaerobic cultures should be collected from aspirates, abscesses or biopsies, and not from superficial sites of colonization, e.g. throat or stools. Cultures should be transported immediately to laboratory in specific transport media, which facilitates anaerobic growth.

Anaerobic cultures are indicated in presence of: (a) foul-smelling putrid odor, (b) severe tissue necrosis, gangrene or deep abscesses, (c) wound crepitus, (d) sterile aerobic cultures despite poor therapeutic response, and (e) clinical states compatible with anaerobic infections.

Treatment of these infections requires adequate drainage of the site with removal of dead tissue and appropriate antibiotic therapy with either: (a) Metronidazole *or* clindamycin in milder cases or (b) Carbapenem *or* imipenem *or* ampicillin+sulbactum in severe cases.

TABLE 10.29: Classification of anaerobic infections

Gram-positive bacilli
Clostridium tetani, C. botulinum, C. perfringens
Lactobacillus. Bifidobacterium
Gram-negative bacilli
Bacteroids, fusobacterium
Gram-positive cocci
Peptostreptococci, peptococci
Gram-positive cocci
Veillonella

TABLE 10.30: Common non-clostridial anaerobic infections

Oro-pharyngeal *(poor oral hygiene)*
Periodontal disease
Vincent angina *or* Ludwig angina
Peri-tonisllar abscess
Upper respiratory tract *(extension from oral flora)*
Chronic sinusitis
Chronic otitis or mastoiditis
Lower respiratory tract *(poor mucus clearance)*
Aspiration pneumonia
Lung abscess
CNS *(extension from otitis, mastoiditis)*
Brain abscess
Subdural/epidural empyema
Intra-abdominal *(extension from gut flora)*
Perforation peritonitis
Appendicitis, typhilitis
Necrotizing enterocolitis
Skin/soft tissue *(bites, penetrating/crush injuries)*
Cellulitis, fasciitis, myositis
Gas gangrene
Female genital tract *(poor hygiene, local extension)*
Vaginitis
Pelvic inflammatory disease (PID)
Chorioamnionitis and septic abortion (in pregnancy)

10.17 RICKETTSIAL FEVERS

Rickettsial diseases are primarily zoonotic infections, with humans infected accidentally. These infections are more common in adults, specially during the warm and humid season.

Incidence: While rarely diagnosed, four rickettesial infections, i.e. *scrub typhus*, *murine typhus*, *Indian tick typhus* and *Q fever* seem to be significantly prevalent in India **(Table 10.31)**. Scrub typhus is prevalent all over India; murine typhus and Q fever in north India; and Indian tick typhus fever in central India. Focal outbreaks of murine typhus occur in coastal cities, due to high rodent population at ports/docks.

Other rickettsial infections, e.g. epidemic typhus (*R. prowazekii*), Rocky mountain-spotted fever (*R. rickettsii*), rickettesial pox (*R. akari*) are rare in India, though prevalent in other parts of world.

Epidemiology: Rickettsiae are obligate *intracellular* bacteria that usually infect arthropods, e.g. ticks and mites, *or* other animals e.g. cattle and sheep. Human infection is acquired by: (a) bite of infected mite or tick (scrub typhus, Indian tick typhus), or (b) inhalation or contact with vector/animal excreta (murine typhus) or (c) ingestion of infected cattle products, e.g. milk (Q fever). Rickettsial diseases are more common in rainy and winter seasons and in rural population.

Pathogenesis of most rickettsial infections involves diffuse vasculitis leading to microvascular leakage and vascular lumen obstruction.

Clinically, most rickettsial diseases present after an incubation period of 1–2 weeks with: (a) sudden onset of high-grade fever with severe myalgia an headache; (b) Rash on day 2–5 of illness, which may be pruritic and petechial, usually involving palms and soles; (c) Eschar formation – a crusty necrotic lesion at the site of vector bite with or without regional lymphadenopathy. Q fever typically presents as acute pneumonia or influenza-like illness.

More serious manifestations may include aseptic meningitis or encephalitis, pneumonia, acute renal failure and acute gastroenteritis or surgical abdomen. Complications, e.g. DIC, ARDS, hemophagocytic lymphohistiocytosis, purpura fulminans, gangrene and myocarditis are not uncommon.

Diagnosis of rickettsial fever should be considered in any fever of > 5 days with suggestive epidemiological, clinical and laboratory indicators **(Table 10.32)**, after exclusion of other causes.

Diagnosis may be confirmed by polymerase chain reaction (PCR) or positive IgM ELISA test. *Weil Felix reaction* is a simple test with low sensitivity but good specificity, specially when higher titer cut-offs of > 1:320 are used. However, a single titre of > 1:80 also indicates possibility of infection.

Epidemiological confirmation is also possible on ELISA or immunofluorescence assay suggesting >4-fold rise in antibody titers after 2–4 weeks.

TABLE 10.32: When to suspect Rickettsial infections

Undifferentiated fever for > 5 days with .....

- **Suggestive epidemiological features**
  - Residence in endemic area
  - Presence of rodents/ticks in/around home
  - Visit to forests and farmlands
  - Animal sheds in proximity of homes
  - Contact with pet/stray dog infested with ticks
  - Similar cases in family, neighbourhood
- **Suggestive epidemiological features**
  - Dengue-like illness with rash, headache, myalgia
  - Eschar formation
  - Hepatosplenomegaly/lymphadenopathy
  - Acute menigoencephalitis
  - Community acquired pneumonia
  - Presence of GIT, liver or kidney involvement
  - Sepsis of unclear etiology
- **Suggestive laboratory features**
  - Normal/low leukocyte count with thrombocytopenia
  - Raised ESR and CRP
  - Others e.g. elevated hepatic transaminases

TABLE 10.31: Important Rickettsial infections in India

Disease	*Agent*	*Reservoir*	*Transmission*	*Clinical features*	*Prevention*
Scrub typhus	*R. tsutsugamushi*	Rat-mite	Mite-bite	Local eschar Prolonged fever Macular rash Lymphadenopathy	Rat control, Insecticide spray Personal protection
Murine typhus	*R.typhi*	Rat (Flea)	Contact[1]	Same, except eschar	Same
Indian Tick typhus	*R. conorti*	Dog-tick	Tick-bite	Same as *S. typhus*	Dog disinfection Avoid dog-contact
Q fever	*C.burnetti*	Cattle, sheep, ticks	Inhalation[2] Ingestion	Acute pneumonia influenza-like illness	Use pasteurized milk Cattle-shed sanitation

[1]contact or inhalation of rat-flea excreta.
[2]or contact with dust contaminated with animal excreta or ingestion of infected products, *e.g.* milk.

Treatment: PO/IV Doxycycline 100 mg BD (2.2. mg/kg in children <40 kg) for three days after defervescence or total 7 days, is the drug of choice for all rickettesial infections, which may be initiated without waiting for laboratory confirmation.

Doxycycline can be used in younger children as well since a short course will not lead to dental staining. Alternative drugs include Azithromycin (PO 10 mg/kg/d x 5 days), or Rifampicin (only in refractory cases). Response to treatment is dramatic and persistence of fever beyond 48 hours of therapy should alert about possibility of alternative or additional diagnosis. Treatment also includes other supportive measures including treatment of organ dysfunction.

Prevention of Rickettsial diseases depend on:

- *Control of reservoir/vector population*, e.g. Rodents (scrub typhus), insecticide sprays (Murine typhus) and disinfection of pet-dogs (Indian tick typhus), etc. and
- Avoidance of personal exposure, e.g. protective clothings (scrub typhus), handling of tick-infested dogs (Indian tick-typhus) and use of pasteurized/boiled milk (Q fever).
- Short-term weekly Doxycycline prophylaxis for up to 6 weeks may be recommended for travellers in setting of high-risk exposure.

10.18 MEASLES

Measles (Rubeola) is the *commonest vaccine-preventable illness*, characterized by fever, upper respiratory tract infection and generalized maculopapular rash with self-limiting course, but high morbidity and mortality. India aims to eliminate Measles and Rubella by 2023.

India contributes to highest number of measles cases in the world, though incidence has substantially declined in recent years. However, intermittent outbreaks are common, recent ones in Mumbai (2022) and Hyderabad (2023).

Epidemiology: Measles virus is an RNA virus of only one known serotype, present in nasopharyngeal secretions of infected clinical/sub-clinical human case. Infection is transmitted by *droplet infection*. Disease is highly contagious with secondary attack rate of as high as 80%, and *period of infectivity* extends from 4 days before to 5 days after the appearance of rash.

Maximum cases are seen in preschool children. Maternal antibodies in endemic regions protect infants till 4–6 months. Immunization or natural infection usually provides life-long immunity. Overcrowding and poor immunization coverage are two important predisposing factors for measles outbreaks in a community, more common in winter or spring season.

Pathogenesis: The sequence of events in pathogenesis of measles are: (a) *local viral multiplication* at the site of entry, i.e. nasopharynx, for short period, (b) *transient, asymptomatic primary viremia*, spreading virus to distant sites, specially lymphoid tissue, (c) *active multiplication* in lymphoid tissue for ~1 week, (d) *symptomatic secondary viremia* with development of clinical disease.

Essential pathology in measles is a generalized inflammatory reaction with perivascular infiltration, specially in skin (*rash*) and mucus membranes (*Koplik spots*) and *lymphoid hyperplasia*, specially in appendix with multinucleated giant cells (*Warthin-Finkeldey cells*). Other important changes include interstitial or Hecht giant cell pneumonia and perivascular demyelination (encephalomyelitis).

Clinical manifestations: While subclinical infections are common, typical case presents after an *incubation period* of ~10–12 days, with three stages:

a. ***Prodromal phase*** *(4–5 days)* with mild to moderate fever, upper respiratory illness with cough, coryza, etc. and conjunctivitis. Conjunctivitis is characterized by a transverse line of inflammation across the bulbar conjunctiva, sharply demarcated along the lid margins. *Koplik spots* are pathognomic lesions in this stage, seen as grayish-white sandy dots surrounded by slightly reddish areola, usually opposite the lower molars on oral mucosa. These spots are present from 2–3 days before to 24 hours after the appearance of rash, and herald the onset of skin rash **(Fig. 10.8)**.

b. ***Eruptive phase*** *(5–7 days):* Skin rashes appear on 4–5th day with transient rise of fever, starting as faint blanching macules, first along the hair-line behind the ears, face and neck. These rashes rapidly turn maculopapular and extend downward, involving whole body in next 2–3 days **(Fig. 10.8)**. Rashes may be associated with moderate cervical lymphadenopathy, constitutional symptoms, e.g. anorexia/malaise, GIT upsets, e.g. diarrhea, vomiting or abdominal pain due to mesenteric lymphadenopathy.

c. ***Convalescent phase*****:** Rashes disappear in the same sequence after 5–7 days, leaving behind a branny brown desquamation (post-measles staining) for next 10–15 days.

Fig. 10.8: Measles: (A) Active disease; (B) Post-measles staining.

TABLE 10.33: Complications of Measles

Early complications:
- *URTI* : Otitis media, laryngitis, tracheobronchitis
- *LRTI* : Pneumonia
- *GIT* : Enteritis (diarrhea), appendicitis*
- *CNS* : Encephalitis**, GBS, retrobulbar neuritis
- *lCVS* : Myocarditis
- *Hematological* : Purpura, DIC

Late complications
- Protein energy malnutrition
- Transient immunodeficiency (till 3 months)
- Re-activation of tubercular focus
- Bronchiectasis

Very late complications
- Subacute sclerosing pan-encephalitis (SSPE)

GBS: Guillain-Barré syndrome
*due to blocked lumen by lymphoid hyperplasia
**usually in second week, incidence ~ 1–2 per 1000 cases

Atypical presentations of measles include:
- ***Hemorrhagic (black) measles***, a life-threatening illness in immunocompromised children, characterized by high fever, confluent ecchymotic rashes, altered sensorium and bleeding diathesis.
- ***Modified measles*** with transient, few and faint macular rashes with minimal fever and constitutional symptoms, seen in immunized cases, young infants <9 months (due to maternal antibodies), *or* children who have received immunoglobulin prophylaxis in incubation period.

Complications: Although most cases recover spontaneously, complications are common in older or malnourished children, specially during convalescent phase **(Table 10.33)**.

Subacute sclerosing panencephalitis (SSPE) is a unique, rare and late complication of measles infection or vaccination, with an estimated incidence of ~ 8/million cases or <1/million doses of vaccine. Clinically presenting as a neurodegenerative disease after at least 4 years of primary infection, SSPE represents slow viral infection of CNS (see Ch.18.15).

Diagnosis of measles is mainly clinical, based on: (a) history of ongoing outbreak and unimmunized child, (b) typical rash after 4th–5th day of prodromal illness, (c) presence of *Koplik spots* for early diagnosis, and (d) *post-measles staining* for retrospective diagnosis.

Laboratory confirmation is rarely required and includes: (a) serological testing with >4-fold rise in IgM antibodies after 15 days, (b) viral culture on human embryonic or rhesus monkey kidney cells, (c) supportive evidences, e.g. leucopenia with relative lymphocytosis and presence of multi-nuclear giant cells or intracellular inclusion bodies in infected tissues after 5–10 days.

D/D include other causes of maculopapular rash (Ch 25.5), specially: (a) other exanthematous fevers **(Table 10.5)**, (b) allergic or drug rash, and (c) miliaria.

Treatment is mainly symptomatic with no specific antiviral therapy and includes: (a) maintenance of nutrition and hygiene, (b) antipyretics, (c) humidification to relieve cough, and (d) treatment of complications. *Two doses of vitamin A at 24 hours interval (PO 50,000 IU < 6 mo age, 1 lac IU in 6–12 mo infants and 2 lac IU in older children), are known to reduce the mortality and morbidity in measles by about 50%.*

Prevention involves avoidance of contact with an infected case along with *universal immunization* with two doses of a live-attenuated combination vaccine (MR) at the age of 9–12 months and 16–24 months, as per NIS. IAP recommends three doses of MMR at 9 mo, 15 mo and 4–6 years. (Ch 9.2.1).

Outbreak-control measures in measles include:
- *Supplementary immunization* rounds in outbreak areas, including *additional* dose to previously immunized children and the immunization in 6–9 months age group (zero dose).
- *Post-exposure prophylaxis* to reduce severity/duration of disease, only if received within 3–5 days of exposure. It is indicated only in high-risk household contacts, as follows:
  - Unimmunized infants (immunoglobulins* with vaccine)
  - Older unimmunized children without past history of disease (only vaccine)
  - Immunocompromised or pregnant contact (only immunoglobulin*)

  *(0.25 ml/kg of human immunoglobulin)
- *Isolation* of the case and susceptible contacts during infectivity period (7 days after exposure to 5 days after appearance of rash).

Measles-Rubella (MR) Elimination Plan in India by 2023 rests on four pillars: (a) 95% coverage with two doses of Measles-containing vaccine, (b) sensitive case-based MR surveillance, (c) rapid response to MR outbreaks, and (d) augmentation of the laboratory network for confirmation of diagnosis and virus typing.

Some other close mimics of Measles with Exanthematous fevers are also discussed as follows.

Rubella (German Measles) is a common RNA viral infection, with asymptomatic or mild self-limiting illness in children/adults. However, maternal infection in first trimester has serious consequences to fetus, e.g. fetal death or congenital rubella syndrome (Ch 12.15.3).

During 2017–2021, India adopted a National Strategic Plan for MR elimination (discussed below) and introduced rubella vaccination in National Immunization Schedule, replacing Measles vaccine with MR (Measles + Rubella) vaccine, apart from intensified surveillance. In 2019, India has adopted the goal of Measles and Rubella Elimination by 2023.

Epidemiology: Rubella is a RNA virus, present in nasopharynx, throat, and urine of infected person. Infection is usually acquired in school-age as droplet infection from a clinical or subclinical case, who is infective from 7 days before to 14 days after the rash.

As ~80% of Indian population is infected by late adolescence and conferred life-long immunity, 15–20% of pregnant mothers are still susceptible for rubella and consequent risk of CRS.

Pathologically, virus replicates in local epithelium and spreads to regional lymph nodes followed by viremia lasting for about 10–14 days. Fetal infection occurs transplacentally during the viremia, leading to extensive tissue damage, specially in brain, heart and auditory nerve.

Clinically, postnatal rubella is either asymptomatic or presents as mild, self-limiting viral illness, with: *(a) prodromal phase* (4–5 days) with mild catarrhal symptoms, and *(b) exanthematous phase* (2–3 days) with transient morbilliform or scarlatiniform rash and generalized lymphadenopathy, specially involving occipital and post-auricular nodes. Other features, e.g. *Forchheimer spots*—a rose-colored enanthem on soft palate and *arthralgia,* are common in adolescent girls.

Complications, other than congenital rubella syndrome after infection during pregnancy are extremely rare and include: (a) early complications, e.g. thrombocytopenia or Guillain-Barré syndrome, and (b) late complication, e.g. progressive rubella encephalitis.

Diagnosis is clinical, often missed due to nonspecific, transient illness. Laboratory confirmation requires elevated specific IgM antibodies *or* rising IgG titers on repeat testing.

Management: Rubella is self-limiting with no specific therapy, except symptomatic care.

Prevention of infection is specially important in prospective mothers and includes:

- ***Routine MR/MMR immunization*** at or after 15 months of age. (Ch 9.2.1). While single dose of rubella containing vaccine provides nearly 100% immunity, two doses of MR are given in India at 9 months and 15–18 months of age under National Immunization Programme. Indian Academy of Pediatrics recommends a third dose at 5–6 years. Vaccine may also be given at any age to unimmunized older children/adults, except during pregnancy. Conception should be strictly avoided for minimum three months after vaccination.
- ***Exposed pregnant and unimmunized women*** of reproductive age should be serologically screened immediately and after four weeks of exposure. Risk of congenital rubella syndrome is very low if mother is seropositive at the time of exposure. Seronegative mother, who turns seropositive after 4 weeks, carry maximum risk of congenital rubella syndrome and should be counseled accordingly. If abortion is not an option, immunoglobulin prophylaxis is indicated immediately after exposure, to reduce the risk of congenital rubella syndrome.

Erythema infectiosum *(fifth disease)* is the prototype illness of *Parvoviral B_{19} infection* in healthy children. Infection is acquired as droplet infection from a clinical or sub-clinical case, usually in *school-age.*

Clinically, infection is asymptomatic or presents as a mild febrile illness, *followed by* hallmark rash. Typical rash evolves in three stages:

a. Initial, transient facial flush (*slapped-cheek appearance*).
b. Discrete macular lesions over trunk and proximal extremities, *sparing palm and soles.*
c. Central clearing of macular lesions, with a lacy, reticular appearance.

Rash resolves spontaneously within 1–3 weeks, *without desquamation,* but may recur for a few weeks after sun exposure, heat, exercise and stress.

Diagnosis is mainly clinical, based on: (a) hallmark rash *without* fever and sick-appearance. Laboratory confirmation is not easily available, but includes: (a) elevated specific IgM titers, or (b) PCR testing. Virus cannot be isolated by culture.

Treatment is supportive and non-specific.

Other parvoviral illnesses: B_{19} is the only serotype of parvovirus, known to cause of human disease. It mainly targets erythroid cell line and other Parvovirus B_{19}-associated illnesses are:

- Transient aplastic crisis in hemolytic anemia, e.g. sickle cell disease,
- Chronic anemia or pancytopenia in immunocompromised host,
- A self-limiting arthropathy in female adolescents or adults, and
- Non-immune hydrops fetalis due to bone marrow depression and anemia in maternal infection.

Roseola infantum *(exanthem subitum)* is the prototype manifestation of a human herpesvirus type 6 or 7 (HHV 6/7) infection, characterized by a mild exanthematous febrile illness in infants and toddlers (d/d fifth disease in older children).

HHV 6/7 virus is present in saliva of infected humans and transmitted by close contact, e.g. kissing. Consequently, infection rate is highest in early infancy.

Clinically, it is characterized by:

- Sudden onset of high fever (>39–40°C) for 3–5 days that resolves with a crisis (suddenly). Typically, baby is apparently normal and active despite high fever. *Roseola is one of the commonest causes of febrile seizures.*

- Transient, discrete, maculopapular or rose-colored rash after 24–36 hours of defervescence, with centripetal distribution, most prominent on trunk and proximal extremities. Rash disappears rapidly within 1–3 days.

Complications are rare, except in immunocompromised host, who may develop aseptic meningitis or encephalitis.

Diagnosis is clinical, though laboratory confirmation is possible with—(a) elevated specific IgM titers, and (b) viral detection by culture or PCR amplification.

Treatment is supportive and non-specific. Ganciclovir and Foscarnet may be used for severe CNS disease in immunocompromised host.

Other HHV 6/7 illnesses, presumably associated with life-long persistence of these infections are:

- Blood disorders, e.g. hemophagocytic syndrome, histiocytosis and immune thrombocytopenia.
- Intussusception.
- Pityriasis rosea.
- Multiple sclerosis in adults.
- It is also considered as a co-factor in progression of HIV/AIDS infection.

10.19 CHICKENPOX

Varicella-zoster virus (VCZ) infection presents either as a primary infection, i.e. *chickenpox* in reviously nonimmune child or as re-activation of earlier latent infection, i.e. *herpes zoster (shingles)*. Chickenpox is a common and highly contagious exanthematous illness in children, usually seen as outbreaks.

Epidemiology: VCZ is a neurotropic human herpes virus, present in respiratory secretions or skin vesicles of a clinical case of chickenpox or herpes zoster (1–2 days before to 5–7 days after the rash).

Infection, transmitted via direct contact or as droplet infection, is highly contagious with secondary attack rate of 80–90% in household contacts and 30–35% in schoolmates. Transplacental fetal infection is possible in pregnant mothers with VCZ infection.

Chickenpox is most common in 5–9 year age group, though no age is immune, *including newborns*. Although infection confers life-long immunity, reactivation of silent infection (herpes-zoster) may occur after many years in ~ 10%, specially in immunocompromised states. Chickenpox outbreaks are more common during January to May months.

Pathogenesis: After primary infection, virus replicates locally in respiratory tract with intermittent subclinical viremia. After incubation period of 10–21 days, secondary or major viremia develops with onset of clinical disease. Gradual development of immune response limits the infection with clinical recovery within 5–7 days. However, VCZ virus invariably persists in body as a latent infection of *sensory ganglion* cells, which may be re-activated later to produce herpes zoster.

Fig. 10.9: Chickenpox.

Pathology: Typical skin vesicles containing *classic giant cells with Cowdry type A eosionophilic intranuclear inclusion bodies* are pathological hallmark of chickenpox. Similar cells may also be seen in other tissues, e.g. esophagus, pancreas, liver, lungs and brain.

Clinical presentation is variable, with milder disease in younger children. A typical case present after *incubation period* of 10–21 days, with:

- ***Short prodromal illness*** (1–2 days) with mild/moderate fever and constitutional symptoms like malaise, anorexia, etc.
- ***Exanthematous phase,*** characterized by typical *pleomorphic* rash, from 2nd day of fever. Rashes appear in crops as intensely pruritic erythematous macules, which evolve rapidly into clear fluid-filled vesicles and crust within 24–48 hours **(Fig. 10.9)**. Lesions are typically *centripetal in distribution,* mainly seen on trunk and back. New rashes continue to erupt for next 3–4 days, leading to *pleomorphism*, i.e. simultaneous presence of rashes in different stages of evolution as macules, papules, vesicles and scabs. Mucosal lesions, i.e. *enanthem,* may be present on oropharyngeal mucosa, airways, conjunctiva and vagina, as ulcerative lesions.
- ***Convalescent phase***, when scabs gradually fall-off in 7–14 days, leaving behind hypopigmented scars for 4–8 weeks.

Atypical variants of chickenpox include:

- ***Modified varicella-like illness (MVLI),*** seen in < 5% vaccinees, presents as mild papulovesicular eruptions after 1–3 weeks, lasting for few days.
- ***Breakthrough varicella*** is defined as a clinical disease after 42 days of immunization (d/d MVLI, within 1–3 weeks), usually seen in 1–4% vaccinees within 2–5 years of vaccination. It is more common in children vaccinated <15 months of age with a single dose and represents inadequate immune response with waning of the immunity over time. Two doses reduce the risk of breakthrough varicella by 3.3 fold.

- ***Hemorrhagic chickenpox*** in immunocompromised host, presenting with severe, hemorrhagic skin lesions, visceral complications and longer course.
- ***Congenital varicella*** *syndrome* may develop in 1–2% cases if mother is infected in before 20 weeks of gestation, characterized by limb hypoplasia, skin scarring, microcephaly and eye problems, e.g. cataracts and microphthalmia.
- ***Neonatal varicella*** is a life-threatening complication following primary maternal varicella infection 5 days prior to delivery and 2 days afterward, seen in 20–30% cases. Transplacental fetal infection may present with severe cutaneous and visceral lesions in first two weeks, with pneumonitis and fatal disseminated disease in 30% cases. Varicella zoster immunoglobulin (VZIG) at birth may reduce the severity of disease. Symptomatic newborns must be intensively treated with IV Acyclovir (10 mg/kg 8-hrly)
- ***Herpes zoster*** rarely presents in childhood, with typical unilateral *dermatomal distribution of grouped vesicular lesions,* which heal spontaneously within 1–2 weeks. Recurrent or multi-dermatomal herpes zoster indicates immunodeficiency state, e.g. HIV.

Complications are extremely rare in younger children, usually seen in older children, adults or immunocompromised host **(Table 10.34)**.

Diagnosis is mainly clinical, although laboratory confirmation is possible using vesicular fluid sample for: (a) virus detection by PCR or culture, (b) serological tests, e.g. immunofluorescence or ELISA, and (c) demonstration of multinucleated giant cells on *Tzanck smear.*

D/D includes other causes of vesicular lesions, e.g. (a) impetigo, (b) herpes simplex, (c) enteroviral rash, (d) drug-rash (e) insect-bites, etc. (Ch 25.6).

Treatment is symptomatic with maintenance of personal hygiene, mild antipyretic, e.g. paracetamol and topical anti-pruritic agents like zinc-calamine lotion. Aspirin is contraindicated in chickenpox due to high-riskof Reye-like syndrome.

Antiviral therapy is indicated to reduce the severity/duration of illness in high-risk cases, i.e. (a) immunocompromised states, (b) older cases >12 years, (c) pre-existing skin or pulmonary disorders, and (d) complications, e.g. encephalopathy, pneumonia and bleeding diathesis. It should be started within 24 hours of appearance of rash, using PO/IV Acyclovir (20 mg/kg/dose QID) for 5–7 days or till no new lesions appear for 48 hours.

Herpes zoster may also be treated with PO acyclovir, though IV therapy is necessary in immunocompromised cases with risk of disseminated disease. Other alternatives include famciclovir or valacyclovir, though rarely used in children.

Prevention of chickenpox includes:

- *Active immunization:* While not included in National Immunization Schedule, IAP recommends varicella vaccine to all children with two doses-first at 15–18 months of age and second after 3–6 months. Catch-up immunization is advised till 18 years with two doses at 8–12 weeks interval.

  Varicella vaccine is specially recommended in high-risk cases, e.g. close contacts of index case (within 3 days), institutionalized children or immunocompromised host (Ch 9.2.2)
- *Passive prophylaxis* with VZIG, i.e. specific varicella-zoster immunoglobulin (IM one vial/10 kg body weight) is indicated in: (a) immunocompromised or close household contacts, (b) pregnant women and (c) newborns born to mothers who develop varicella within 5 days before or 2 days after the delivery. It is effective only if given within 48–96 hours of exposure.
- *Isolation* is difficult but the child should not be sent to school during infectivity period. A case is contagious from 24–48 hours before the rash to 5–7 days after rash, till all vesicles have crusted.

TABLE 10.34: Complications of chickenpox

• *Skin*	:	Secondary bacterial infection of rash
• *Resp*	:	Interstitial pneumonia
• *Blood*	:	Thrombocytopenia, *P. fulminans*, DIC
• *CNS*	:	Cerebellar ataxia, encephalopathy, GBS
• *Renal*	:	HUS, acute nephritis, nephrotic syndrome
• *GIT*	:	Transient hepatitis or Reye-like syndrome*
• *Cardiac*	:	Pericarditis, myocarditis
• *Others*	:	Arthritis, pancreatitis, orchitis

HUS: Hemolytic-uremic syndrome, **GBS:** Guillain-Barré syndrome
*associated with use of aspirin in these cases

10.20 MUMPS

Mumps is a common vaccine preventable illness, characterized by acute, self-limiting, painful enlargement of parotids and other salivary glands, rarely associated with systemic complications.

Epidemiology: Mumps is a RNA virus (Paramyxovirus) of only one known serotype, with a clinical or subclinical infected human case as reservoir. A case is usually contagious from 24 hours before the swelling to 3 days after its disappearance and infection spreads by exchange of highly-infective saliva *via* direct contact, air-borne droplets or contaminated fomites.

It is most common in 5–9 year age group, though no age is immune except infants <6 months due to presence of maternal antibodies. Lifelong immunity develops after clinical/subclinical attack or immunization. Outbreaks are common in late winter or spring season.

Pathogenesis: After infection, virus multiplies in respiratory mucosa during incubation period, followed by viremia and localization of virus in *salivary glands*-the

Fig. 10.10: **Mumps: (A) Unilateral parotitis; (B) Bilateral parotitis**

commonest site of clinical disease, and other tissues. About 40% of infections are subclinical.

Clinical manifestations: After an *incubation period* of ~17–18 days, mumps presents with:

- *A brief prodromal phase (1–2 days)*, which is less prominent in younger children and includes moderate fever, malaise, pre-auricular pain and difficulty in chewing.
- *Shiny, tender, parotid swelling after 24–48 hours*, which gradually increases in size for next 2–3 days. Parotid enlargement is bilateral in 75% cases, though one side usually involve earlier than other side. Severity of parotid enlargement may vary from: (a) fullness of pre-auricular region, (b) lifting of ear pinna, (c) obvious parotid swelling, and (d) bull-neck appearance in bilateral parotitis **(Fig. 10.10)**. Opening of the *Stensen's duct*, opposite upper second molar, is red and swollen. Submandibular and submaxillary glands may be mildly enlarged.
- *Convalescence* begins after 3–4 days of swelling with complete recovery within 7–10 days.

Complications are rare (<1%), most important being aseptic meningitis, meningoencephalitis, orchitis and pancreatitis **(Table 10.35)**.

Aseptic meningitis is the commonest complication of mumps in childhood in 8–10% cases, though ~90% of them are asymptomatic, except CSF pleocytosis. Symptomatic cases present with headache, photophobia and neck stiffness within few days of parotid swelling usually to recover spontaneously within a week.

Meningoencephalitis, is relatively less common and may develop either in acute phase due to direct viral invasion or after 2–3 weeks of disappearance of swelling due to post-infectious demyelination.

Orchitis is more common in adolescents or adults (~25%), presenting as sudden testicular pain and swelling during 2nd weeks of parotid swelling, which improves spontaneously in 3–4 days. Testicular atrophy may occur in ~30% cases, though sterility is uncommon except in bilateral orchitis.

Pancreatitis presents in ~4% cases, with acute abdominal pain during 2nd week, though sub-clinical pancreatitis with >3–4 fold rise in serum amylase level is more common. Mumps virus has been proposed to infect pancreatic beta cells to trigger onset of juvenile diabetes mellitus.

TABLE 10.35: Complication of Mumps

Common
- CNS : Meningoencephalitis, aseptic meningitis
- Gonadal : Orchitis, epididymitis and oopheritis
- Pancreatitis

Uncommon
- CVS : Myocarditis, endocardial fibroelastosis
- CNS : Transverse myelitis, sensory-neural deafness
- Ocular : Dacroadenitis, uveokeratitis
- Others : Arthritis, nephritis, thyroiditis

Antenatal infection *(mumps embryopathy)*
- Abortion, stillbirth, low birth weight
- Endocardial fibroelastosis
- Aqueductal stenosis and hydrocephalus

Antenatal mumps infection may be associated with abortion, stillbirth or *mump's embryopathy*-characterized by intrauterine growth retardation, endocardial fibroelastosis and hydrocephalus.

Diagnosis is usually clinical, but may be confirmed by IgM-ELISA test, or viral cultures from saliva, CSF and urine. Serum amylase levels are raised in proportion to the size of swelling and normalize within 2–3 weeks.

D/D of mumps include *other causes of parotitis* like: (a) acute suppurative parotitis, usually due to staphylococci, (b) salivary calculus, (c) parotitis due to other viruses, e.g. HIV, coxsackievirus etc., (d) recurrent allergic parotitis; or *other causes of neck swelling*, e.g. (e) pre-auricular lymphadinitis.

Treatment: There is no specific antiviral therapy and treatment is entirely symptomatic including antipyretics, e.g. paracetamol, bed rest, maintenance of oral hygiene with warm-saline oral washes and soft-liquid diet. Cases should avoid contact with others during infectivity period (~10 days after onset of swelling) to prevent the spread.

Prevention: Routine immunization with single-dose, live-attenuated, combination MMR vaccine at the age of 15–18 months has >97% protective value. MMR is not yet included in National Immunization Schedule due to lack of sufficient data on disease and severity burden of mumps. However, IAP recommends three doses of MMR at 9 months, 15–18 months and 5–6 years to all children, the last dose to prevent outbreaks in older age groups as antibody titers tend to decline over time. Only two doses of MMR, given 8 weeks apart, are enough if the first dose is given after 12 months of age.

10.21 ACUTE POLIOMYELITIS

After successful eradication of smallpox in 1978, poliomyelitis is the second infectious disease on the

verge of eradication. Sporadic cases of poliomyelitis due to wild poliovirus are being reported only from two countries—Pakistan and Afghanistan. No such case has been reported from India since 13th January 2011 and WHO has declared India polio-free w.e.f. 27th March 2014.

Epidemiology: Polioviruses are the small RNA enteroviruses with three serotypes—types 1, 2 and 3.

All global cases presently are due to type 1, as wild type 2 and 3 virus have been eradicated in 1999 and 2020 respectively.

Reservoir of infection is a symptomatic or carrier case, excreting virus in stools. As the virus cannot survive outside human body for >48 hours, presence of large number of non-immunized hosts is essential for propagation of infection.

Infection is mainly transmitted *feco-orally* due to contaminated water supply, rarely by contaminated fingers or as droplet infection in close contacts.

Poliomyelitis largely affects young children <5 years. Infants <3 months are relatively protected by transplacental immunity.

Maximum cases occur in late summer or rainy season. Poor sanitation and inadequate immunization coverage are important determinants of polio outbreaks.

Pathogenesis: After ingestion, virus replicates in intestines and regional lymph nodes for few days, followed by transient *primary viremia,* during which the reticuloendothelial system is infected. Subsequently, sustained viral replication in reticuloendothelial system leads to *secondary viremia* and CNS involvement. Virus traverses to the CNS, either along the nerve pathways or through the blood stream. *Local IgA-mediated intestinal immunity* is the first line of defence against polio virus invasion, while systemic immunity may neutralize the virus before CNS involvement.

While ~90% of infections are subclinical, some provoking factors increase the risk of symptomatic disease, by increasing spinal vascularity and risk of viral invasion and include: (a) intramuscular injections, (b) surgery, (c) muscle trauma and (d) strenuous physical exercise.

CNS injury is caused by direct viral invasion as well as immunological mechanisms and selectively affects the *anterior horn cells* of spinal cord, cranial nerve nuclei and vital centers in the brain stem and motor cortex, *sparing* rest of the cerebral cortex and spinal white matter.

Clinically, symptomatic cases present after an incubation period of 7–14 days, with:

- ***Abortive poliomyelitis*** (4–8%), as self-limiting non-specific febrile illness,
- ***Non-paralytic poliomyelitis*** (1–2%), which may or may not progress to paralytic stage, with intense headache, nausea/vomiting and soreness/stiffness of neck and back muscles. *Nuchal-spinal rigidity* is the clinical hallmark of these cases,
- ***Paralytic poliomyelitis*** (<1%) presents as acute *spinal, bulbar or spino-bulbar* paralysis.

Spinal poliomyelitis is characterized by *acute flaccid paralysis* of different group of muscles involving neck, trunk or limb, with/without diaphragmatic involvement. Paralysis is typically a*symmetric and patchy* with variable severity. Involves muscles are quite tender urinary retention and constipation is common (20%) due to autonomic involvement. New areas of weakness may appear till next 3–7 days, followed by gradual recovery to some extent. Involvement of diaphragmatic/intercostal muscles indicates impending respiratory failure.

Bulbar poliomyelitis due to involvement of cranial nerve nuclei and/or respiratory center in the brain stem may also develop in some cases, presenting with feeding and breathing difficulties. Isolated encephalitic poliomyelitis is extremely rare.

Diagnosis: *Each case of acute flaccid paralysis (AFP) is considered as potential poliomyelitis for surveillance purpose, however unlikely it may be, and needs to be reported (discussed later).*

Clinical diagnosis rests on—(a) epidemiological history, (b) unimmunized child, and (c) acute onset of asymmetrical/patchy flaccid paralysis with pain/tenderness of involved muscles.

Laboratory diagnosis depends on *viral culture from stools,* which should be collected (~8 gm or thumb size) and transported to designated laboratory in ice pack (reverse cold-chain) as early as possible, under AFP surveillance program.

D/D of acute paralytic poliomyelitis includes: (a) vaccine associated illness, e.g. VAPP or VDPV, (b) other causes of AFP **(Table 10.36)**, or (c) *pseudoparalysis* due to pain, e.g. in scurvy, osteomyelitis, trauma, etc.

Possibility of vaccine related disease (VAPP/VDPV) should be considered in any case of AFP with history of: (a) OPV vaccination in preceding 30 days, (b) contact with recently immunized child in preceding 60 days, or (c) mass immunization program, i.e. *pulse polio* in the community, in preceding 60 days.

Management is non-specific, aims to: (a) provide supportive care during acute phase, (b) treat complications, e.g. respiratory failure, and (c) minimize residual functional loss with physiotherapy, orthotic corrections and occupational rehabilitation. All suspected cases should be hospitalized and notified to public health authorities

Prevention largely depends on adequate immunization, using an oral live-attenuated *Sabin* vaccine or a parenteral, inactivated *Salk* vaccine (Ch 9.2.1).

Polio Eradication in India

In May 1988, WHO launched a *global polio eradication initiative* and wild poliovirus 2 and 3 have been

TABLE 10.36: D/D common causes of acute flaccid paralysis (AFP)

*2–3 weeks before. **Flaccidity rarely lasts for > 72 hours, changes to spasticity. ***with near normal cell count, i.e. albumino-cytological dissociation

eradicated in 1999 and 2020 respectively. However, sporadic cases of WPV1 are still being reported from two countries – Pakistan and Afghanistan.

Despite being polio-free since 2014, eradication measures need to be continue here till disease is eradicated globally due to potential risk of spread through travellers from endemic countries.

Strategies for polio eradication in India included: (a) routine immunization, (b) supplementary immunizations, e.g. pulse polio immunization, (c) AFP surveillance, (d) environmental surveillance, and (e) outbreak control measures.

Pulse polio immunization (PPI) is a mass immunization campaign to supplement routine immunization and to facilitate development of herd immunity, conducted annually and simultaneously (pulse) throughout the country on pre-fixed dates (national immunization day/s or NIDs).

Principle: Since the vaccine-virus is excreted in stools for 4–6 weeks, simultaneous OPV administration to large population leads to extensive dissemination of vaccine virus in community, which competes with wild-virus for gut uptake. As wild-virus cannot survive in external involvement for long, it is expected to be flushed-out from community, replaced by non-virulent vaccine virus.

Target population for PPI is all children <5 years of age (including newborns), irrespective of previous immunization status. OPV doses during PPI are additional and should not replace regular immunization dose. There are no contraindications for PPI, even if routine dose was given a few days back.

Immunization days: First country-wide pulse polio campaign was launched on 9th December, 1995 and presently one polio immunization day is held nationally (NID) and with 1–2 additional state immunization days (SIDs) in high risk-states. These days are decided in advance using a Sunday and during winter season, as the wild-virus circulation is least common in these months and consequently, vaccine uptake is better. All infants are administered 2 drops of oral polio dose on this day at designated community centers or by door-to-door outreach for missed cases during next one week.

Acute flaccid paralysis (AFP) surveillance is an essential component of global polio eradiation initiative, "*to detect all cases of wild polio virus disease and eliminate remaining foci of polio transmission*", undertaken in India since 1997 as National Polio Surveillance Project (NPSP). Surveillance is carried out for all cases of AFP and not only for polio.

What is AFP? AFP is defined as "*any illness presenting with acute onset of flaccid paralysis in a child <15 years, for which no obvious cause such as trauma or electrolyte imbalance is found or a person of any age, with clinical suspicion of polio*". Generally, AFP of < 4 weeks is considered as acute.

Why all cases of AFP should be investigated? Since it is often difficult to exclude the diagnosis of poliomyelitis in a suspected case at the time of presentation, it is essential to investigate each case of AFP, to ensure that all cases are detected, reported and investigated and no case is missed out.

Components of AFP surveillance include, regular reporting system, investigation of suspected case and outbreak-control measures after suspected case report.

- ***Reporting:*** All *field-reporting units, e.g.* district health centers or pediatric units of major hospitals collect and send weekly reports of suspected case/s. If no case is seen during reporting week, the report has to be sent as *'nil or zero report'*
- ***Investigation of suspected AFP case*** includes: (a) *immediate reporting* to the designated person, (b) detailed data collection and *line-listing of all* reported

cases with a unique EPID number, to prevent duplication of reports, (c) *collection of stool cultures* for virus isolation, as specified earlier.

- ***Outbreak-containment measures*** are activated for every reported case of AFP with: (a) immunization of under-5 children in vicinity of suspected case, (b) intensified *collection of random stool and water/sewage samples* to detect the presence of wild-virus, and (c) *active case surveillance by door-to-door survey.*

Classification of an AFP case: All cases of reported AFP are classified after detailed epidemiological and viral studies as polio or non-polio cases.

An AFP case is confirmed as *poliomyelitis only* if: (a) wild polio virus isolated from stool sample, or in absence of adequate stool sample, (b) cases continues to have residual weakness after 60 days of onset *or* 60 days-follow-up not available due to death or absence *and* expert review concludes that these cases could not be discarded as *non-polio* based on available data.

10.22 ENTEROVIRAL INFECTIONS (NON-POLIO)

Enteroviral infections are caused by a large group of RNA viruses, which typically inhibit the intestinal tract. These infections include 3 distinct subgroups—(a) polioviruses, (b) echoviruses and (c) coxsackieviruses A and B, each with various serotypes.

Non-polio-enteroviral infections are usually caused by echo 4, 6, 9, 11, 30, coxsackie-A9, 16 and coxsackie B 2–5 viruses, most prevalent being echovirus 9.

Epidemiology: These viruses are widely present in soil and sewage water, sourced from human reservoirs and infection spreads via fecooral route or as droplet infection. Outbreaks are common in summer season, specially in overcrowded settings, e.g. slums, day-care centers, etc.

Clinical spectrum of these infections varies from asymptomatic infection to non-specific febrile illness to serious systemic illnesses **(Table 10.37)**.

Diagnosis of enteroviral illness should be considered in any febrile illness with rash or mucosal lesions, specially during outbreaks. Confirmation requires—(a) *viral cultures* from rectum swab or stools, throat and other infected sites, e.g. CSF, followed by serotyping, (b) PCR test for early diagnosis, and (c) serological studies, i.e. neutralizing antibody titers, for retrospective diagnosis.

Treatment is non-specific and supportive. *steroids are contraindicated*. No vaccine is available, though passive prophylaxis with human immunoglobulins may be useful during nursery outbreaks with virulent strains.

Some common and important enteroviral infections in Indian children are as follows:

Hand-foot-mouth disease *(HFMD)* is the commonest enteroviral illness in infants and toddlers, usually seen as localized outbreaks in winter season.

Etiologically, most cases are caused by *coxsackie A16 or Enterovirus A71,* though other serotypes have also been implicated.

Clinically, HFMD present with acute onset of: (a) oropharyngeal ulcers, and (b) tender vesicular lesions over dorsum of hands/feet, bony prominences like knee/elbow, palm/soles and buttocks, after incubation period of 3–7 days **(Fig. 10.11)**. Presence of lesion over palm and soles is characteristic in HFMD. Fever is rarely prominent and does not last for >24–48 hours. Patient is most infectious during the first week.

Most cases recover within 7–10 days and complications are extremely rare, though interstitial pneumonia, myocarditis or aseptic meningitis/encephalitis have been reported in few cases.

Diagnosis is clinical, though virus may be isolated from oropharynx and stools for 4–6 weeks.

Management is supportive with assurance about self-limiting nature of disease, analgesics and topical soothing agents, e.g. zinc-calamine lotion over skin or anesthetic mouth paints. Adequate nutrition and hydration must be ensured as children avoid oral intake due to ulcers.

Herpangina, is a self-limiting illness due to *Echovirus 9*, characterized by: (a) sudden onset of fever, headache and vomiting, (b) oropharyngeal discrete vesicles/ulcers with erythematous base, (c) morbilliform or petechial

TABLE 10.37: Clinical spectrum of enteroviral infections

• Asymptomatic infection (~50%)
• Non-specific febrile illness
• *Exanthemous illness:* Herpangina, HFMD
• Acute hemorrhagic conjunctivitis
• *Respiratory:* URTI, bronchitis, pleurodynia, ? asthma
• *GIT:* Vomiting, diarrhea, Abd. pain (d/d surgical abd.)
• *CNS:* Aseptic meningitis, encephalitis, GBS, C. ataxia
• *Others:* Myositis, arthritis, myocarditis, orchitis*
• *Neonatal infections:* Sepsis-like illness, myocarditis

*Enteroviruses are 2nd common cause of orchitis after mumps.
HFMD: Hand-foot-mouth disease, **GBS:** Guillain-Barré syndrome

Fig. 10.11: Hand-foot-mouth disease: (A) Skin lesions; (B) Oral ulcers.

rash in some cases. Most cases recover spontaneously in 3–5 days, though some may develop aseptic meningitis.

Acute hemorrhagic conjunctivitis, due to echovirus 70, presents with epidemics of viral conjunctivitis during post-monsoon season, characterized by-red-eye, conjunctival follicles and sub-conjunctival hemorrhages. Conjunctival discharge is highly contagious and epidemic spreads via hand-fomite-eye route. Recovery is spontaneous in 3–5 days, though rarely complicated by keratitis/corneal ulcers and polyradiculoneuropathy.

Pleurodynia (Bornholm disease), due to various serotypes of coxsackie B, is a self-limiting epidemic illness, presenting as acute high fever and severe spasmodic chest pain that is aggravated on deep inspiration. Pleural rub is common but effusions are rare. Most cases recover spontaneously in 1–3 days, though some may develop aseptic meningitis or pericarditis/myocarditis.

10.23 DENGUE

Dengue, the commonest *Arthropod-borne (ARBO) viral* illness, is a major public health problem in India with many outbreaks in recent years, usually in urban population.

Disease presents with many clinical variants-asymptomatic illness, classical dengue fever (DF), dengue hemorrhagic fever (DHF) and dengue shock-like syndrome (DSS).

Epidemiology: Dengue fever is caused by one or more of the four serotypes (DENV 1–4), though severe disease, e.g. DHF/DSS is more common with serotype 2.

An infected case is the usual reservoir of infection, which is mainly transmitted by a mosquito '*Aedes aegypti*'. This mosquito has typical daytime biting habit and breeds on stored water in houses. Rain water collected on terrace junks, is a major cause of increased vector density and focal outbreaks in urban slums at the end of rainy season. As the vector cannot fly for long distance, movement of infected persons is the major cause of distant transmission in dengue fever.

Mosquito is infected after feeding on a patient in viremic stage (1–5 day after onset of illness) and becomes infective after an extrinsic incubation period of 8–10 days. Vector, once infected, remains infective for life.

Etiopathogenesis is complex and still evolving.

- *First infection* in previously unexposed person leads to transient viremia after an incubation period of 5–7 days, which is either asymptomatic or presents with nonspecific febrile illness or classical dengue fever. At the end of viremia, these patients develop—(a) *homo-type neutralizing antibodies* to provide life-long immunity against same serotype; and (b) *hetero-type nonneutralizing antibodies,* which unfavourably alter the course of second infection with different serotype.
- *Second infection* with same serotype is asymptomatic but by different serotype may present with severe DHF/DSS due to pre-existing non-neutralizing antibodies, immune complex formation and intense inflammatory response.

Pathology of DHS/DSS is mediated by activation of complement system and release of many inflammatory mediators, like cytokines, leading to:

- *Vasculopathy*, i.e. increased permeability with extravascular shift of fluids, leading to shock and hemoconcentration,
- *Coagulopathy,* due to activation of clotting/fibrinolytic mechanisms with DIC-like bleeding manifestations, and
- *Multi-organ dysfunction* due to above changes.

Clinical spectrum of dengue spans from asymptomatic infection to severe life-threatening disease, and includes:

Undifferentiated dengue fever, more common in younger children, presents as non-specific febrile illness, usually associated with—(a) generalized *erythematous flush* over body with suffused face **(Fig. 10.12)**, and (b) *absence of catarrh,* despite nasopharyngeal and ocular congestion. Signs of bleeding or capillary leakage are absent.

Classic dengue fever usually presents as biphasic illness as follows:

- ***Febrile phase** with*—(a) sudden onset of continuous high fever, (b) severe headache, myalgia, arthralgia and *retro-orbital* pain, (c) generalized macular rash/flush after 48–72 hours, usually sparing palms and soles, (d) disproportionate bradycardia, and (e) conjunctival congestion, rhinopharyngitis and nausea/vomiting. Fever usually comes down by lysis and profuse sweating after 3–5 days.
- ***Critical (leakage) phase*** begins after 3–5 days with development of increased capillary permeability and signs of plasma leakage from intravascular to extravascular compartment, e.g. hypotension, pleural

Fig. 10.12: Dengue: (A) Suffused or flushed face; (B) Macular rash.

effusion and rising hematocrit. Many warning signs during this phase **(Table 10.38)**, may herald the onset of dengue hemorrhagic fever (DHF) and/or dengue shock syndrome (DSS), discussed later. This phase usually lasts for 36–48 hours.

- ***Convalescent (recovery) phase*** begins after 6–7 days of fever with clinical improvement due to control of capillary leakage and return of the leaked plasma back into intravascular compartment. Patient may develop pulmonary edema due to fluid overload, if the overzealous fluid replacement continues.

Dengue hemorrhagic fever or shock-like syndrome (DHF/DSS), is a serious, life-threatening manifestation, with first phase similar to classical dengue fever. However, these cases deteriorate rapidly on 2nd–5th day, with bleeding tendency, thrombocytopenia, evidence of plasma leakage with or without circulatory shock. Severity of DHF/DSS may be classified into four grades, according to two clinical hallmarks—*bleeding* and *shock* **(Table 10.39)**. After 24–36 hours of crisis, recovery begins in adequately treated cases, though mortality is high (40–50%) in others.

Expanded dengue syndrome denotes multiple organ involvement in these cases, e.g. encephalopathy, hepatitis, renal failure, myocarditis or ARDS, more common in adults or those with co-morbidities.

National guidelines for clinical management of dengue fever (2023) classify dengue fever as asymptomatic and symptomatic, later further sub-classified as *mild* (without warning signs), *moderate* (with warning signs) or *severe* (with shock, bleeding or organ involvement) dengue based on various indicators **(Fig. 10.13)**.

Diagnosis rests on clinical suspicion, with laboratory tests to confirm the presence of virus, antigen or antibodies. Timing of the tests is important, dependent on the course of disease. Commonly used diagnostic tests include:

- ***NS1 antigen test:*** Non-structural protein (NS1) antigen is present in the serum during first 5–7 days of fever and its detection by an ELISA-based test helps in early diagnosis of dengue. However, the antigen disappears after 4–5 days and the test becomes negative. While rapid card tests for qualitative detection of NS1 using immunochromatography are also available, results are unreliable as compared to ELISA test, due to poor sensitivity.
- ***Anti-dengue IgM antibody test:*** These antibodies are detectable usually by day 5 of the illness and persist for ~ 60 days. Detection of these antibodies by ELISA or rapid tests help in diagnosis of disease after 5 days. However, rapid tests are not recommended due to high rate of false-negativity.
- ***Polymerase chain reaction (PCR):*** Molecular diagnosis based on detection of viral nucleic acid by RT-PCR is confirmatory in acute phase but the test may be negative after first week of illness.

Viral isolation or IgG antibody tests are of limited value in the diagnosis of acute disease.

Supporting investigations include hematocrit, platelet count and relevant tests for organ dysfunction, which need to be repeated frequently to monitor the progression of disease. Hematocrit and platelet count should be monitored at least every 24 hours for early detection of warning signs, i.e. hemoconcentration (due to capillary leak) and thrombocytopenia, though more frequently in severe dengue.

Table 10.40 presents current WHO/NVBDCP case definitions for dengue fever and related conditions.

D/D of dengue includes other causes of viral and non-viral hemorrhagic fevers (Ch. 10.1.14). Dengue-like illnesses have also been reported in India from other arboviruses, e.g. chikungunya virus and West Nile virus.

Management is essentially symptomatic and supportive, depending on the severity of disease, as follows:

DF without warning signs need not be hospitalized and may be managed at home with bed rest, antipyretics, adequate oral hydration and monitoring for the warning signs. NSAIDs, e.g. aspirin or Ibuprofen should be avoided due to risk of gastritis, platelet dysfunction and bleeding. ORS or fruit juices are preferable to plain water for rehydration to replenish fluid and electrolyte losses due to excessive sweating or vomiting. However, parents should be counselled about the need to observe for warning signs, which require urgent medical attention.

DF with warning signs: Immediate hospitalization is recommended to all cases with warning signs for close

TABLE 10.38: Warning symptoms and signs in dengue fever

- Persistent vomiting
- Abdominal pain or tenderness
- Lethargy, restlessness or irritability
- Hepatomegaly (>2 cm)
- Clinical fluid accumulation (ascites, pleural effusion)
- Bleeding manifestations, usually mucosal bleeds
- Rising hematocrit with concurrent drop in platelet count

TABLE 10.39: Severity grading of DHF/DSS

I	Dengue fever + positive tourniquet test and evidence of plasma leakage
II	*As above* + spontaneous bleeding and abdominal pain
III	*As above* + evidence of circulatory failure
IV	Profound shock with undetectable BP/pulse
Plus	Thrombocytopenia <100000 cells/mm^3, *and* more than 20% rise in hematocrit.

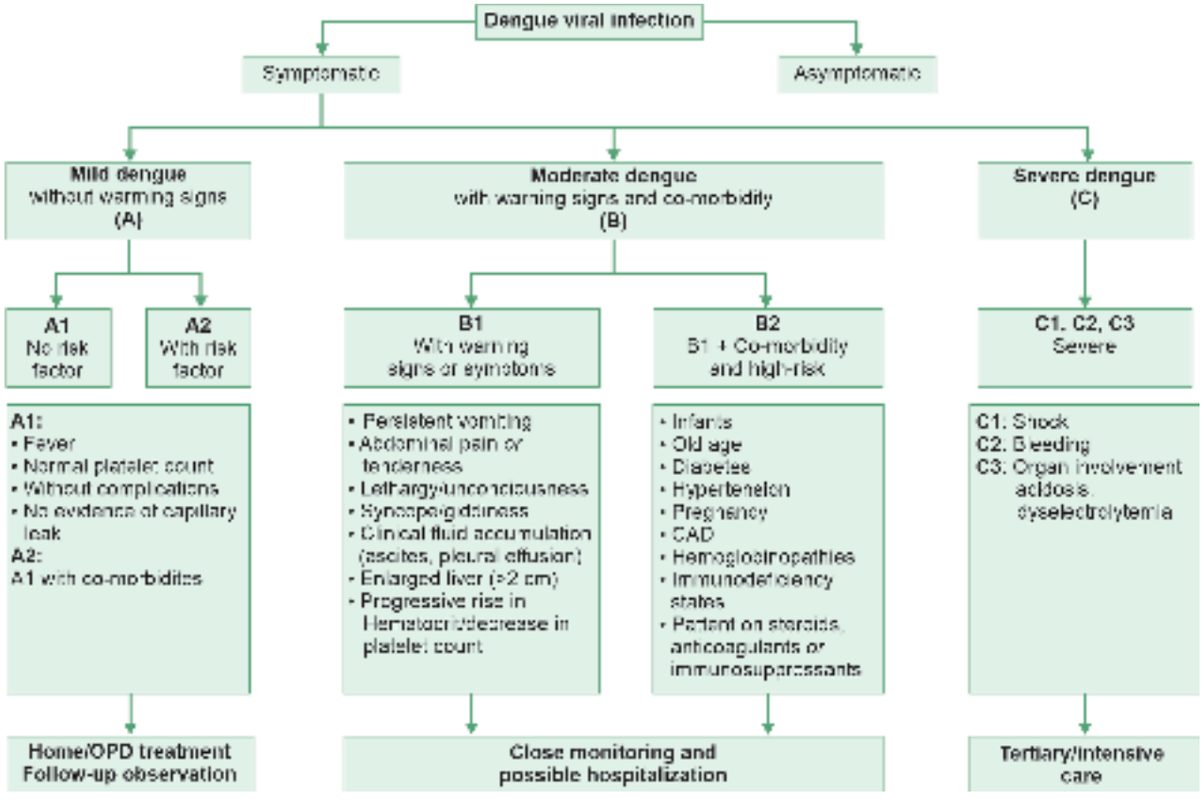

Fig. 10.13: Clinical case classification of Dengue: National Guidelines 2023.

TABLE 10.40: Case definitions for dengue fever/DHS/DSS

Probable dengue fever *(any one of following)*
- Acute febrile Illness (2–7 days) with *(any 2 of following)* Headache, retro-orbital pain, rash, myalgia, arthalgia, bleeding, thrombocytopenia or leucopenia, warning signs or symptoms
- Positive NS1/IgM test (non-ELISA based)

Confirmed dengue fever *(Clinically compatible, with any one of following)*
- Positive NS1 test by ELISA
- Positive anti-dengue IgM antibodies by ELISA
- Positive dengue PCR test
- Viral isolation from serum, plasma or leukocytes
- >4 fold rise in IgG antibodies after 2 weeks

Dengue hemorrhagic fever* *(all four of following)*
a. Clinical criteria for dengue fever, as above
b. Hemorrhagic tendency (any one of following)
   - Positive touniquet test
   - Petechiae, ecchymoses or purpura
   - Bleeding from mucosa, GIT, injection or other sites
c. Thrombocytopenia (<100,000 cells/mm^3)
d. Evidence of plasma leakage *(any one)*
   - Rise in hematocrit >20% over baseline for age/sex
   - Drop in hematocrit >20% after volume replacement
   - Signs, e.g. pleural effusion, ascites, hypoproteinemia

Dengue shock syndrome* *(both of the following)*
a. All of the above criteria for DHF *with*
b. Circulatory failure: Rapid/weak pulse, pulse pressure <20 mm Hg, hypotension, cold-clammy skin, restlessness

*As per National guidelines 2014; (DHS/DSS are not defined in Guidelines 2023).

monitoring with serial hematocrit and platelet count daily, till the patient is afebrile for 1–2 days. Cases with persistent vomiting may need parental fluids and electrolyte therapy.

Admission criteria in dengue include presence of: (a) warning signs, (b) significant bleeding, (c) persistent high fever, (d) sudden drop in body temperature, (e) rapid fall in platelet counts, (f) hypotension, and (g) organ dysfunction, e.g. renal, hepatic or CNS involvement.

Hemoconcentration due to plasma leakage from intravascular compartment is the major concern in these cases. These patients require closely monitored intravenous fluid therapy with crystalloid fluids along with supportive measures. **Fig. 10.14** presents an algorithm for fluid replacement in these cases, as per national guidelines.

Severe Dengue with Shock: These cases essentially need intensive care with close monitoring for vital signs, hematocrit and bleeding. Fluid therapy may be supplemented by colloids and if necessary, whole blood transfusions in selected cases. **Fig. 10.15** presents an algorithm for fluid replacement in these cases, as per national guidelines.

Fluid replacement therapy: Some general principles of fluid replacement therapy as follows:

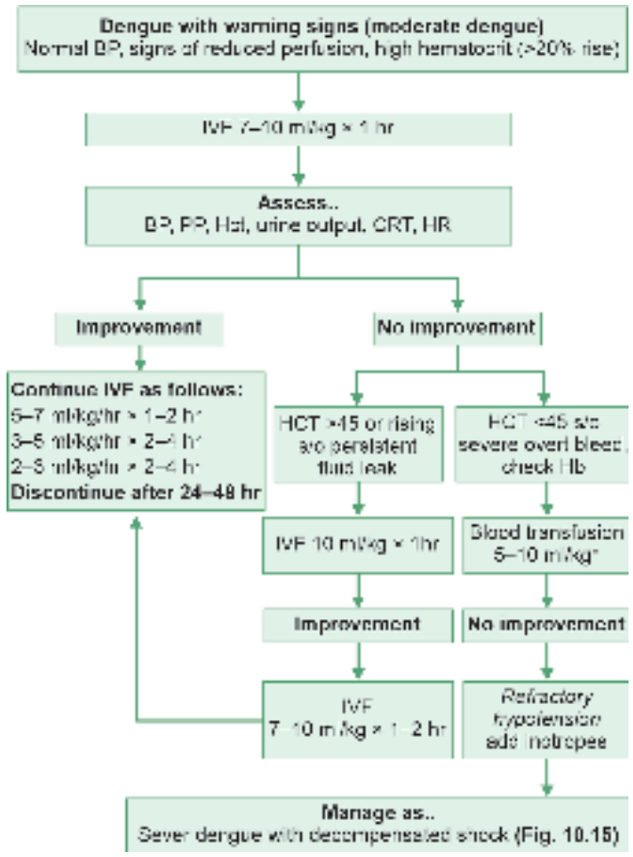

Fig. 10.14: Fluid management in moderate Dengue with warning signs.
Improvement: Hct falls, HR and BP stable, urine output rises.
No Improvement: Hct and HR rises, pulse pressure fall < 20 mm Hg, urine output falls
*Whole blood 10 ml/kg or packed cells 5 ml/kg.
IVF: IV fluids; **Hct:** Hematocrit

- Volume of fluid therapy should be calculated on the basis of body weight with 5% deficit, revised every 1–3 hours.
- First-hour fluid therapy should begin with 6 ml/kg in moderate dengue without shock and 10–20 ml/kg in severe cases with compensated shock, while those with decompensated shock must be infused 10–20 ml/kg over 15–30 minutes.
- Ringer lactate, normal saline or DNS 5% are preferred fluids for this purpose.
- Hematocrit, vital signs, e.g. heart rate and blood pressure, and urine output must be monitored along with indicators of fluid overload, e.g. hepatomegaly or breathlessness due to pulmonary edema. Central venous pressure (CVP) monitoring is advised in unstable cases, if possible.
- In cases showing improvement with falling hematocrit and stable vitals, infusion rate must be reduced gradually after every 2–4 hours. IV fluid may be discontinued after 24–48 hours.
- In cases with no improvement or deterioration, further treatment must be decided on the basis of hematocrit:
  - *In cases with rising hematocrit* suggestive of continuous plasma leak, infusion rate must be increased or maintained at 10–20 ml/kg/hr. Colloids, e.g. dextran-40, may be used in these cases.
  - *In cases with falling hematocrit*, suggestive of bleeding, blood transfusion with whole blood (10 ml/kg) or preferably packed cells (5 ml/kg) is indicated.
- Further management of non-improving cases also includes IV inotropes and cardio-respiratory support, as required.

Management of bleeding: Cases with severe bleeding are best managed with whole blood transfusion, till the specific cause is identifiable, e.g. severe thrombocytopenia or coagulopathy due to hepatic dysfunction. Platelet transfusions are recommended only in cases with: *(a) platelet count <10,000/mm^3 and/or (b) severe clinical bleeding.* Packed cell transfusions or fresh frozen plasma may be needed in some cases.

Management of organ dysfunction: Hepatitis, myocarditis and acute kidney injury is common in dengue and need to be managed intensively. Fluid therapy must be closely monitored in cases with renal dysfunction due to potential risk of pulmonary edema. Comorbidities, e.g. malaria, tuberculosis may sometimes complicate these cases and must be considered in non-responding cases.

Antiviral agents, steroids and immunoglobulins have no role in management of dengue.

Criteria for discharge in a dengue case include: (a) absence of fever >24 hours without antipyretics, (b) Stable vital signs for >2–3 days, (c) platelet count > 50,000 cells/mm^3, and (d) visible clinical improvement with no respiratory distress and good urine output.

Prevention and control of outbreaks depends on:

- *Vector-control measures*, e.g. avoidance of breeding sites, e.g. prolonged indoor water-storage and use of larvicides, insecticides.
- *Personal protection* measures, e.g. repellents, nets and avoidance of travel to outbreak area.

Currently no dengue vaccine is available in India. CYD-TDV (Dengvaxia®) is the first and only licensed vaccine against dengue, being used in some endemic countries of Asia and Latin America, though several other candidates (including one indigenous vaccine by Serum Institute of India, Pune) are under development. (Ch 9.2.4).

Other important arboviral illnesses are as follows:

Chikungunya is a benign, dengue-like syndrome, characterized by sudden onset of fever, arthralgia, maculopapular rash and leukopenia. Recent years have witnessed intermittent outbreak of this disease in many parts of India.

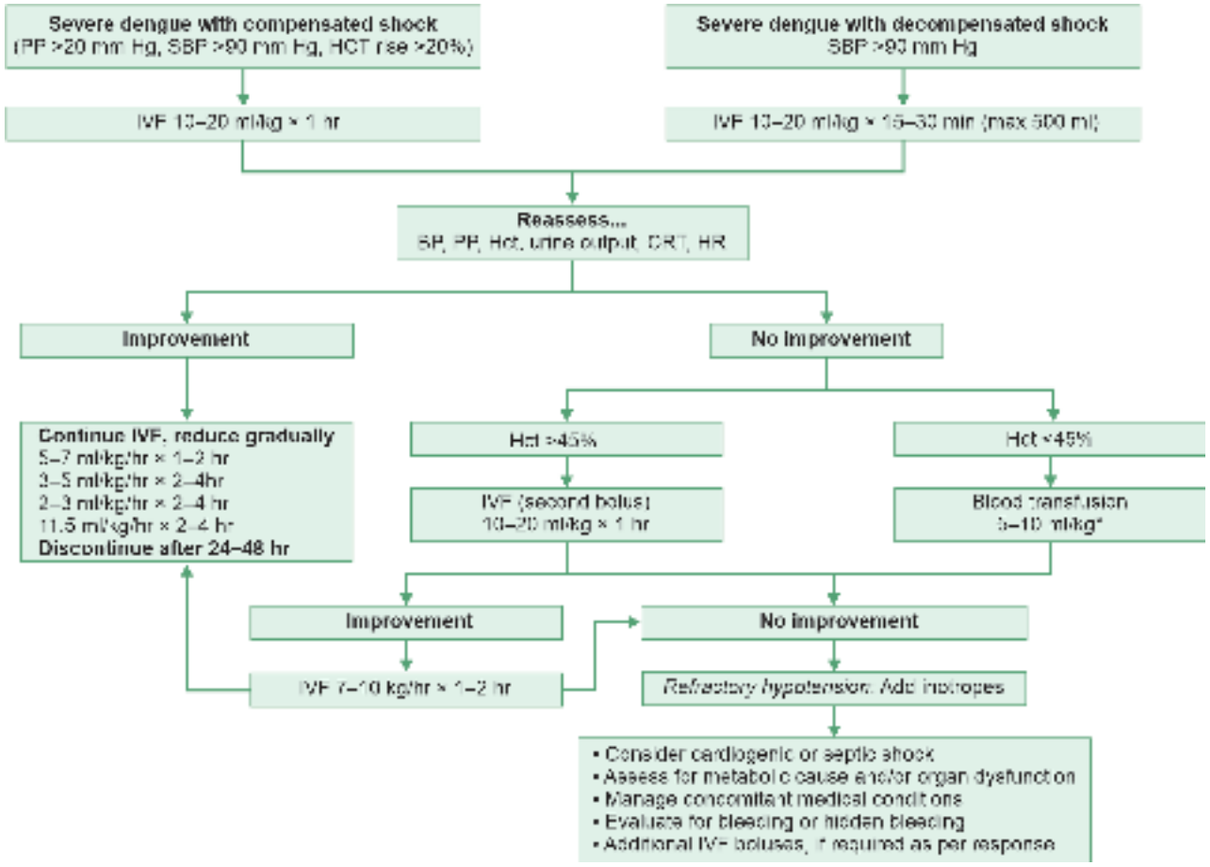

Fig. 10.15: Fluid management in severe Dengue with compensated or decompensated shock.

Improvement: Hct falls, HR and BP stable, urine output rises

No Improvement: Hct and HR rises, pulse pressure fall < 20 mm Hg, urine output falls

*Whole blood 10 ml/kg or packed cells 5 ml/kg.

IVF: IV Fluids; **Hct:** Hematocrit

Epidemiology: Chikungunya is a *zoonotic RNA virus*, widely distributed in many vertebrate species with asymptomatic or symptomatic infections. Humans are infected via mosquito bite, with *Aedes aegypti* being the commonest vector in India. Though subclinical infections are common, chikungunya outbreaks generally indicate substantial rise in susceptible human and *A. aegypti* population above a threshold level.

Clinical presentation: After an *incubation period* of 2–4 days, the infection generally follows a different course in different age-groups:

- *In infants*, clinical illness begins with sudden onset of high fever, flushed skin, conjunctival congestion and pharyngitis, followed by a generalized maculopapular rash and lymphadenopathy after 3–5 days. However, *arthralgia*-the hallmark of disease in older population, is rare in this age group. Unlike other viral infections, Enanthems are absent.
- *In older children*, acute onset fever is typically associated with severe headache, arthralgia and myalgia; followed by maculopapular rash and lymphadenopathy after 3–5 days, just before the defervescence. Febrile convulsions are common. Rash, arthralgia and lymphadenopathy disappears in next 2–3 days. Residual arthralgia beyond first week is uncommon in children.
- *In adolescents/adults*, severe *fleeting polyarthritis/* arthralgia, is the hallmark of disease. Typically, the pain shifts from joints to joints, more prominent in morning and worsens with movements. Swellings of ankle, wrist and fingers is common. Arthralgia may persist for many weeks, often confused with rheumatoid arthritis.

Diagnosis depends on: (a) history of on-going outbreak, (b) clinical suspicion, and (c) serological studies with IgM ELISA after at least a week of complaints. Viral isolation is possible though rarely feasible.

D/D includes other causes of dengue-like illnesses. Important differences with dengue include: (a) shorter duration of fever, generally <72 hours, (b) more pronounced arthralgia, terminal rash and conjunctival congestion, and (c) rarity of shock and hemorrhagic manifestations.

Treatment is largely supportive, including bed rest, NSAIDs to control pain and inflammation in cases with arthralgia, nutritional support and correction of fluid and electrolyte balance, if necessary.

Despite acute explosive onset with dengue-like illness, complications, e.g. shock and bleeding are extremely rare and mortality is almost unknown. Though older children/adolescents may continue to experience intermittent arthralgia for many months, complete recovery is the rule except a few reports of destructive arthropathy.

Prevention mainly includes mosquito control and bite prevention strategies. No vaccine is available, though a formalin inactivated and a live attenuated vaccine is in experimental stage.

Kyasanur forest disease is currently prevalent in Mysore region (Karnataka), transmitted by ticks. Monkeys or forest-rodents act as amplifying reservoirs of infection apart from human host. It mainly occurs in adults, exposed during forest-visits and presents with high fever, severe myalgia, prostration, pneumonia and bleeding. Renal/hepatic failure and meningoencephalitis may develop after a latent phase in some cases (biphasic illness). Diagnosis rests on serology and treatment is supportive.

10.24 HERPETIC VIRAL INFECTIONS

Important viral infections of genus *herpes* include: (a) herpes simplex, (b) infectious mononucleosis, (c) cytomegalovirus disease, (d) varicella-zoster or chickenpox, and (e) Roseola infantum due to HHV 6/7 infections. A relatively new herpes virus, i.e. HHV 8, identified in 1994, has been implicated in etiology of: (a) Kaposi sarcoma in AIDS, (b) multiple myeloma in elderly, and (c) other malignancies, e.g. lymphoma in immunodeficient host.

A distinguishing features of all herpetic infections is the life-long persistence of virus after primary infection (*latent phase)* with intermittent *reactivation* or viral shedding.

10.24.1 HERPES SIMPLEX

Herpes simplex (HSV) infections are caused by two strains—HSV_1, which commonly infects skin and mucus membranes; and HSV_2 that mainly infects genital tract.

Epidemiology: HSV_1 is transmitted by close human contact, while HSV_2 is transmitted by direct sexual or genital-hand-genital contact. Newborns are usually infected during their passage through infected birth canal (*perinatal* infection), rather than transplacentally.

HSV_1 infections are common in early childhood in overcrowded living conditions, while HSV_2 usually infects in adolescence. A breech in skin/mucosal continuity facilitates HSV entry.

Pathogenesis of HSV infections may be divided into 3 stages—(a) primary infection, (b) latent infection, and (c) reactivation of latent infection *or* secondary infection with other serotype (HSV_1 > HSV_2 or vice versa).

- *Primary HSV infection* is usually asymptomatic or limited to localized skin/mucosal lesions. Sporadic encephalitis is perhaps the only systemic manifestation of primary HSV infection.
- *Latent phase:* After primary infection, inactive HSV always persists life-long in ganglions as latent infection, with intermittent clinical reactivation or virus shedding.
- *Re-activation* is usually precipitated by *external stimuli*, e.g. cold or ultraviolet rays exposure or *internal stimuli*, e.g. fever, emotional stress and menstruation.
- *Secondary infection* is usually asymptomatic except the risk of perinatal transmission. All infections, whether primary, reactivation or secondary, in an immunocompromised host, i.e. newborn, malnutrition, malignancies and AIDS, may produce severe invasive disease.

Clinical manifestations: *Grouped vesicular lesions* are hallmark of primary as well as reactivated HSV disease, presenting as follows:

- *Skin lesions* (HSV_1) are characterized by grouped thin-wall vesicles with erythematous base, which rupture, scab and heal within 7–10 days without scarring. Eruptions may be preceded by local pruritus or neuralgic pain and more common at the site of trauma/irritation, e.g. contact dermatitis. Herpetic whitlow involving fingers is commonly seen in thumb-sucking children.
  - *Mucosal lesions* (HSV_1) manifest as—(i) *herpetic gingivostomatitis*, i.e. acute onset of painful oral ulcers with drooling and high fever, lasting for 7–14 days, (ii) *herpes labialis*, i.e. perioral grouped vesicles on or near lips, or (c) *ocular lesions*, e.g. keratoconjunctivitis.
  - *Genital lesions* (HSV^2) are mostly seen in adolescents as vesicles/ulcers over vulvovaginal region or penis.
  - *CNS infection*, e.g. encephalitis or aseptic meningitis with/without mucocutaneous lesions are common even in immunocompetent children. HSV_1 is a leading cause of sporadic encephalitis in India with acute necrotizing infection of frontotemporal cortex and limbic system.

HSV in immunocompromised children may present with chronic/recurrent orogenital lesions *or* invasive disease, e.g. sepsis, hepatitis, DIC, pneumonitis or esophagitis.

Perinatal HSV infection is acquired *in utero* (<5%), during vaginal passage (~ 80%) or as postnatal nosocomial infection, discussed in Ch 12.15.4.

Diagnosis depends on: (a) characteristic grouped vesicular lesions, (b) virus detection by PCR or tissue

culture, (c) serology, or (d) typical histology, i.e. multinucleated giant cells and intranuclear inclusion bodies on *Tzanck* staining of vesicle scrapping, CSF or tissue biopsy.

Treatment: IV Acyclovir therapy is the mainstay of treatment in HSV infections, either orally (60 mg/kg/day q6hr for 7 days, maximum 200 mg/dose) for localized skin/mucosal lesions or intravenously (30 mg/kg/day q8hr slowly for 21 days) for encephalitis or invasive disease, apart from supportive care. Long-acting valacyclovir (500 mg BD) or famciclovir (125 mg BD) for 3–5 days may be used in adolescents with genital lesions. Half of these doses may be used for reactivation lesions (for 5 days) or prophylaxis for recurrent lesions in immunocompromised host.

10.24.2 INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is a clinical illness characterized by acute fever, sore throat and generalized lymphadenopathy, along with presence of atypical lymphocytes in blood. Over 90% cases are caused by *Epstein-Barr virus* (EBV). Remaining may be due to other *viruses*, e.g. CMV, adenovirus, rubella, HIV, etc. or *parasites*, e.g. toxoplasma.

Epidemiology: EBV is intermittently excreted in oropharyngeal secretions of the infected person (reservoir) and transmitted by close contact, e.g. kissing. Primary infection is common in children <3 years and usually remains dormant except intermittent viral shedding throughout life. Clinical disease denotes either primary infection or reactivation of latent infection.

On entry, EBV replicates in oral epithelial cells and salivary glands, followed by viremia with disseminated infection of B-lymphocytes and lymphoreticular system. Characteristic *atypical lymphocytes* in these cases are actually CD_8 lymphocytes, formed to prevent the spread of infected B-cells. Infection persists life-long in oropharyngeal cells and B-cells, to re-activate any time, specially in immunocompromised states.

Clinically EBV infection is mostly asymptomatic, though symptomatic disease, i.e. *infectious mononucleosis* presents after an incubation period of 4–6 weeks, with:

- *Prodromal phase* with mild fever, malaise, headache, myalgia, sore throat and abdominal pain for 1–2 weeks.
- *Characteristic phase* with—(i) progressively rising fever, (ii) sore throat, (iii) generalized lymphadenopathy (90%), (iv) splenohepatomegaly, and (v) maculopapular rash (5–15%). Epitrochlear lymphadenopathy and development of rash on ampicillin therapy are useful indicators of infectious mononucleosis.
- *Convalescence* in 6–8 weeks with spontaneous recovery except in immunodeficient cases.

Complications are uncommon, usually seen during 2nd–3rd weeks of illness **(Table 10.41)**. Splenic rupture is the most dreaded complication in these cases.

TABLE 10.41: Complications of infectious mononucleosis

- Splenic rupture
- *Respiratory:* Pneumonia, obstruction (? adenoids)
- *Neurological:*
  - Aseptic meningitis,
  - Acute cerebellar ataxia
  - Guillain-Barré syndrome
  - Alice in wonderland syndrome**
- *Hematological**: Anemia, thrombocytopenia

*autoimmune or due to bone marrow depression
**loss of perceptual capabilities

Diagnosis must be suspected in a clinical triad of *prolonged fever, pharyngitis and generalized lymphadenopathy,* supported by:

- *Lymphocytosis with atypical lymphocytes* (larger lymphocytes with eccentric, large, indented nucleus and lower nuclear-cytoplasm ratio). Other causes of atypical lymphocytosis include: CMV, toxoplasmosis, rubella, roseola, mumps, viral hepatitis, mycoplasma, and drugs.
- *Paul-Bunnell-Davidsohn test,* for presence of *nonspecific* heterophile IgM antibodies with titers <1:28 taken as positive. A rapid qualitative slide test (*mono-spot*) based on similar principles is available to detect EBV infection in >50–90% cases.
- *Specific EBV antibodies* tests, anti-VCA (viral capsid antigen) or anti-EA (early antigen) antibodies detect early infection, while anti-EB nuclear antigen antibodies are positive in convalescent phase or due to previous infection.
- *Viral culture* from oropharynx is positive for ~ 1 year after primary infection or during intermittent shedding.

Treatment is non-specific, including *supportive measures* like bed rest, antipyretics and avoidance of splenic trauma.

Steroids (PO prednisolone 1 mg/kg/d × 2 weeks) are indicated only in complicated cases with – (i) severe airway obstruction, (ii) symptomatic thrombocytopenia, (iii) autoimmune hemolytic anemia, and (iv) aseptic meningitis.

High doses of acyclovir with/without steroids reduce viral shedding but do not affect the severity or course.

Prognosis is excellent with complete recovery in 4–8 weeks in absence of acute complications and recurrence in unknown. Rare case may develop chronic active EBV infection with progressive immunodeficiency and often succumb to opportunistic infections, hemophagocytosis, multiorgan failure, or EBV-positive lymphomas. Stem cell transplantation is the only option in cases of chronic active EBV infection with complications.

Prevention involves avoidance of contact with an infected case and no vaccine is available at present. Contact sports should be avoided to prevent splenic rupture.

Note: EBV was the first virus found to be associated with malignancies and has been implicated in:

- *Benign lymphoproliferative illnesses, e.g. hemo-phagocytic syndrome, oral hairy leukoplakia and lymphocytic interstitial pneumonitis (LIP) in AIDS.*
- *Malignancies, e.g. Burkitt's lymphoma, Hodgkin disease, nasopharyngeal carcinoma, leiomyosarcoma.*

10.24.3 CYTOMEGALOVIRUS DISEASE

Cytomegalovirus (CMV) is the *largest herpes virus*, present in body fluids of an infected person, (e.g. saliva, urine, milk, stool and blood) and transmitted by close person-person contact.

While primary infection in early childhood is very common and almost always asymptomatic, it persists life-long with potential risk of reactivation. CMV infection in newborn (Ch. 12.15.4) or immunocompromised states is associated with high mortality and morbidity.

Clinical presentation of CMV infection varies with age and immune status.

- *In immunocompetent children,* CMV infection is almost always asymptomatic, rarely presenting as mild infectious mononucleosis-like illness.
- *Perinatal CMV or postnatal infection in immuno-compromised host,* may present with serious systemic illnesses, e.g. pneumonitis, hepatitis, chorioretinitis, leukopenia/thrombocytopenia, enteritis, or pro-gressive encephalitis.

Diagnosis of active infection rests on: (a) detection of virus in urine, saliva or other secretions/infected sites by PCR or DNA hybridization techniques, *or* (b) serology, i.e. elevated anti-CMV IgM titers or rising IgG titers after 4 weeks.

Treatment with IV ganciclovir (2.5 mg/kg/dose TDS for 3–6 weeks), is indicated only in infected newborns or immunocompromised host with severe disease. PO valganciclovir may be more effective and less toxic than IV ganciclovir, if available.

Prolonged prophylaxis with ganciclovir or valganci-clovir is indicated in cases of transplant recipients and AIDS with CD4 count <100 cells/mm^3.

10.25 COVID-19 INFECTION

Despite the lesser incidence and severity, SARS-CoV-2 (COVID-19) infection in children posed unique challenges during the pandemic due to large pool of asymptomatic cases to facilitate spread of infection, different modes of presentation, e.g. multi-systemic inflammatory syndrome (MIS-C) and long-term effects on their physical and mental health, education and immunization status.

Children <19 years of age contributed to ~10% of reported COVID-19 cases but with <5% of hospitalizations and <0.5% of mortality, globally as well as in India.

Epidemiology: Children usually contract infection from a household contact (75–90%), rarely from other in schools, child-care centers or health-care settings. Infected children, even if asymptomatic, have higher nasopharyngeal viral loads than adults and shed the virus for a longer period.

Pathogenesis: SARS-CoV-2 is transmitted as droplet infection or by contaminated fomites and surfaces. On entry, virus gets attached to angiotensin converting enzyme-2 (ACE_2) receptors present on the ciliated respiratory epithelium and gastrointestinal mucosa. After local replication, viremia develops followed by development of either appropriate immune response to clear the virus or dysregulated immune response with development of cytokine storm – responsible for clinical deterioration with acute respiratory distress syndrome (ARDS), multi-organ failure and sometimes, death. It is also characterized by elevation of inflammatory markers, e.g. CRP, procalcitonin, interleukin ($IL_{6/10}$) and D-dimer levels, also leading to increased thrombosis. Patients may also have abnormal coagulation parameters due to high expression of ACE_2 receptors in vascular endothelial cells.

Children usually have milder disease, due to: (a) immaturity of ACE_2 receptors, (b) relatively immature immune system, unable to mount intense inflammatory response and cytokine storm. However, children <1 year or with underlying medical conditions, e.g. obesity, immunocompromised states, chronic lung/heart disease, diabetes or other metabolic diseases are at higher risk of severe disease.

Clinically, while ~15–20% cases are asymptomatic, rest present after an incubation period of ~4–6 days with fever, upper respiratory infection, myalgia, diarrhea and vomiting as initial symptoms. Further course may be classified as follows:

- *Mild cases*, presenting as uncomplicated upper respiratory infection with fever, sore throat, rhinorrhea, cough and breathlessness, which usually recover in 1–2 weeks.
- *Moderated cases* progressing to non-severe pneumonia with tachypnea but without severe hypoxia or danger signs and SpO_2 ranging between 90–94% in room air.
- *Severe COVID* cases develop severe pneumonia with *danger signs,* e.g. inability to breastfeed or drink, grunt-ing, severe lower chest in drawings, cyanosis, lethargy, somnolence, or *organ dysfunction* with ARDS, septic shock, coma and/or seizures and MODS.

Diagnosis: RT-PCR test to detect presence of SARS-CoV-2 nucleic acid from nose and throat swab is the gold standard for diagnosis, though the sensitivity varies from 60–70%. Rapid antigen test may be used in symptomatic cases (only) with sensitivity of 40–50%, if RT-PCR is not available. HRCT of the chest is not recommended for

diagnosis in children. However, Chest X-ray is required in cases with lower respiratory symptoms to exclude other cases.

Moderate to severe cases with COVID-19 need monitoring for inflammatory markers, e.g. CRP, procalcitonin, interleukin (IL_6), TNF-α, D-dimer assay, etc.

Management: Immediate swab collection (preferably nasal) is recommended in all suspected cases for diagnosis with RT-PCR or RAT (if symptomatic), along with initiation of infection prevention control measures, e.g. isolation, hand hygiene, use of personal protective equipment (PPE), safe waste management and disinfection of equipment as per guidelines. Further management depends on the severity of disease as follows:

Mild cases can be managed at home with symptomatic treatment with paracetamol and adequate feeds/fluids, without antibiotics or antiviral drugs. Parents should be counseled about COVID-appropriate behavior, watch for danger signs and report in cases of worsening.

Moderate cases with non-severe pneumonia must be hospitalized with:

- Oxygen therapy with nasal cannula (<4 L/min) or face mask (<6 L/min) to maintain SpO_2 as 94–98%.
- Supportive therapy to ensure adequate nutrition as well as fluid and electrolyte balance.
- Antibiotics, *only* if there is a strong suspicion of bacterial infection
- Steroids, *only* if rapid deterioration and >5 days have passed since onset of disease.
- *Monitoring* for deterioration of clinical status (respiratory distress, hypotension) and SpO_2,
- Communication with parents to alleviating anxiety and ensure COVID-appropriate behavior.

Severe cases with severe pneumonia and *danger signs* or *organ dysfunction* must be transferred to intensive care unit for continuous monitoring and managed with:

- Oxygen therapy with targeted saturation of 94–98%, using high-flow nasal cannula or HFNC (2 L/kg/min) or non-rebreathing mask or NRBM (10–15 L/min) to provide ~100% FiO_2.
- Ventilatory support using low tidal volume (4–8 ml/kg) with optimum positive end-expiratory pressure (PEEP) to keep P plateau <28 cm H_2O and driving pressure <15 cm H_2O. Use of cuffed endotracheal (ET) tube, in-line suction with minimal disconnection of ventilator circuits and early-proning should be considered in children with severe ARDS.
- Supportive therapy to ensure adequate nutrition as well as fluid and electrolyte balance. Children with shock must be managed with isotonic crystalloid boluses, inotropes and hydrocortisone (IV 2–4 mg/kg/24 hours) for catecholamine-resistant cases, if they are not on steroids. Fluid restriction may be needed in cases with ARDS/MODS.
- Empiric antibiotics, as per the hospital policy after collection of blood cultures.
- Steroids if >5 days have lapsed since the onset of symptoms with a increasing oxygen demand on HFNC, NRBM, non-invasive ventilation, invasive ventilation, or extracorporeal membrane oxygenation with Dexamethasone 0.15 mg/kg (maximum 6 mg) or Methylprednisolone 0.75 mg/kg OD (maximum 30 mg) for 5–7 days.
- Antivirals, e.g. R*emdesivir*: are not recommend in children but may be considered in hospitalized cases with emergent/increasing need for supplemental oxygen and: (a) age 16 years, (b) age 12 years with presence of the high-risk factors for severe disease, and, (c) age < 12 years in consultation with pediatric infectious disease specialist. A 3–5 day course of remdesivir (IV 5 mg/kg, to maximum 200 mg over 30–120 min followed by 2.5 mg/kg to maximum 100 mg daily single dose for 3–5 days) early in the disease has shown up to 87% reduction in deaths. There is no role for remdesivir beyond 10 days of infection, and can cause hepatic derangement.
- *Prophylactic anticoagulation* is not routinely recommended except in hospitalized children with: (a) strong personal/family history of venous thromboembolism, (b) indwelling central venous line with additional risk factors, (c) D-dimer >5 times of upper limit, and (d) children already on anticoagulation therapy. Low molecular weight heparin may be used as SC 0.5 mg/kg twice daily till discharge, provided there is no renal dysfunction cases with confirmed thrombosis need therapeutic anticoagulants, i.e. low molecular weight heparin as SC 1 mg/kg twice daily for ~12 weeks.
- Transfusions is indicated in children with < 7 g/dl with stable oxygenation and hemodynamics or <10 g/dl for those with refractory hypoxemia or shock.
- Intensive monitoring is needed in all cases for vital signs, inflammatory markers, blood gases and coagulation profile.

Management of the Newborn of COVID-19 Infected Mothers

All COVID positive deliveries should be conducted preferably in dedicated centers with standard infection containment protocols. IAP recommends that:

- Neonatal resuscitation should follow standard guidelines, using appropriate COVID-protective measures. Risk of postnatal infection in the baby may be reduced if mothers wear a triple-layer mask and adheres to respiratory etiquettes.
- Mother-infant dyads should be roomed-in and exclusive breastfeeding should be encouraged, regardless of maternal COVID-19 status.
- Kangaroo care is recommended for low birth weight neonates, regardless of the COVID-19 status of the mother or neonate.

- Symptomatic/neonates should be isolated with mother in a designated area, segregating suspect and confirmed cases.
- All forms of respiratory support are at risk of generating aerosols and HCWs must wear appropriate PPE, preferably in a negative air pressure area.
- Baby should be tested as follows:
  - *Within 24–48 hours*, if mother tested positive within 14 days before or 2 days after delivery. However rooming-in should not be delayed. Repeat testing is advised in asymptomatic newborns before discharge to prevent further transmission.
  - *Within 5th-7th day*, if mother or a family member/HCW dealing with baby is exposed to a COVID positive case,
  - *Immediately* in all symptomatic neonates, which may be repeated after 24–48 hours, if first report is negative despite strong suspicion.
- Neonates with asymptomatic or mild disease require no additional laboratory tests and stable mother/baby dyad may be discharged after 24–48 hours but must be followed-up for 14–28 days.
- All moderate to severe cases must be investigated and managed as per regular protocols with full infection control measures.

Multisystem Inflammatory Syndrome in Children (MIS-C)

MIS-C, also termed as pediatric inflammatory multisystem syndrome (PIMS), is a rare but life-threatening complication of COVID-19 infection in children, characterized by hyperinflammatory syndrome with involvement of multiple organs, usually seen after 2–6 weeks of acute infection.

Diagnosis of MIS-C depends on fulfillment of all six parameters included in WHO diagnostic criteria 2020 **(Table 10.42)**.

Investigation depends upon severity of disease and include:

- ***Tier-1 screening*** in all cases on admission including – CBC, CRP, ESR, liver and renal function tests, blood sugar, blood gas analysis, and SARS-CoV-2 serology/RT-PCR. Tier-one screen is considered as positive if both of these criteria are fulfilled:
  - CRP > 5 mg/dl and/or ESR > 40 mm/hour
  - *At least one of these*: Absolute lymphocyte count (ALC) < 1,000/µl, platelet count < 150,000/µl, Na < 135 mEq/L, neutrophilia, and hypoalbuminemia
- ***Tier-2 tests*** are required in cases positive on tier-one screening and include: ECG, echocardiogram, B-type natriuretic peptide (BNP), troponin-T, ferritin, lactate dehydrogenase, procalcitonin, interleukin 6 (IL-6), prothrombin time, activated partial thromboplastin time, D-dimer, and fibrinogen.

TABLE 10.42: WHO criteria for MIS-C (All Six)

- Age 0–19 years
- Fever > 3 days
- Clinical signs (any two)
  - Rash, bilateral non-purulent conjunctivitis, or mucocutaneous inflammation signs (mouth, hands or feet)
  - Hypotension or shock, cardiac dysfunction, pericarditis, valvulitis, or coronary abnormalities (including echocardiographic findings or elevated troponin/BNP)
  - Evidence of coagulopathy (prolonged PT/PTT, elevated D-dimer)
  - Acute gastrointestinal symptoms (diarrhea, vomiting, or abdominal pain)
- Elevated markers of inflammation e.g. ESR, CRP or procalcitonin
- No other obvious microbial cause of inflammation, including bacterial sepsis, toxic shock syndromes or tropical infectious diseases, i.e., malaria, dengue etc.
- Evidence of COVID-19 infection: positive RT-PCR/RAT or Serology or contact with an individual with COVID-19

(**BNP:** B-type natriuretic peptide; **CRP:** C-reactive protein; **ESR:** Erythrocyte sedimentation rate; **PT:** Prothrombin time; **PTT:** Partial thromboplastin time; **RAT:** Rapid antigen test)

A child is considered to have MIS-C only if: (a) both, Tier 1 and 2 tests are positive, and (b) other causes or tropical infections have been excluded. Isolated elevated COVID-19 antibodies are *not synonymous* with MIS-C.

Management: For management, MIS-C may be classified into four categories:

1. *MIS-C without shock;*
2. *MIS-C with shock* (tachycardia, hypotension, requiring fluid bolus 30 ml/kg, or inotropic support) or MODS with two or more organ involvement;
3. *MIS-C with Kawasaki phenotype,* meeting complete/incomplete Kawasaki disease criteria **(Table 24.11)**;
4. *MIS-C with refractory disease,* not responded to first-tier therapy with IVIG and low-dose steroids within 48 hours.

Important components of management include: (a) stabilization in terms of ventilation and perfusion, (b) treatment of organ dysfunction, (c) anti-inflammatory therapy, (d) monitoring for disease progression, and (e) long-term follow-up for complications.

- ***Anti-inflammatory therapy*** to reduce tissue inflammation or prevent progression of myocardial dysfunction usually includes: IVIG (2 gm/kg maximum 100 gm) infusion over 8–12 hours along with low-dose IV Methylprednisolone (2 mg/kg/day), slowly switching to PO prednisolone and tapered over 2–3 weeks. While only Methylprednisolone (without IVIG) is enough in cases without shock, oral low-dose Aspirin (PO 3–55 mg/kg/day) must be added in those with Kawasaki phenotype.

In children with refractory MIS-C despite above treatment, IV/SC Anakinra (>4 mg/kg/day) can be

used after expert consultation. *Infliximab/tocilizumab* are not recommended in children.

- ***Anticoagulation:*** MIS-C with documented thrombosis, ejection fraction < 35%, coronary artery Z score ≥ 10 or giant aneurysm with diameter > 8 mm need anticoagulation with low molecular weight heparin SC 1 mg/kg/dose (0.75 mg/kg/dose in <2 months) for 2 weeks after discharge. Low-dose aspirin (PO 3–5 mg/kg/day; max 80 mg/day) should be used if platelets >80,000/µl and continued till normal coronary arteries are confirmed at 4 weeks after diagnosis.

Outcome: Mortality rate is 1–2%, higher in cases with delayed diagnosis/treatment. Late complications include coronary artery aneurysm (25%), cardiac dysfunction, renal involvement and systemic thrombosis.

10.26 INFLUENZA

Influenza is a highly contagious viral illness of respiratory tract with seasonal outbreaks (seasonal influenza) and intermittent pandemics (pandemic influenza). *Seasonal influenza* is common in winter season and outbreaks tend to subside after 4–6 weeks with low morbidity and mortality.

Pandemic influenza refers to particularly contagious strains of virus that spread rapidly to create a worldwide pandemic. Latest global pandemic by novel influenza strain (H1N1) was originated in USA and initially affected pigs (Swine flu). India was affected soon after in 2009, though it has gradually weakened now with development of herd immunity.

Etiology: Influenza is a large RNA virus of family Orthomyxoviridae, with three major serotypes affecting humans—A, B, and C. While all pandemics have been caused only by serotype A, seasonal outbreaks are usually due to A and B serotypes. Type C virus is responsible for sporadic and mild upper respiratory tract infections.

Serotype A is further classified on the basis of two surface proteins—hemagglutinin (HA) and neuraminidase (NA) and strains are named on the basis of the combination of HA and NA proteins, e.g. H1N1, H2N2, H3N2, etc.

On-going global pandemic has been caused by H1N1 infection, though seasonal outbreaks due to H3N2 serotype B infections are common.

Epidemiology of influenzae virus is interesting, as prevalent serotypes during outbreaks are known to change every year, due to minor antigenic changes following point mutations, termed *antigenic drift,* seen in both A and B serotypes. Infrequently, subtypes changes dramatically due to reassortment of viral gene segments, resulting in emergence of novel subtypes by the process termed *antigenic shift,* seen only in serotype A.

Pathogenesis: Human influenza virus is usually transmitted as a droplet infection from the infected host and enters the host cells through specific cell-surface virus receptors, mostly located in upper respiratory tract. In usual cases of seasonal influenza, viral replication remains limited to upper respiratory tract, while extension to lower airways and lung parenchyma contributes to more serious illness with pneumonia and ARDS. Each infection leaves behind the strain-specific immunity, but re-infections due to similar strains are common due to antigenic drifts.

Pathology involves direct tissue damage as well as immune-mediated inflammatory damage, due to release of pro-inflammatory cytokines, e.g. IL-6 and interferon. While direct viral damage is essentially confined to upper respiratory tract or airways, pneumonia, ARDS and systemic damage is usually caused the *cytokine storm*. Secondary bacterial pneumonia is common.

Clinical spectrum: *Season influenza* is more common in younger population, usually presenting as *influenza like illness* (ILI). Severe disease or mortality is rare except at extremes of age.

Influenza-like illness (ILI) usually begins as a non-specific respiratory viral illness after an incubation period of 1–3 days (maximum 7 days), with fever, sore throat, cough, nasal congestion, malaise headache, myalgia and loss of appetite. Nausea, vomiting and diarrhea may also develop. Most cases recover spontaneously within a week. Over 1/3rd of infections are asymptomatic.

Complications are rare except in high-risk cases, e.g. young infants or those with cardio-respiratory disease, hemoglobinopathies and immunocompromised states; and include acute hemorrhagic pneumonia, myocarditis, myositis, toxic-shock syndrome and rarely, neurological complications including Guillain-Barré syndrome.

Diagnosis must be suspected on epidemiological and clinical considerations. Confirmation usually depends on RTPCR, though rapid diagnostic tests are available with poor sensitivity (10–80%) but higher specificity (95–100%). Specimen for laboratory diagnosis must be obtained by multiple swabs from nasopharynx, throat or trachea and must be transported in specific liquid media with reverse cold-chain.

Viral cultures are possible and serodiagnosis with fourfold rise in specific neutralizing antibodies may be used for epidemiological studies.

Management depends on categorization of cases according to the severity of illness and a risk-based approach for home isolation, testing, treatment and hospitalization has been recommended by Government of India 2015, updated 2022 **(Table 10.43)**, some important steps in the management include:

a. Category A cases must be managed at home with isolation measures and supportive therapy including bed rest, adequate hydration and antipyretics, e.g.

TABLE 10.43: Categorization, diagnosis and management of seasonal influenza (Governement of India Guidelines 2015)

	Category			
	A	***B1***	***B2***	***C***
Symptoms	Mild fever *and* cough/sore throat *with/without* bodyache, headache, diarrhea, vomiting	***Category A with*** High fever + severe sore throat	***Category A with*** High-risk group, e.g. • Children with risk factors* • Pregnancy • Age >65 years	***Category A or B with*** Breathlessness, chest pain drowsiness, hypotension, hemoptysis, cyanosis ***Red-flag signs (children):*** Somnolence, poor feeding, seizures, breathlessness worsening of underlying condition
Diagnostic testing	No	No	No	Yes
Management	Home isolation No Oseltamivir	Home isolation Oseltamivir		Hospitalization Oseltamivir

***Risk factors:** Underlying lung disease, heart disease, liver disease, kidney disease, blood disease, neurological disorders, cancer, diabetes, HIV/AIDS, long-term steroid therapy

paracetamol. Aspirin should be avoided due to potential risk of Reye syndrome. All home managed cases should be reviewed after 24–48 hours for any change in the severity. Antibiotics may be used, if required as per community-acquired pneumonia guidelines.

b. ***Category B cases*** can also be managed at home, like category A, but with antiviral therapy without viral testing, discussed below.

c. ***Category C cases*** should be hospitalized and managed in isolation with infection control measures, along with fluid and electrolyte therapy, parenteral nutrition, oxygen/ventilatory support, cardiovascular support and antibiotics for secondary infection.

Antiviral therapy with *PO Oseltamivir* for 5 days is indicated only in category B and C disease and should be started preferably with 48 hours of the onset of symptoms, as follows:

- *Infancy age-wise:* <3 months: (12 mg BD), 3–5 months: (20 mg BD); 6–11 months (25 mg BD)
- *Post-infancy weight-wise:* <15 kg (30 mg BD), 15–23 kg (45 mg BD), 24–40 kg (60 mg BD) and >40 kg (75 mg BD).

Alternative therapy with other neuraminidase inhibitors, e.g. zanamivir and peramivir, is not approved in children <5 years.

Prevention involves general measures to prevent spread of airborne infections and vaccination of high-risk cases. *Chemoprophylaxis* or presumptive treatment with Oseltamivir, in close household contacts has been used but generally not recommended in children.

IAP recommends influenza vaccine to all children from 6 months to 5 years of age and to high-risk children beyond this age including those with – chronic cardiac, pulmonary (excluding asthma), hematologic, renal (including nephrotic syndrome) and liver disease and diabetes mellitus, and immunodeficiency states. Currently available influenza vaccines are inactivated trivalent or Quadrivalent vaccines containing WHO recommended strains. All of them include H1N1 strain **(Fig. 9.2.2)**. Two doses of vaccines are recommended in the first year (after 6 months of age), followed by single dose annually before the onset of season.

Some other influenza-like illnesses (ILI) are as follows:

Rhinovirus infections: Although no age is immune, these infections are more common in young children and during winter or late summer season.

Clinical spectrum: Apart from *common cold*, the commonest manifestation (Ch 16.5.1), rhinoviral infections are associated with—(a) pneumonia in very young children, (b) acute asthmatic exacerbations in schoolchildren, and (c) chronic bronchitis in adults.

Treatment is symptomatic. Antiviral drugs do not seem to affect the course or severity of disease.

Parainfluenza viruses have four serotypes, of which seasonal outbreaks in summer/rainy season are usually due to type 1 and 2, while type 3 is endemic.

Clinical spectrum: Fever is typically *uncommon* in parainfluenza infections, which may present with: (a) acute laryngotracheobronchitis or croup (commonest cause), (b) acute bronchiolitis or bronchitis, and (c) persistent pneumonia in an immunocompromised host.

Treatment is symptomatic and specific antiviral therapy with *Ribavarin* is indicated only in immunocompromised children.

Adenovirus infections, usually due to three serotypes (1, 2, 5), are more prevalent in spring and winter season and many states have witnessed outbreaks of respiratory

TABLE 10.44: Clinical spectrum of adenoviral infections

• *URTI*	:	Pharyngitis, pharyngoconjunctival fever
• *LRTI*	:	Pertusis-like syndrome, pneumonia*
• *Eye*	:	Epidemic keratoconjunctivitis, follicular conj.
• *Cardiac*	:	Myocarditis, cardiomyopathy
• *GIT*	:	Acute diarrhoea, intussception
• *Hepatic*	:	Reye's-like syndrome, hepatitis*
• *Renal*	:	Hemorrhagic cystitis, interstitial nephritis*
• *CNS*	:	Chronic meningoencephalitis*

*in immunocompromised host only.

adenoviral infections in 2022–23, often indistinguishable from influenza or COVID-19 infections.

Clinical spectrum of these infections is very wide **(Table 10.44)**, the commonest being acute upper respiratory or conjunctival infections. Adenoviruses are most common cause of follicular conjunctivitis and epidemic keratoconjunctivitis.

Pharyngoconjunctival fever is a distinct presentation of adenoviral 3 infection, characterized by high fever, pharyngitis, conjunctivitis and cervical lymphadenopathy, lasting for 3–5 days.

Diagnosis, apart from viral studies, is supported by characteristic histology, i.e. dense lymphocytic infiltrates, destruction of bronchiolar epithelium, focal necrosis of mucosal glands, hyaline membrane formation and nuclear inclusion bodies.

Treatment is non-specific, although Ribavarin has been used on immunocompromised cases.

Prevention: A monovalent vaccine is available for US military recruits, but not for general use.

Respiratory syncytial virus (RSV) infections are most common in infancy, during winter season or as nosocomial outbreaks.

Clinical spectrum: RSV infections are commonest cause of: (a) acute bronchiolitis, apart from causing, (b) acute laryngotracheobronchitis (croup) and rarely, (c) pneumonia in high-risk infants, e.g. those with cyanotic heart disease, bronchopulmonary dysplasia or severe immunodeficiency.

Treatment is symptomatic, though Ribavarin aerosol therapy has been used with modest effect on RSV pneumonia in high-risk cases.

Prevention: No vaccine is currently available, but passive prophylaxis with '*Palivizumab*'—a monoclonal antibody, or *RSV-enriched IVIG* is recommended in high-risk cases with chronic cardiopulmonary disease.

10.27 RABIES

Rabies is an easily preventable but essentially fatal CNS infection that continues to be a major public health problem in India, accounting for >50% of total world cases. *Union territories of Lakshadweep and Andaman/Nicobar islands are free from this disease.*

Epidemiology: Rabies, caused by a neurotropic bullet-shaped RNA virus—*Lyssavirus seortype 1*, is primarily a zoonotic disease of warm-blooded animals. Man is accidentally affected after bite or licks of rabid animals. Dog is the commonest source (99%) in India, though rare cases may involve cats and wild canines, e.g. fox and wolves. Vampire bat-related rabies, common in USA and Latin America, is not reported from India. Barring few anecdotal reports, there is no asymptomatic carrier state and infection is essentially fatal in animals.

Virus is secreted in saliva of rabid animal only from 3–6 days before the onset of symptoms and hence, human infection is unlikely if the dog survives or remains well till 10 days of biting incident. Less than 50% bites by proven rabid animals result in human rabies. Human-to-human transmission, though theoretically possible, is extremely rare.

Pathogenesis: After inoculation with contaminated saliva, virus replicates in muscles or connective tissue. Unless neutralized at this stage by natural or vaccine induced immune response, it eventually and irreversibly gets attached to the peripheral nerves and development of disease becomes inevitable. Virus spreads centripetally within neuronal sheaths to CNS, mainly involving brainstem, basal ganglia, thalamus and hippocampus, but *sparing* cerebral cortex (no loss of consciousness).

Neuronal destruction at brain-stem level, including inhibitory neurons to nucleus ambiguous that controls inspiration, is responsible for classical presentation of hydrophobia and inspiratory muscle spasms. Following CNS infection, virus also descends centrifugally along the nerves to distal muscles, skin and saliva.

Clinical manifestations: Incubation period is extremely variable, ranging from 4 days to 7 years (usual: 20–60 days), being *shorter* in children, facial bites and after severe mauling. Clinical progression is also variable, but may be divided into:

- ***Prodromal phase*** (2–10 days), with—(i) pain, pruritus or paresthesias at wound site, (ii) mental changes, e.g. apprehension, anxiety or agitation and (iii) non-specific symptoms, e.g. mild fever, headache, vomiting, etc.
- ***Acute neurological phase*** (2–21 days) is of furious (80%) or paralytic (20%) variety, characterized by:
  - *Pathognomonic hydrophobia or aerophobia*, i.e. reflex spasms of pharyngeal and neck muscles, during swallowing, wind-movement, etc.
  - *Intermittent bizarre hyperactivity* or combative activity in furious variety, with intervening lucid periods and typical apprehensive appearance.
  - *Ascending asymmetrical flaccid paralysis*, in paralytic variety.
- ***Terminal phase***, characterized by increasing frequency of unprovoked spasms, opisthotonus, labored

breathing, hypoxic coma and ultimately, cardiorespiratory arrest. Death is inevitable, though a few unconfirmed survivors have been reported among those who were vaccinated *before* the exposure.

Diagnosis is mainly clinical, based on history of dog bite and typical presentation. Antemortem laboratory diagnosis, though rarely needed, is possible by:

- Antigen detection using fluorescent antibodies (immunofluorescence) in corneal scrapping, skin biopsy from hairline or saliva, and
- Presence of neutralizing antibodies >100 IU/ml in CSF or serum after 10th day of illness.

Presence of *Negri bodies*—a cytoplasmic inclusion containing clumped viral nucleocapsid in neurons, confirms the diagnosis after death. However, absence of these bodies does not exclude the diagnosis.

D/D of *furious rabies* includes viral encephalitis (loss of sensorium), tetanus (trismus) and hysteria; while *paralytic variety* may be confused with other causes of acute flaccid paralysis, e.g. Guillain-Barré syndrome, poliomyelitis and post-rabies vaccine encephalomyelitis.

Management is non-specific, unrewarding and aims to ally suffering in terminal phase. Important steps include:

a. Isolation in a quiet room, protected from external stimuli, e.g. light, sound, etc. to prevent spasms,
b. Sedatives and muscle relaxants to reduce anxiety/spasm,
c. Parenteral hydration and nutrition, and
d. Cardiorespiratory support, till possible.

Since these cases are potentially infectious (from a week before the onset of symptoms to death), self protection of health staff by gloves, masks, etc. And proper disposal of contaminated fomites and biological fluids is advisable. *However, man-to-man transmission is virtually unknown*.

Prevention of rabies may be divided into:

- ***Primary prevention*** by
  - Avoidance of contact with potentially rabid dogs,
  - Vaccination of pets, and
  - ***Pre-exposure prophylaxis*** (PrEP) of occupation-exposed personals, e.g. animal handlers, veterinarians, forest workers, etc. with two doses of single site IM or two-site ID tissue-culture vaccine (IM 1.0 ml/ID 0.1 ml) on day 0 and 7 are recommended by WHO and IAP. However, total three IM/ID doses are used for pre-exposure prophylaxis in national rabies prophylaxis program, given on day 0, 7, and 21/28.

    PrEP is generally not required in children, though IAP recommends it after discussion with parents, in view of higher risk of exposure in Indian children.
- ***Secondary (post-exposure) prophylaxis*** is the key of survival after potential rabid bite, discussed below.

MANAGEMENT OF DOG BITE

Important steps in the management of a dog bite include: (a) local wound care, (b) evaluation of exposure, (c) passive immunization with anti-rabies immunoglobulin and (d) active immunization.

Step I. Local wound care is essential in all cases presenting soon after bite, to kill the virus by mechanical and virucidal action. Proper wound care reduces risk of rabies by 80% and includes:

- *Cleaning*, i.e. immediate washing of wounds/licks and adjoining area with soap and running-water for at least for 5–10 minutes.
- *Irrigation of deep wounds* with virucidal agents, e.g. povidone iodine or alcohol. Cauterization with carbolic acid is no longer recommended.
- *Avoidance of suturing*, as further trauma increases local vascularity and facilitates spread of virus in deep tissues. If essential, it should be deferred as long as possible and done after local infiltration of Rabies immunoglobulin (RIG).

Step II. Evaluation of exposure: A dog bite is considered as potential risk for rabies if:

- *Bite by* a stray, domestic but unvaccinated, untraceable, or abnormally aggressive dog,
- *Bite was unprovoked*, and
- *Severity of bite* involved actual bite/scratch with skin penetration *or* licks over previous scratch, abrasion, mucous membrane or open wound.

A classification system, depending on the severity of exposure and risk of disease is frequently used to decide the need for post-exposure prophylaxis **(Table 10.45)**.

Step III. Passive immunization aims to prevent immediate attachment of virus to the nerve endings, till vaccine-mediated immunity develops.

Presently, there are two options for passive immunization-human rabies immunoglobulin (HRIG), and

TABLE 10.45: WHO categories for exposure risk and post-exposure ARV prophylaxis

Category	*Type of contact*	*Intervention*		
		Local	*HRIG*	*ARV*
I	Licks on unbroken skin Touching/feeding of animals	Yes	No	No
II	Nibbling of uncovered skin Minor scratches, no bleeding Licks on broken skin	Yes	No	Yes*
III	Single/multiple transdermal bites Contamination of mucus memb with saliva (licks)	Yes	Yes	Yes*

HRIG: Human rabies immunoglobulin; **ARV:** Anti-rabies vaccine
*ARV may be discontinued after 10 days (observation period), if animal remains asymptomatic or killed humanly and found negative for rabies on laboratory workup

monoclonal antibodies, e.g. Rabishield® or Twintab®. Equine rabies immunoglobulin (ERIG) are no longer recommended due to serious side effects.

WHO as well as IAP encourages use of monoclonal antibodies instead of RIG due to easier availability, lower cost, lesser side effects, and possibly greater effectiveness. These antibodies bind ectodomain of G glycoprotein of the virus to block its entry into neighboring cells, both products (Rabishield® or Twintab®) are nearly comparable in efficacy and cost. Rabishield® is available 40 IU/ml, with recommended dose of 3.3 IU/kg, Twinrab® is available as 300 or 600 IU/ml with recommended dose of 40 IU/kg.

Passive immunization, is most effective when given immediately after exposure, but may be given till 7th day of first vaccine dose, by which the active immune response to vaccine is expected to develop. These antibodies must be infiltrated locally at the time of the first vaccine dose or upto 7th day of first dose. If the calculated dose is insufficient to infiltrate all the wounds, it may be diluted in sterile normal saline to get a volume enough to be infiltrated around all the wounds.

Step IV. Active immunization: Two types of anti-rabies vaccines are available in India—(a) *cell-culture vaccines*, e.g. purified chick-embryo vaccine (PCEV), human diploid-cell vaccine (HDCV), purified Vero-cell vaccines (PVRV), and (b) embryonated egg-based vaccines, e.g. *purified duck-embryo vaccine* (PDEV). All are safe, stable and equally effective with >99% protective efficacy. All these vaccines contain minimum 2.5 IU antigen/dose, available in lyophilized form with sterile water as diluents and must be stored at 2–8°C. Side effects are rare and insignificant, e.g. local pain, fever or malaise, though a few cases resembling Guillain-Barré syndrome are reported with HDCV. PCEV should be avoided in children with history of egg-allergy.

Post-exposure prophylaxis (PEP): All vaccines are given as 1.0 ml/dose (0.5 ml for PVRV) over deltoid or anterolateral thigh region as total four doses intramuscularly on *day 0, 3, 7 and 14–28, as recommended by WHO and IAP,* though 5 doses (0, 3, 7, 14 and 28 days) are used in National Rabies Prophylaxis Programme.

Intradermal (ID) vaccination is cost-effective alternative to intramuscular vaccination due to lesser dose requirement (0.1 ml/dose), when large number of vaccines are available simultaneously, as in major public health centers. Government of India provides ID vaccination (under National Rabies Control Programme, given as two ID doses on both deltoids on days 0, 3, 7 and 28). ID vaccination is not recommended for individual practice or in immunocompromised cases.

Re-exposure prophylaxis in previous vaccinated children needs only two IM/ID doses on *day 0 and 3*, if the last dose was received 3 months back. Rabies immunoglobulin is not required in these cases.

10.28 PEDIATRIC HIV INFECTION

Human retroviral infections include two distinct groups: *human T lymphocytic viruses* (HTLV-1 and 2) and *human immunodeficiency viruses* (HIV-1 and 2). HTLV infections have been found associated with leukemia, lymphomas, myelopathy and tropical spastic paraparesis; while HIV infections are responsible for the current AIDS pandemic, discussed here.

Since the first case reports in 1981, HIV/AIDS pandemic has been the major global challenge to recent medicine. In India, first case, a sex worker, was reported from Madras in 1986 while first HIV-infected child was diagnosed in Mumbai in 1987.

Magnitude of problem: While HIV/AIDS pandemic began from North America and Africa, it spread rapidly throughout the world. In recent years, infection is decreasing due to social and therapeutic interventions, though continues to be a major public health problem in India.

Currently ~38 million people are estimated to living with HIV/AIDS (PLHA) globally, including ~23 lakhs in India (NACO 2021) pediatric HIV/AIDS infection in India accounts for <5% of total cases (~76000 children <15 years, NACO 2021) with a declining trend in recent years due to effective perinatal transmission prevention program. *Children living with HIV* (CLHIV) is the new term used instead of HIV infected children.

Virology: Causative virus was isolated by *Luc Montagnier* in France and *Robert Gallo* in USA during 1982–83, but named as Human immunodeficiency virus or HIV in 1986.

Two distinct but structurally related types of HIV virus have been identified in human disease—*HIV-1*, responsible for >90% cases; and *HIV-2*, which is less common (<3%) and associated with less severe disease. Dual infections occur in ~5–7% cases.

Structurally, HIV virus includes a *central cylindrical virion core*, surrounded by two major viral *envelope proteins*—gp120 (outer layer) and gp41 (inner layer). Virion core contains a single strand RNA (viral genome) and various structural proteins encoded on this genome, e.g. p24, reverse transcriptase, integrase, etc.

Modes of transmission: While virus is excreted in various body fluids, it is extremely labile in external environment and adult infection is acquired by direct contact with infected blood during—(a) homo/heterosexual intercourse, (b) blood product transfusions, (c) shared IV needles in drug users, or rarely, (d) occupational exposure in health care workers.

Unlike adults, >95% of HIV infection in children are acquired perinatally (vertical transmission) from infected mothers. Rare horizontal modes of infection in children

TABLE 10.46: Risk factors for perinatal HIV transmission

Maternal factors:
- Severity of infection
  - Symptomatic infection (AIDS)
  - Low CD4 count
  - High viral load
- No anti-retroviral prophylaxis/treatment
- Other less important factors
  - Infection with HIV1 viral type
  - Primary infection during pregnancy
  - Co-existing vitamin A deficiency

Obstetrical factors:
- Postmaturity
- Premature rupture of membranes/chorioamnionitis
- Prolonged labor or interventions, e.g. forceps
- Vaginal delivery

Post-natal factors:
- Breastfeeding
- Maternal breast/nipple problems

include-blood product transfusions, e.g. in thalassemics/hemophiliacs, sexual abuse and very rarely, IV drug abuse in adolescents.

Perinatal transmission: All infected mothers do not transmit infection to their babies with overall risk of ~30–40% in absence of any interventions, depending on many maternal and obstetric factors **(Table 10.46)**. Perinatal mother to child transmission may be acquired as:

- *Peripartum infection* (~60%) during the passage of baby through infected vaginal canal, is the commonest mode of infection, specially in instrumental deliveries.
- *Transplacental infection* (~25%) is rare before 20 weeks of gestation and usually occurs in last trimester due to degenerative placental changes, thus the risk being directly proportional to duration of gestation.
- *Postpartum infection (~15%)* via breastfeeding usually occurs in early stages of breastfeeding, when breast/nipple problems are common. Although ingested virus is usually destroyed in gut, it may enter baby's circulation through oral/intestinal mucosal lacerations, common in newborns.

Pathogenesis of HIV infection revolves around the *special* affinity (tropism) of virus towards human cells bearing CD_4 markers on their surfaces, i.e. (a) immunological cells, e.g. T-lymphocytes, monocytes and macrophages, (b) neuronal cells, e.g. dendritic cells, microglia, astrocytes, etc. and (c) others, e.g. placenta, skin and deeper tissues. Natural history of HIV infection may be divided into four phases:

a. **Primary infection:** Immediately on entry, the virus infects dendritic neuronal cells (in skin), circulatory CD_4 lymphocytes and gut-associated lymphoid tissue, and replicates rapidly, leading to: (a) destruction of the infected cell *(cytopathic effect)*, (b) further infection of other cells and (c) transport of infected cells to regional lymphoid tissues. This phase is associated with significant decline in CD_4 cells with inversion of CD_4/CD_8 ratio.

b. **Initial viremia** after 1–3 weeks with rapid increase in virus infected cells, leads to: (a) dissemination to other tissues, e.g. CNS, (b) rapid fall in CD_4 counts, and (c) reactive lymphoid hyperplasia, clinically presenting as *acute retroviral syndrome* (flu-like illness) for 2–4 weeks. During above two phases, plasma virus may be detected by culture, antigen tests or molecular methods (PCR) but antibody-tests are negative. (*Window period*).

c. **Latent period** due to development of vigorous HIV-specific humoral/cellular immunity after 4–6 weeks of primary infection, which *limits the viral replication but does not eliminate the virus*. During this phase, CD_4 counts recover and viral load is substantially reduced but ELISA test becomes positive. However, substantial viral population survives in lymph nodes and neuronal cells, which act as *sanctuary* for residual infection. In acquired infections of adults, this period may be as long as 10–15 years.

d. **Progressive immunodeficiency** due to slow but continued viral replication within various body cells with CD_4 markers, leads to development of AIDS-indicator illnesses, e.g. opportunistic infections (OIs), HIV encephalopathy, etc. Progression from HIV infection to disease depends on many known and unknown factors, most important being the balance between T-helper (CD_4) and killer/suppressor cell (CD_8) population and ability of the lymph nodes to limit the infection.

Natural course of perinatal infection in children is faster than in adults due to:

- Higher viral load due to sustained exposure in intrauterine, peripartum and postnatal period.
- Large and expanding CD_4 cell-pool in growing baby, facilitating viral multiplication
- Relative immaturity of HIV-specific immune responses, to limit the infection

Consequently, HIV infection in children progresses rapidly, with *shorter latent period* and development of symptomatic disease within few months or years. If not diagnosed and treated, 35% of HIV infected children die by first birthday and 60% by three years.

Clinical presentation of HIV infection in perinatally infected children depends on the age, immune status, presence of co-existing diseases, e.g. malnutrition and tuberculosis and probably, the timing of infection. Four recognized variations in clinical course of perinatal infection are:

- ***Early progressors*** (50–60%), which present in early infancy with severe bacterial illnesses or *Pneumocystis*

carinii pneumonia (PCP) and usually do not survive beyond infancy. These children are probably infected *in utero*, during early gestation.

- ***Intermediate or slow progressors*** (30–40%), which present in late infancy or soon after, with failure to thrive, chronic diarrhea, recurrent infections, encephalopathy and opportunistic infections (OI). These children are probably infected in late gestation or during vaginal delivery.
- ***Long-term survivors or non-progressors*** (5–15%), presenting beyond 3–5 years of age with signs of relatively preserved immunity, e.g. lymphadenopathy, hepatosplenomegaly, lymphocytic interstitial pneumonitis (LIP) and chronic parotitis.
- ***Elite controllers*** (<1%) which are least common but most fortunate children, who remain asymptomatic with undetectable viral load (< 50 copies/ml) without antiretroviral therapy.

Clinically, HIV infection in children may begin as non-specific illnesses with abnormal course or with typical AIDS indicator illness. Some important presentations are as follows:

- **Failure to thrive** is the commonest presentation in Indian children. However, *Wasting syndrome*, seen in adults, is not as common in children and diagnosis requires presence of three features: (a) failure to thrive, (b) chronic diarrhea/enteropathy, and (c) prolonged pyrexia.
- **Respiratory manifestations** are second commonest manifestations, presenting as: (a) recurrent/persistent upper respiratory infections, e.g. sinusitis or otitis media, (b) recurrent/serious lower respiratory infections, e.g. bacterial/PCP pneumonia, or (c) chronic lung disease, e.g. tuberculosis or lymphocytic interstitial pneumonitis (LIP).

  P. carinii (P. Jirovecii) pneumonia (PCP) is the commonest OI in infants and ~70% cases present <1 year of age with acute/sub-acute onset of fever, respiratory distress and progressive hypoxemia. X-ray findings vary from diffuse interstitial infiltrates or ground-glass appearance in early disease to nodular lesions in late stages.

  Lymphocytic interstitial pneumonitis (LIP) is a common chronic lung disease in HIV-infected children, usually without significant immunosuppression. An association with Epstein-Barr virus has been postulated. Most cases present in 3–5 years age group, with insidious cough, dyspnea, wheeze, progressive hypoxemia and digital clubbing (d/d bronchiectasis). Confirmation requires lung biopsy, though chronic lung disease, X-ray findings (diffuse lace-like reticulonodular pattern) and exclusion of tuberculosis point towards the LIP.
- **GIT manifestations** vary from: (a) upper GIT manifestations, e.g. oral/esophageal candidiasis, recurrent herpes stomatitis, (b) lower GIT manifestations, e.g. chronic diarrhea, and (c) accessory manifestations, e.g. chronic parotitis, hepatosplenomegaly and coexisting hepatitis.

  Chronic diarrhea, the commonest GIT manifestation, may be due to: (a) HIV *enteropathy*, i.e. primary HIV infection of gut, (b) common infections, e.g. bacterial, viral, giardia, amebiasis, etc., (c) local gut OIs, e.g. candidiasis, Cryptosporidium, Isospora, etc., and (d) systemic OIs, e.g. CMV, *Mycobacterium avium intracellulare* (MAC), etc. Frequently associated with failure to thrive (*Wasting syndrome*), it may accelerate progression of HIV disease.

  Candidiasis, the commonest OI of GIT, present as persistent oral or esophageal thrush, dysphagia due to esophageal candidiasis, or chronic diarrhea due to intestinal candidiasis.
- **CNS involvement** may be due to p*rimary* HIV encephalopathy or *secondary to OIs, e.g.* bacterial meningitis/abscess, tubercular meningitis, and toxoplasmosis. Unlike adults, cryptococcal meningitis and CNS tumors are less common in HIV-infected children.

  HIV encephalopathy develops in >40% survivors beyond infancy due to direct viral infection and cytopathic damage to neuronal cells and usually presents in 2nd year of life with: (a) regression of milestones/cognitive function, (b) microcephaly, and (c) progressive symmetrical spastic paresis with gait abnormalities. cerebral atrophy and basal ganglia calcification are common on neuroimaging.
- **Skin manifestations** are seen in ~30% cases at some time, and include recurrent impetigo, severe scabies, molluscum contagiosum, herpes simplex or varicella-zoster infections. *Kaposi sarcoma*, a common skin tumor in HIV-infected adults, is extremely rare in children.
- **Hemato-oncological manifestations** include moderate/severe anemia, thrombocytopenic purpura and malignancies, e.g. non-Hodgkin's or CNS lymphomas.
- **Opportunistic infections (OIs)** are hallmark lesions in AIDS, though causative pathogens vary with the severity of immunosuppression and CD_4 counts **(Table 10.47)**. Four commonest OIs in Indian children are severe/recurrent bacterial infections, candidiasis, PCP and tuberculosis.

  Tuberculosis is the commonest co-infection in HIV-infected children, present in ~40–50% cases. Disseminated/extrapulmonary tuberculosis is more common than pulmonary disease. Diagnostic confirmation may be difficult due to false-negativity of tuberculin test in immunocompromised state, non-specific X-ray findings, and usually AFB-negative disease in children. A tuberculin test of >5 mm is considered as positive in HIV-infected children.

TABLE 10.47: Common OIs, according to CD_4 count

CD_4 count	*Common OIs*
>500	Rare
500–200	RBI, TB, Candida[1], HSV[1], VCZ
200–100	PCP, Toxoplasma, Candida[2], HSV[2]
100–50	CMV, Cryptococci
<50	MAC

[1]superficial/mucocutaneous disease [2]invasive disease,
RBI: Recurrent bacterial infections

- **Non-infective systemic lesions** are rare in children and include cardiomyopathy, nephropathy and hepatitis (usually due to co-HBV/HCV infection).

Diagnosis: Possibility of HIV infection should be suspected in children with:

- Known HIV infection or high-risk behavior in parents,
- History of multiple transfusions,
- High-risk for sexual abuse, e.g. street-children, and
- Presence of clinical indicators for HIV disease.

These cases require laboratory screening after appropriate pretest counseling of parents.

While many diagnostic tests are available for HIV infection, the choice differs according to the age of child.

Diagnosis of HIV in children >18 months rests on detection of IgG antibodies against HIV by ELISA/rapid tests as follows:

- Two positive HIV-antibody tests done sequentially using different principles/antigens but using same serum/plasma sample in a symptomatic child, ***or***
- Three positive HIV-antibody tests done sequentially using different principles/antigens but using same serum/plasma sample in an asymptomatic child. Indeterminate results (two positive and one negative test in asymptomatic child) must be tested again on a second sample after 14–28 days.

Currently used rapid tests detect both-HIV1 and HIV-2. Samples, which are reactive for both HIV-1 and HIV-2 or to HIV-2 with only one kit, need confirmation from a reference laboratory.

Other diagnostic tests, e.g. Western blot test, viral cultures and p24 antigen assays are rarely used in practice.

Diagnosis in children <18 months cannot rely on the antibody testing due to transplacental transfer of IgG antibodies from seropositive mother, which may persist till 6–12 months. Diagnosis in these cases rests on detection of total nucleic acid of virus by polymerase chain reaction (PCR-TNA). It is a qualitative test to both DNA and RNA, superior to the previously used DNA-PCR with high sensitivity (99%) and specificity (99%) after 6 weeks of age.

An infant is considered as HIV positive if two PCR tests are positive and HIV Negative if two PCR tests are negative, of which at least one is done after 4–6 months of age.

All perinatally exposed infants, born to a seropositive mother must be tested as per early infant diagnosis (EID) guidelines, recommended by NACO 2021, discussed later.

Presumptive diagnosis is rarely necessary at present due to wide availability of diagnostic facilities. However, in cases where the final confirmation is getting delayed due to some reasons, presumptive diagnosis can be made for the purpose of initiating ART provided: (a) child is HIV-antibody positive ***and*** (b) have *any of two of the following*: (a) oral thrush, (b) severe pneumonia, (c) severe sepsis, or (d) any AIDS indicator illness, e.g. PCP, cryptococcal meningitis, severe wasting, Kaposi sarcoma or extrapulmonary tuberculosis, etc.

Prevention of HIV infection in children largely revolves around prevention of perinatal or parent to child transmission (PPTCT) with four-pronged strategy: (a) Primary prevention to reduce the general HIV prevalence, (b) Prevention of unintended pregnancies, (c) Prevention of mother to child transmission, and (d) care and support to HIV positive mothers.

NACO guidelines 2021 recommends that:

- **Universal HIV testing of pregnant mothers with opt-out option:** *All pregnant women attending antenatal care must be offered HIV counseling and testing, with an opt-out option*, i.e. choice to refuse it. However, those who opt-out of HIV testing must be re-counselled to explore reasons for the same, address any misunderstanding and encourage to reconsider her decision. However, no mother should be tested without her consent.
- **Anti-retroviral therapy to HIV infected mothers:** All HIV-positive pregnant women including those presenting in labour and breastfeeding should be initiated on a triple-drug ART regardless of CD_4 count and clinical stage (Treat all), for preventing mother to child transmission and should continue lifelong ART. Preferred regimen for this purpose is PO *Tenofovir (300 mg) + Lamivudine (300 mg) + Dolutegravir (50 mg), once a day*. While it is important to obtain blood samples for CD4 count and baseline tests before initiating ART, initiation of therapy should not be delayed for want of results.

Rule of 95% includes that: (a) >95% pregnant mothers are registered with at least one antenatal care check-up, (b) >95% of pregnant women are tested for HIV, and (c) >95% of HIV positive pregnant women are on ART.

- **Antiretroviral prophylaxis to HIV-exposed baby,** as discussed later in section of management of a HIV-exposed infant.

TABLE 10.48: Universal safety precautions

Personal protection
- Handwashing with soap and running water
- Use of gloves/gowns and masks during procedures
- Use of long handle wet-mops and gloves by cleaners

Recyclables - disinfection
- *Gloves:* dip in 1% hypo* (20 min) before autoclaving
- *Linen:* Soak in 2–4% hypo* (30 min), before laundry
- *Instruments:* Heat sterilization for min 30 minutes

Waste disposal
- *Sharps:* Dispose in metal container, filled with 1% hypo*
- *Biomed waste:* Dispose in buckets filled with 4% hypo*
- *Spilt blood:* Cover with 4% hypo* (10 min) > mopping

Hypo: Sodium hypochlorite solution

Prevention of HIV infection also involves minimizing the risk of transfusion-related infections by appropriate screening of blood-products and preventing health-care facility exposures by observing universal safety precautions **(Table 10.48)**.

Management of HIV in children, for the sake of discussion, may be broadly divided into:
- Management of a HIV-exposed child
- Management of a HIV-infected child or child with advanced disease

Management of a HIV-exposed child, i.e. child born to a seropositive mother, while still awaiting confirmation of infection in him/herself, involves following components: (1) immediate care at birth, (2) infant feeding, (3) antiretroviral prophylaxis, (4) immunization and vitamin A supplementation, (5) cotrimoxazole prophylaxis, (6) growth and development assessment, (7) early infant diagnosis, and (8) regular follow-up and counseling.

1. **Immediate care at birth:** Care of HIV-exposed infants in delivery room should follow standard neonatal care including the following precautions:
   - Baby's mouth and nostrils should be wiped as soon as the head is delivered.
   - Baby should be handled with gloves until all blood/maternal secretions have been washed off.
   - Cord should be clamped soon after birth, and milking should be avoided. It should be covered with gloved hand and gauze before cutting to avoid blood splattering.
   - Initiate feeding within the first hour of birth according to the preferred and informed choice.
2. **Early infant feeding:** Feeding should be initiated within the first hour of birth in accordance with the preferred and informed choice of the mother.

   As the virus is excreted in breast milk, breastfeeding increases the risk of mother to child transmission by 15–20% and ideal intervention would be not to breastfeed the baby. However, this issue should be viewed in conjunction with potential risks of top feeding, e.g. diarrhea and malnutrition, as well as economical considerations. Risk of HIV transmission via breast milk can be minimized by interventions, e.g. antiretroviral therapy to all seropositive mothers and prophylaxis to their babies. *NACO guidelines 2021* recommend that:
   - All pregnant women should be counselled in antenatal period about advantages and risks of feeding options, i.e. exclusive breastfeeding (EBF) or exclusive replacement feeding (ERF), to assist in informed decision making.
   - EBF is the preferred option for first 6 months and should continue even when complementary feeding is initiated, till nutritionally adequate diet can be provided without breastfeeding and may continue till 24 months as in general population.
   - ERF is an option only if breastfeeding is not possible (maternal death, severe illness, twins) or in cases of individual mother's informed choice. However, AFASS criteria must be fulfilled in ERF cases (***a****cceptable,* ***f****easible, affordable,* ***s****ustainable and* ***s****afe*), in addition to the easy access to health services. Use of bottle for ERF should be strictly avoided due to risk of diarrhea.
   - Mixed feeding increases the risk of transmission and should be avoided at all cost. Top feeds are known to alter gut mucosal barrier, which may facilitate viral entry from breast milk. However, current evidence suggests that in continued presence of maternal ART, mixed feeding is also rendered safe and may be preferred over no breastfeeding at all. Hence, while EBF is still recommended during first 6 months, practicing mixed feeding is not a reason to stop breastfeeding in the presence of ART.
   - If mother plans to return to work, she can be reassured that shorter duration of breastfeeding is still better than never breastfeeding at all.
   - Complementary feeding should be started at 6 months with similar principles as for other children. However, HIV-infected children need additional 10% calories if growing well, 20–30% calories if having poor weight gain and 50–100% calories if having SAM.
3. **Antiretroviral prophylaxis to HIV-exposed baby:** *NACO guidelines 2021* recommends that all infants born to HIV-infected women must receive ART prophylaxis as follows:
   - ***Low-risk infant*** born to mothers with suppressed viral load (<1000 copies/ml) done any time after 32 weeks of gestation, should receive *single drug prophylaxis with Nevirapine* (NVP) for minimum 6 weeks. Syp NVP (10 mg/ml) should be given

a *single oral daily dose* of 15 mg <6 weeks of age (10 mg in infants <2.5 kg), 20 mg in 6 weeks–6 months of age, 30 mg in 6–9 months age and 40 mg above 9 months.

Syrup Zidovudine (ZDV), instead of NVP, is recommended till 6 weeks of age only in setting when NVP will not be effective, i.e. infant born to a mother: (a) with confirmed HIV-2/dual infection, (b) who had received single dose of NVP during earlier pregnancy/delivery, and (c) who is on PI-based ART due to treatment failure. Syp Zidovudine (10 mg/ml) should be given *twice a day* as 5 mg BD (<2000 gm), 10 mg BD (2000–2500 gm) and 15 mg BD (> 2500 gm).

- ***High-risk infants*** (all except as above including mothers not on ART/detected seropositive within 6 weeks of delivery) should receive *dual drug prophylaxis* with NVP and ZDV for minimum 6 weeks, in dose as above (if on exclusive replacement feeding) or 12 weeks (if on exclusive breastfeeding).

4. **Immunization and vitamin A prophylaxis:** HIV-exposed children may be infected or not infected. Even infected children are also unlikely to be severely immunosuppressed in early infancy. While live vaccines are generally contraindicated in immunocompromised states and immune response to may not be optimal in them, HIV-infected children are in fact more susceptible for infections and hence, in higher need of vaccinations. *NACO guidelines 2021* recommends that:

   All HIV-exposed infants should be immunized as per regular schedule, including vitamin A and live vaccines, e.g. BCG, MR and Rotavirus with following exceptions:

   - BCG, if not given at birth and baby has been confirmed as HIV-infected, should be delayed until ART has been started and the infant confirmed to be immunologically stable (CD4 >25%).
   - Measles containing vaccine (MCV) should not be given in HIV-infected children, only in presence of severe immunosuppression. An additional dose of MCV is recommended to HIV-infected children on ART following immune reconstitution (CD4 count >20%). A supplemental dose of MCV may also be considered in HIV-exposed or infected infants >6 months, who are not on ART but at a higher risk of measles.
   - Rotavirus vaccine is recommended to all HIIV-exposed infants, except in those with confirmed HIV infection with severe immunodeficiency.
   - Pneumococcal conjugate vaccine (PCV) should be given at 2, 4 and 6 months with booster at 12–15 months. In addition, HIV infected children >2 years of age should also be given pneumococcal polysaccharide vaccine (PPSV23), at least 8 weeks after the last dose of PCV.
   - Double-dose schedule for HBV is recommended in HIV-infected children due to poor seroconversion, along with frequent assessment of antibody titers and booster, if required.
   - Additional hepatitis A, varicella, influenza and meningococcal vaccines are recommended to HIV infected children, along with human papillomavirus vaccine in adolescents.

5. **Cotrimoxazole prophylaxis:** All HIV-exposed infants should get Cotrimoxazole prophylaxis against PCP with 5 mg/kg/d as single oral dose, starting from the age of 6 weeks till 5 years of age. PO Dapsone 2 mg/kg is the alternative drug in children with serious adverse reactions to Cotrimoxazole or G6PD deficiency. It may be discontinued at 5 years only child is in clinical stage I or 2 and CD count is >350 cells/mm^3 on two occasions, not more than 6 months apart.
6. **Growth and developmental assessment:** All HIV exposed children should be periodically assessed for growth and development as any other child, using standard reference tools.
7. **Early infant diagnosis:** NACO recommends use of PCR-TNA on a dried blood spot (DBS) sample of the infant for diagnosis of HIV-1 infection during infancy, **(Fig. 10.16)** with following considerations:
   - First PCR-TNA should be performed at 6 weeks of age (sensitivity is poor before 6 weeks due to window period). A positive test should be confirmed by repeating the same on a second DBS as soon as possible. However, a negative test should be repeated again at or after 6 months to exclude the infection, after pre-screening the child for HIV antibodies by a rapid test.
   - In a breastfed infant, due to continuing risk of transmission through breast milk, PCR-TNA should be conducted 6 weeks of age and then at 12 weeks after cessation of breastfeeding (or 18 months of age, whichever is later) to exclude the infection.
   - An infant is considered as HIV-positive, if two PCR tests are positive and HIV-negative if two PCR tests are negative, of which at least one is done after 4–6 months of age.
   - All infants, irrespective of the PCR results, should also be tested by ELISA/Rapid test at or after 18 months for confirmation.
   - An infant is considered as seroreverter, if born to a seropositive mother but has been HIV antibody negative by two tests at 6 and 18 months or one test at 18 months, with no other clinical or laboratory evidence of HIV/AIDS.

   Note: In infants >6 months, TNA-PCR is performed only if rapid test is positive as maternal

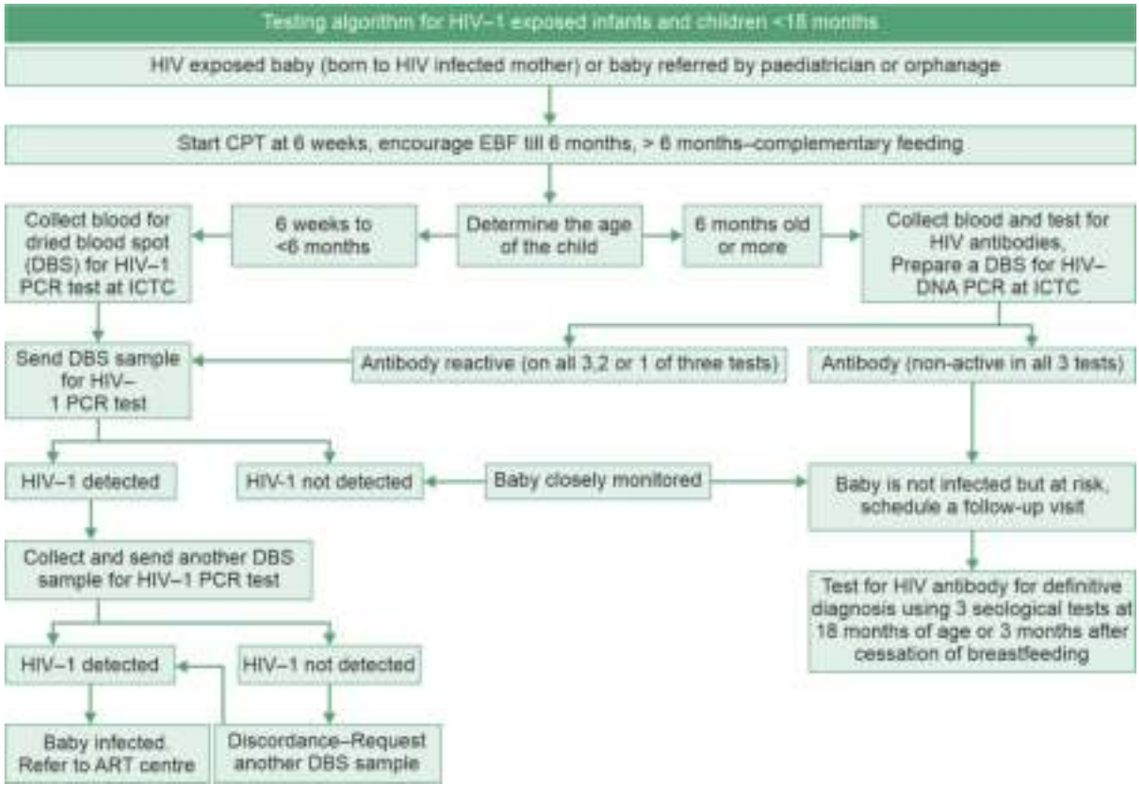

Fig. 10.16: Early infant diagnosis: Testing algorithm for HIV-1 exposed infants < 18 months.

antibodies disappear in 74% and 96% of HIV-uninfected exposed children by 9 and 12 months respectively. In a HIV-exposed child, who is antibody negative at 6 months of age, there are two situations:

- If the infant is not breastfed in the last 3 months, s/he is probably not infected and does not need TNA-PCR testing.
- If the infant continues to receiving breastfeeding, HIV antibody test should be repeated after 3 months of complete cessation of breastfeeding to rule out HIV infection.

All HIV testing should be provided following *five essential Cs*: ***C**onsent, **C**onfidentiality, **C**ounseling, **C**orrect test results and immediate **C**onnection/linkages to services* for HIV prevention, treatment and care.

8. **Follow-up and counseling:** All HIV-exposed infants should be followed up at 6 weeks for collect DBS and initiate Cotrimoxazole prophylaxis and then at 10 and 14 weeks and then at 6, 9, 12 and 18 months for growth monitoring, developmental assessment and nutritional counseling, along with early infant diagnosis, ART/Cotrimoxazole prophylaxis and clinical assessment, as required.

Management of a HIV-infected baby, once the diagnosis is confirmed includes: (a) clinical and immunological staging of the disease, (b) baseline assessment for OIs and primary prophylaxis, (c) initiation of Antiretroviral therapy, and (d) periodic follow-up for adherence and side effects as well as clinical/virological/immunological monitoring for early detection and management of treatment failures, (e) diagnosis and management of concurrent OIs, including secondary prophylaxis, (f) nutrition and feeding, and (g) counseling.

1. **Clinical and immunological staging of the disease:** All HIV-infected children must be assessed clinically in detail, not only for the staging of disease but also for growth and development, nutrition, immunization and presence of co-morbidities, e.g. tuberculosis. Cascade screening of parents and other siblings is also warranted for HIV and other infections.

   Current WHO classification for clinical staging of HIV/AIDS in children <13 years is given in **Table 10.49**.

   All HIV-infected children must be assessed for CD_4 counts to detect and monitor the extent of immunosuppression. According to CD_4 counts, HIV-infected children are categorized into various stages of the immunosuppression **(Table 10.50)**. CD_4 percentage values are preferred in children <5 years than absolute values due to physiologically high cell counts in them.
2. **Baseline assessment to identify presence of OIs and primary prophylaxis:** All HIV infected children should be assessed for presence of OIs, specially tuberculosis on clinical indicators and relevant investigations.

TABLE 10.49: Clinical classification for HIV infection in children <13 years (WHO 2006)

Clinical stage 1 (asymptomatic)
- Asymptomatic
- Persistent generalized lymphadenopathy

Clinical stage 2 (mild)
- Persistent hepatomegaly*
- Papular pruritic eruptions
- Extensive wart virus infection
- Extensive molluscum contagiosum
- Fungal nail infections
- Recurrent oral ulcerations
- Persistent parotid enlargement*
- Linear gingival erythema
- Herpes zoster
- Recurrent/chronic upper respiratory infections (otitis media, otorrhea, sinusitis, tonsilitis)

Clinical stage 3 (advanced)
- Moderate malnutrition* (no response to treatment)
- Persistent diarrhea* (>14 days)
- Persistent fever* (>1 month)
- Persistent oral candidiasis (>8 weeks of age)
- Oral hairy leukoplakia
- Acute necrotizing ulcerative gingivitis/periodontitis
- Lymph node tuberculosis
- Pulmonary tuberculosis
- Severe recurrent bacterial pneumonia
- Symptomatic lymphoid interstitial pneumonitis (LIP)
- Chronic lung disease, e.g. bronchiectesis
- Unexplained anemia (<8 gm/dl), neutropenia (<500/mm^3) or chronic thrombocytopenia (50,000/mm^3)

Clinical stage 4 (severe)
- Severe wasting, stunting, malnutrition*
- *Pneumocystis carinii* pneumonia
- Recurrent severe bacterial infections, e.g. empyema, bone/joint infection, meningitis excluding pneumonia
- HSV (orolabial/skin for >1 mo or visceral at any site)
- Extrapulmonary TB
- Kaposi sarcoma
- Esophageal candidiasis (or of trachea, bronchi or lungs)
- CNS toxoplasmosis (>1 mo age)
- HIV encephalopathy
- CMV retinitis or infection of other organs >1 mo age
- Extrapulmonary cryptococcosis (including meningitis)
- Disseminated mycosis, e.g. histoplasmosis
- Chronic cryptospridiosis or Isosporiasis
- Disseminated nontuberculous mycobacterial infection
- Cerebral or B cell non-Hodgkin lymphoma
- Progressive multifocal leukoencephalopathy
- Symptomatic nephropathy or cardiomyopathy

*unexplained

TABLE 10.50: Immunological classification (WHO 2006)

*Categories**	*Age-related CD_4 values*			
	<11 mo	*12–35 mo*	*>36–59 mo*	*>5 year**
Not significant	>35%	>30%	>25%	> 500*
Mild	30–35%	25–30%	20–25%	350–499*
Advanced	25–30%	20–25%	15–20%	200–349*
Severe	<25% or <1500*	<20% or <750*	<15% or <350*	<15% or <200*

*absolute values (cells/mm^3), rest are in %.

Prophylaxis against OIs may be divided into: (i) *primary prophylaxis* before the first attack in high-risk cases, and (ii) *secondary prophylaxis* after the first attack to prevent recurrence.

Primary prophylaxis is indicated with: (a) cotrimoxazole for PCP and toxoplasmosis as discussed earlier, (b) isoniazid (PO 10 mg/kg/day for 6 months) for tuberculosis in all newly diagnosed cases after excluding active disease. In addition, primary prophylaxis is also indicated during the course of disease with (c) Azithromycin (PO 20 mg/kg once a week) for *Mycobacterium avium* intracellular complex when CD_4 count drops <100 cells/mm^3, and (d) Ganciclovir (PO 30 mg/kg TDS) when CD_4 count drops < 50 cells/mm^3.

3. **Antiretroviral therapy (ART):** Life-long highly active ART (HAART) is the cornerstone of management of HIV infected children, while many antiretroviral drugs are available, safety and efficacy of many is not well established in children, as also lack of child-appropriate formulations.

   Depending on the mode of action, commonly used ART drugs in children may be classified as: (a) *nucleoside reverse transcriptase inhibitor* (NRTI), e.g. Zidovudine, Lamivudine, Abacavir, Tenofovir, etc. (b) *non-nucleoside reverse transcriptase inhibitor* (NNRTI), e.g. Nevirapine, Efavirenz, etc. (c) *protease inhibitor* (PI), e.g. Lopinavir, Ritonavir, Nelfinavir, etc. and (d) integrase strand transfer inhibitors (INSTI), e.g. Dolutegravir.

NACO guidelines 2021 recommend following principles for ART in children, as follows:

- ***When to start?*** ART should be initiated in *all children and adolescents living with HIV, regardless of age, CD4 count and WHO staging*. However, initiating ART should be deferred until: (a) acute infections and OIs are treated, if possible, (b) parents have been adequately counselled about the need for adherence and expected side effects.

  In cases associated with confirmed or presumptive tuberculosis, antitubercular therapy (ATT) should be initiated about two weeks before the ART, except in tubercular meningitis when r it should be delayed for 4–8 weeks.
- ***Which drugs to use?*** Standard HAART treatment includes three drugs (*Triple drug therapy*), though choice depends on the age and weight of the child, previous drug exposure, side effects and feasibility. Fixed drug combinations, especially suitable for children, are preferred over to improve adherence. NACO 2021 guidelines recommends that:
  - Children <6 years and Wt <20 kg should be treated with *Abacavir (ABC) + Lamivuduine (LMV) +*

TABLE 10.51: Doses and common side effects of recommended ARTs in children

	Doses (in mg) for different weight bands						
Drug	**<6**	**6–10**	**10–14**	**14–20**	**20–25**	**>25**	***Side-effects***
ABC	120	180	240	300	360	600	Hypersensitivity, ILI
3TC	60	90	120	150	180	300	Rash
LPV/r (4:1)	80 BD	120 BD	160 BD	200 BD	300/200 BD	300 BD	Hepatitis, rash
DTG	5	15	20	25	50	50	Insomnia, Wt gain
TDF	–	–	–	–	–	300	Nephrotoxicity

*All doses once a day, except LPV/r, which is to be given twice a day.
For super boosting, add additional Ritonavir 50 mg < 6 kg and 100 mg above 6 kg

Lopinavir/ritonavir (LPV/r) regimen, in doses as per **Table 10.51**.

- Children aged 6–10 years and Wt 20–30 kg, should be treated with *ABC+ LMV+ Dolutegravir (DTG)*, in doses as per **Table 10.51**.
- Children >10 years and Wt >30 kg should be treated with *Tenofovir (TDF)+ LMV+ DTG*, in doses as per **Table 10.51**.

However, children with HIV-TB co-infection should be provided double-dose DTG (given BD rather than OD) and super-boosted LPV/r (ratio 1:1) with additional dose of Ritonavir, till two weeks after the last dose of rifampicin.

Children/adolescent already initiated on ART in childhood should continue with same regimen with weight adjusted dosing as long as they are virologically suppressed.

- ***How to monitor?*** All cases on ART should be followed up clinically and for relevant laboratory parameters to assess: (a) general well-being including nutritional and development assessment, (b) change in clinical status, e.g. development of new OIs or immune reconstitution inflammatory syndrome (IRIS, discussed later), and (c) adherence to the treatment as well as recognition of side effects.

  CD4 counts should be repeated every 6 months and viral load after 6 months, 12 months and then annually.
- ***When to consider treatment failure?*** Resistance to ART drugs may develop rapidly, but treatment failure should be considered only after fair trial of regimen for minimum 6 months, defined as:
  - *Clinical failure*, with a new/recurrent stage IV event, or progressive developmental deterioration or growth failure;
  - *Immunological failure* with:
    - CD_4 count fall <15% or persists <200 cell/mm^3 in children 1–3 yrs, or
    - CD_4 count falls <10% or persists < 200 cells/mm^3 in children 3–5 yrs, or
    - CD_4 counts fall >50% from peak on treatment level or persist <100 cells/mm^3 or falls to CD4 pre-treatment levels, in older children
  - *Virological failure* with two HIV-1 plasma viral load persistently >1000 copies/ml after 6 months of ART, despite >95% adherence in last 3 months and at least three adherence counseling.

  Children with poor clinical response despite adequate virologic and immunologic responses should be carefully evaluated as all such cases may not represent ART failure. Clinical deterioration after initiation of ART may be due to paradoxical worsening of a known OI, or unmasking of previously undiagnosed OI due to IRIS.
- ***What to change?*** All cases of treatment failure should be managed only at specialized centers, after excluding a complicating OI or drug side effects.

4. **Early detection and management of OIs** is the critical aspect of care in HIV-infected child tuberculosis is the commonest co-infection in Indian HIV-infected children and some base-line information to recognize, diagnose, prevent and treat these OIs have been summarized in **Table 10.52**.
   - ***Cotrimoxazole preventive therapy*** is indicated in all HIV-infected children (as discussed earlier for HIV-exposed children) with 5 mg/kg/d as single oral dose: (a) from 6 months to 5 years of age irrespective of the clinical or immunological staging, (b) from 5 years onwards, if having CD_4 count <350 cell/mm^3 or WHO clinical stage 3 or 4 disease, irrespective of CD_4 count. All cases with history of PCP infection should receive CPT as secondary prophylaxis.
   - ***Life-long secondary prophylaxis*** after first episode/s to prevent recurrence is indicated for: (a) recurrent serious bacterial infections (>2 in a year) with IVIG, (b) PCP with Cotrimoxazole, (c) CMV with Ganciclovir), (d) Toxoplasmosis with Sulfadiazine and pyrimethamine, (e) MAC with Azithromycin and ethambutol, (f) herpes simplex or varicella with Acyclovir.
5. **Nutrition and feeding:** Considering the higher nutritional needs in HIV infected children due to poor nutritional status and impaired immune system with high-risk of infections, WHO recommends that

TABLE 10.52: Common opportunistic infections in HIV infected children

Opp. Infections	*Main presentation*	*Diagnosis*	*Prophylaxis (Indication/drug of choice)*	*Treatment*
Pneumocystis jirovecii (PCP)	Progressive pneumonia with CD4 <200	Bronchoalveolar lavage with special staining	*Primary:* Cotrimoxazole[1] *Secondary:* Cotrimoxazole[1]	Cotrimoxazole[2] + steroids ***Alt:*** *Primaquine + clindamycin*
Bacterial infection	Recurrent/serious infection	Bacterial cultures	*Primary:* Vaccines (sp Hib, PCV) *Secondary:* IVIG[3]	Specific antibiotics
Tuberculosis	Disseminated/ Extrapulmonary disease	Clinical, contact, TT, X-ray Microbial tests	INH PO 10 mg/kg/day x 6 mo (in all cases after excluding active disease)	Specific therapy (*see* Ch 10.13)
Mycobacterium avium intracellulare (MAC)	Disseminated disease with CD4 <50	Blood/marrow/tissue culture	*Primary :* Clarithro/ azithromycin[4] *Secondary:* Clarithro/ azithromycin + ethambutol	Clarithromycin + ethambutol with/without rifabutin or ciproflox[6] ***ALT:*** *Azithromycin[6] + ethambutol*
Candida	Mucocutaneous disease Invasive disease	Clinical appearance Histology/culture	*Primary:* Not recommended *Secondary:* Fluconazole[7]	*OPC:* Clotrimazole *Esophageal:* Fluconazole[8] *Invasive*: Amphotericin B[9]
Cryptococci	Meningitis/Diss. disease	Serology (CSF/serum) India-ink staining (CSF)	*Primary:* Not recommended *Secondary:* Fluconazole[7]	Amphotericin + Flucytosine[10]
Cytomegalovirus disease (CMV)	Ocular: Retinitis CNS: Encephalitis GIT: Esophagitis/colitis	Ophthalomoscopy, CSF serology/MRI Endoscopy/biopsy	*Primary:* ? Ganciclovir [11](CD_4 <50) *Secondary*: Ganciclovir[11]	Ganciclovir[12] ***Alt:*** Foscarnet[12]
Varicella zoster (VCZ)	Recurrent/ multidermatomal Herpes zoster	Clinical, serology	*Primary*: VZIG on exposure *Secondary*: Not recommended	Acyclovir[13] ***Alt:*** Foscarnet[13]
Herpes simplex (HSV)	Recurrent stomatitis, esophagitis, encephalitis	Clinical, serology, viral cultures	*Primary*: Not recommended *Secondary*: Acyclovir[14]	Acyclovir[13] ***Alt:*** Foscarnet[13]
Toxoplasma	Encephalitis Chorioretinitis	Neuroimaging, serology Tissue culture/PCR	*Primary:* Cotrimoxazole[1] *Secondary:* SDZ+PYM+LCV[15]	SDZ+PYM+LCV[16] ***Alt:*** *Clindamycin + PYM+LCV*
Cryptosporidium	Chronic diarrhea	Stool exam	Hygiene	Nitazoxanide[17] or Azithromycin
Isospora	Chronic diarrhea	Stool exam	Hygiene, Cotrimoxazole	Cotrimoxazole[18]
Giardiasis	Recurrent diarrhea	Stool exam	Hygiene	Metronidazole

Alt: Alternative therapy, **OPC:** Oropharyngeal candidiasis, **VZIG:** Varicella-zoster immunoglobulin, **IVIG:** Intravenous immunoglobulin, **Hib:** *H. influenzae* B, **PYM:** Pyrimethamine, **SDZ:** Sulfadiazine, **LCV:** Leucovorin

1. PO Cotrimoxazole 5 mg/kg of (TMP) OD.
2. IV/PO Cotrimoxazole 15–20 mg/kg/d q6hr + IV Dexamethasone 0.3–0.5 mg/kg QID 21 days.
3. IV Immunoglobulin 400 mg/kg/month.
4. PO Clarithromycin 15 mg/kg/d q12hr ***or*** PO Azithromycin 20 mg/kg/week.
5. PO Clarithromycin ***or*** Azithromycin (as above) + PO Ethambutol 15–20 mg/kg/d q24hr ***or*** PO Ciprofloxacin 20–30 mg/kg/d q12–24hr.
6. PO Clarithromycin 7.5–10 mg/kg/d q12hr ***or*** PO Azithromycin 10–12 mg/kg/d q24hr + PO Ethambutol 15–20 mg/kg/d q24hr ***with/without*** PO/IV ciprofloxacin 20–30 mg/kg/d *or* IV/IM Amikacin 5–30 mg/kg/d.
7. PO Fluconazole 3–6 mg/kg OD (in severe recurrent mucocutaneous candidiasis/esophageal candidiasis).
8. IV Fluconazole 3–6 mg/kg OD x 21 days.
9. IV Amphotericin B 0.5–1.5 mg/kg OD × 2–3 weeks after clinical recovery and last positive culture.
10. IV Amphotericin B 0.7–1.5 mg/kg OD + PO Flucytosine 100 mg/kg/d q6hr × 2 weeks followed by IV/PO Fluconazole 10–12 mg/kg/d q12hr × 10 weeks.
11. PO Ganciclovir 30 mg/kg TDS ***or*** IV Ganciclovir 5 mg/kg OD 5 days a week.
12. IV Ganciclovir 5 mg/kg BD × 2–3 weeks. IV Foscarnet 60 mg/kg TDS 14–21 days
13. IV Acyclovir 10 mg/kg TDS × 7–14 days (in severe disease) ***or*** PO Acyclovir 20 mg/kg TDS × 7 days (in mild disease). IV Foscarnet 120 mg/kg/day q8hr × 7 days.
14. PO Acyclovir 80 mg/kg/d q6–8hr.
15. PO Sulphadiazine 80–100 mg/kg/d q6-12hr + PO Pyrimethamine 1 mg/kg OD + Leucovorin (Folinic acid) 5 mg/d alternate day.
16. PO Suphadiazine 25–50 mg/kg QID + Pyrimethamine 2 mg/kg OD × 2 day >1 mg/kg/d + 2–6 mo >1 mg/kg/Alt. day × total 6 mo + Leucovorin 10–25 mg/kg OD.
17. PO Nitazoxanide 100–200 mg BD × 3 days (200 mg BD in children >3 years). PO Azithromycin 5 mg/kg OD × 10 days (10 mg/kg on Day 1)
18. PO Cotrimoxazole 20 mg/kg/d of TMP q6hr × 10 days than q12hr × 3 days.

these children need high-energy, caloric-dense food as follows:
- Caloric requirements should be enhanced by 20–30% in CLHIV with symptomatic HIV or episode of OI, while those with growth faltering may need up to 50–100% additional calories.
- Proteins should supply 12–15% of the energy intake to maintain and/or recover lean body mass.
- Micronutrient supplementation is needed as per RDA.
- Issues related to early infant feeding have been already discussed earlier. Breastfeeding can be continued till 2 years.

6. **Counseling** is a vital component of HIV care and parents should be counselled at all available opportunities for treatment adherence, regular follow-up, timely reporting for opportunistic infections, proper nutrition, etc. Older children and adolescents need age-appropriate disclosure and counseling to ensure treatment adherence.

Immune reconstitution inflammatory syndrome (IRIS) is a collection of signs and symptoms resulting from the ability to mount an immune response to antigens or organisms associated with immune recovery on HAART. It may develop in ~10% cases after starting ART, specially in those with severe immunosuppression.

Clinically, most cases present within 2–12 weeks of initiating ART with unexpected deterioration of clinical status due to unmasking or worsening of sub-clinical co-infections, e.g. tuberculosis, HBV, HCV, MAC and cryptococcal disease.

Diagnosis depends on the high index of suspicion and differentiation from a new OI due to treatment failure may be difficult.

Treatment involves management of unmasked OI. ART should be continued, if possible. Steroids, e.g. prednisolone 0.5–1.0 mg/kg/d × 5–10 days may be used in severe or life-threatening cases to suppress exaggerated inflammatory response. In most cases the symptoms resolve after a few weeks.

10.29 LEPTOSPIROSIS

Leptospirosis (Weil's disease) is an important public health problem in urban India, with localized outbreaks during monsoons. While most cases are asymptomatic, clinical spectrum may range from non-specific febrile illness to severe disease with meningitis or hepato-renal dysfunction.

Epidemiology: *Leptospira interrogans*—the only pathogenic leptospires in humans, is primarily a zoonotic infection, with accidental human infection. *Rat is the main source of human infection,* though other animal reservoirs include dogs, cats and cattle. Infected animals excrete spirochetes in urine, which may be transmitted to humans via exposure to contaminated water or soil.

While sporadic cases are seen in animal-handlers, e.g. agricultural/veterinary workers, localized outbreaks are common in urban slums after heavy rains/floods, due to contact of rat-excreta-contaminated water with human skin.

Pathogenesis: Leptospira enter the body through moist and abraded skin/mucus membrane and spread to all organs via blood stream. Initial spirochetemia is pathologically characterized by vascular endothelial damage and resultant ischemia in liver, kidneys, meningitides and muscles, leading to early manifestations (*septicemic phase*). With appearance of circulating antibodies after 2–7 days, leptospires disappear from circulation but immunological damage may lead to further complications (*immune phase*).

Clinical spectrum: Most cases of human leptospirosis are asymptomatic. In symptomatic cases, the *incubation period is 7–12 days* and clinical presentation may be *biphasic*, divided into:
- *Septicemic phase (3–7 days),* characterized by abrupt onset of high fever with chills, severe headache, conjunctival suffusion, myalgia and nausea/vomiting. On examination, these children have: (a) dehydration with hypotension, (b) extreme muscular tenderness, (c) generalized lymphadenitis and hepatosplenomegaly, and (d) uncommon manifestations, e.g. rash, pneumonia, arthritis, myocarditis, polyserositis, etc.
- *Asymptomatic or silent phase* for few hours or days, though it may be absent in icteric leptospirosis.
- *Immune phase* presenting as either aseptic meningitis (*anicteric leptospirosis*) or hepatorenal dysfunction (*icteric leptospirosis*).

Anicteric leptospirosis is characterized by aseptic meningitis with headache, neurological signs and CSF abnormalities, which resolve spontaneously within a week.

Icteric leptospirosis (Weil's syndrome) is less common in children (<10%) and characterized by—(a) hepatic abnormalities, e.g. progressive jaundice, hepatomegaly and hepatic failure, (b) renal abnormalities, e.g. hematuria or renal failure (c) hypotension/shock and (d) hemorrhagic manifestations, e.g. epistaxis or gut bleeding. Immune phase is relative long (10–30 days) in icteric leptospirosis.

Diagnosis must be suspected in any acute febrile illness with severe myalgia/headache, icterus or renal failure, during rainy season, which may be confirmed by:
- *Elevated IgM antibody titers from 5th day of illness,* >1:100 in at least two specimens *or* >2–4-fold rise over 2 weeks, by standard slide agglutination test or ELISA, with sensitivity of 80–90%,

- *Positive microscopic agglutination test* (MAT) is considered as the gold standard for serodiagnosis, though diagnostic titers vary with endemicity of disease. In regions where leptospirosis is common, there may be a substantial proportion of the population with elevated titers of MAT.
- *Direct identification of leptospires in urine or infected tissues*, by dark-field microscopy, fluorescent antibody staining or phase-contrast microscopy, though sensitivity declines after first week of illness.
- *Molecular tests, i.e. PCR-DNA* in blood, urine or spinal fluid are as diagnostic as direct identification, but cannot identify serovars.

In addition, most cases have thrombocytopenia and must be assessed for liver function tests, renal profile and CSF examination, if clinically indicated.

Modified Faine's criteria may be useful for presumptive diagnosis of leptospirosis awaiting confirmatory reports, based on clinical, epidemiological and laboratory criteria with assigned individual scores.

Treatment is supportive and specific (antibiotics).

- ***Antimicrobial therapy*** is most effective if started within 7 days of onset and drugs of choice include:
  - IV Crystalline Penicillin (50,000 100,000 U/kg/d for 5–7 days) in severe cases with Ceftriaxone (IV 75–100 mg/kg/d for 5–7 days) or Cefotaxime as alternatives, or
  - PO Doxycycline (5–10 mg/kg/d for 7 days) in milder cases. PO Azithromycin (10 mg/kg/d for 3 days) *or* Amoxycillin (50–100 mg/kg/d for 76 days) are alternatives in younger children.
- ***Supportive therapy*** includes antipyretics, cold compresses for muscle pain, correction of fluid and electrolyte abnormalities, continuous monitoring and management of hepatorenal dysfunction, including dialysis.

Prevention of leptospirosis includes: (a) Rodent-control measures, (b) avoidance of contact with contaminated water during floods, (c) prophylactic Doxycycline (200 mg/week) in travelers to outbreak area, and (d) immunization of live-stocks.

10.30 FUNGAL INFECTIONS

Fungal infections may be *superficial*, e.g. oral thrush, skin/nail mycosis, etc. or *invasive*, involving fungemia or systemic tissue disease. While superficial fungal infections are common, invasive disease is rare except in immunocompromised children.

This chapter deals with three important fungal infections—candidiasis, aspergillosis and cryptococcal meningitis. Others, e.g. histoplasmosis (*H.capsulatus*) blastomycosis (*B.dermatitidis*), coccidiomycosis (*C. immitis*), and mucormycosis are extremely rare in Indian children.

Candidiasis is the commonest human fungal infection due to *C. albicans*, though *non-albicans* species are emerging as important pathogens for invasive disease. As candida is a common colonizer of gut, respiratory tract and vaginal flora, the term *candidiasis* usually refers to superficial overgrowth or invasive systemic disease.

High-risk factors: Candidiasis is the commonest opportunistic infection in immunocompromised children and those on prolonged antibiotics, though also seen in normal newborns (as oral thrush or diaper dermatitis) and adolescent females (as vulvovaginitis).

Clinical spectrum of candidiasis depends on the risk factors and usually include:

Oral candidiasis (thrush) is commonest candidal infection, seen in: (a) normal newborns and infants <3 months, (b) prolonged antibiotic therapy, (c) prolonged use of steroid inhalers, and (d) immunocompromised children. *Clinically*, it is characterized by superficial white plaque on oral mucosa, tongue and palate that leaves punctate bleeding on removal (Ch 14.3.3).

Diaper dermatitis presents as confluent popular erythema with red satellite pustules over diaper area. It is common in infants on antibiotics, chronic diarrhea or contact dermatitis.

Systemic (invasive) candidiasis is seen in: (a) extreme preterms/low birth weight newborns, (b) immunocompromised states, and (c) after prolonged vascular/urinary catheterization. Infection form colonized sites may spread directly (esophageal candidiasis, candiduria) or hematogenously, to produce systemic illness, e.g. pneumonia, meningitis and candidemia.

Chronic mucocutaneous candidiasis is a heterogeneous group of *T-cell defects*, characterized by persistent/recurrent mucocutaneous candidiasis, usually associated with endocrinopathies, e.g. Addison's disease and other autoimmune disorders. Invasive disease is rare and treatment is prolonged topical antifungal therapy.

Diagnosis of superficial candidiasis is largely clinical, while invasive disease may be confirmed by: (a) direct demonstration of yeast cells/hyphae from skin/mucosal scrapping, *or* (b) fungal cultures from blood, CSF or urine. In catheter-related cases, removed catheter-tip should always be cultured to confirm the source of infection.

Treatment: Superficial candidiasis is treated with topical anti-fungal preparations, e.g. miconazole, clotrimazole, nystatin or gentian violet, apart from supportive measures, e.g. frequent change of diapers and topical steroid creams, if severe inflammation is present.

IV Liposomal Amphotericin (5 mg/kg/d for 2–3 weeks after last positive culture) is the drug of choice for invasive candidiasis. A second antifungal-Flucytosine or Fluconazole may be added in CNS/renal disease.

Fluconazole is not effective against many non-albicans strains.

Aspergillosis refers to a group of diseases, usually caused by *Aspergillus fumigatus*. Infection is acquired by inhalation of spores (*conidia*), present in soil/decaying plants or rarely by wound contamination.

Risk factors for aspergillosis include: (a) inherent atopic states (*asthma*), (b) heavy/prolonged exposure (*Farmer's lung*), (c) chronic lung disease (allergic bronchopulmonary aspergillosis), and (d) immunocompromised host, e.g. HIV, neutropenia or malignancies (invasive disease).

Clinically, it may present as: (a) non-invasive disease pulmonary or sinus aspergilloma or otomycosis, (b) invasive pneumonia or disseminated aspergillosis, and (c) hypersensitivity syndromes, e.g. asthma, bronchopulmonary aspergillosis, etc.

Diagnosis depends on: (a) clinical suspicion, (b) presence of fungal mycelia/hyphae in tissue lesions or sputum on microscopy/culture, and (c) allergy tests, e.g. skin test, specific IgE levels or radioallergosorbent test (RAST) in hypersensitivity syndromes.

Treatment of choice is: (a) IV/PO voriconazole or liposomal Amphotericin B *in invasive disease*, (b) topical antifungals and steroids in *non-invasive disease*, and (c) steroids for hypersensitivity manifestations; along with supportive therapy. Duration of therapy depends on the site of infection, severity of disease and clinical response.

Cryptococcosis (*C. neoformans*) is the second commonest fungal infection in HIV +ve population, after candidiasis. Infection is acquired by inhalation of spores, present in soil or vegetations contaminated by bird-droppings.

Clinically, sub-acute meningitis is the commonest feature of invasive disease in immunodeficient children, followed by sepsis-like syndrome, lymphonodular disease, cutaneous ulcers/warts and skeletal disease. Cryptococcosis is extremely rare in immunocompetent individuals, except asymptomatic/progressive pneumonia in heavily-exposed adults, e.g. pigeon breeders or bird-traders.

Diagnosis rests on clinical suspicion in immunodeficiency state, supported by latex agglutination test in serum or CSF (titers >1:32). Confirmation requires recovery of fungus on CSF/serum culture or in biopsy tissues.

Treatment of choice for invasive cryptococcosis, (e.g. meningitis) is IV Amphotericin B, with/without Flucytosine till complete response, followed by *life-long maintenance therapy with Fluconazole*. Mild cases limited to lung involvement may be treated with oral Fluconazole.

10.31 CHLAMYDIAL INFECTIONS

Chlamydiae are obligate intracellular bacteria, which are unable to generate their ATP for metabolic activity and hence, depend on host cells for energy. Two species are important in humans—*C. pneumoniae* and *C. trachomatis.*

C. pneumoniae is an emerging cause of community acquired pneumonia in school children. Organisms are present in nasopharynx of a clinical/subclinical human host (reservoir) and transmitted as a droplet infection.

Clinically, it present as atypical pneumonia, with disproportionately less clinical signs than X-ray findings.

Diagnosis depends on serology, i.e. IgM titers >1:16 on immunofluorescence test. Tissue-cultures from nasopharynx, sputum or bronchoalveolar lavage are confirmatory but rarely possible.

Treatment of choice is PO erythromycin/clarithromycin for 10 days *or* azithromycin for 5 days, in usual doses.

C. trachomatis infections in children are almost always caused by its *trachoma biovar*, though another *lymphogranuloma biovar* is responsible for a rare STD in adults, i.e. *lymhphogranuloma venerum*.

Clinical spectrum of *trachoma biovar* in children varies with age and mode of infection and includes:

- Trachoma (Ch 27.1.4),
- Genital infections, and
- Neonatal disease (conjunctivitis or pneumonia) in infected mothers.

Genital infections are acquired as sexually transmitted disease in adolescents or sexually-abused children. These infections may be asymptomatic or present as urethritis or epididymitis in males; and cervicitis, salpingitis or pelvic inflammatory disease in females.

Neonatal infection is acquired during vaginal delivery through infected birth canal, with premature rupture of membranes as a high-risk factor. While nasopharyngeal colonization is common, clinical disease usually presents with—(a) conjunctivitis, during 2nd week of life, and/or (b) atypical pneumonia at 1–3 months of age. Chlamydia is the leading cause of community-acquired neonatal conjunctivitis after control of gonococcal infections.

Diagnosis is mainly clinical, confirmed by demonstration of organisms in nasopharyngeal, ocular or genital smears, either on fluorescent antibody staining (characteristic inclusion bodies) or tissue-culture.

Treatment depends on the site and severity of infection, though PO erythromycin for 1–2 weeks, is the drug of choice in all cases, including newborns and for trachoma. WHO recommends single dose Azithromycin (PO 20 mg/kg) for treatment of Trachoma. Contacts, e.g. sexual partners and mother in neonatal case, should be treated simultaneously.

10.32 MYCOPLASMA INFECTIONS

Two mycoplasmal infections are of interest in human disease – *M. pneumoniae* and Genital mycoplasma, i.e. *M. hominis* and *Ureaplasma urealyticum*.

***M. pneumoniae* (Eaton agent),** the *smallest self-replicating organism,* is the commonest cause of community-acquired pneumonia in schoolchildren.

Epidemiology: Infection is acquired via droplets from infected host, though development of clinical disease depends on age and immune status. Overt illness is unusual before 3–4 years of age, while children with immunocompromised illness or sickle cell disease are at risk for serious disease.

Clinical spectrum: *Primary atypical pneumonia* is the commonest mycoplasmal illness, responsible for >1/3rd cases of community-acquired pneumonia in school children. Other rare manifestation include: (a) upper respiratory illnesses, e.g. pharyngitis, otitis or sinusitis, (b) airway illnesses, e.g. croup, bronchiolitis, and (c) exacerbation of asthma. Mycoplasma infections may also lead to extra-respiratory complications after 2–3 weeks of respiratory illness, due to autoimmune mechanisms, e.g. (a) Steven-Johnson syndrome, (b) neurological disease, e.g. aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, cerebellar ataxia, and (c) autoimmune hemolytic anemia.

Diagnosis usually rests on serology, i.e. elevated cold agglutinin titers (>1:64) *or* positive IgM-ELISA test. Cultures take >1 week for results and molecular diagnostic tests, e.g. PCR are not commercially available.

Treatment of choice is Macrolides, e.g. Clarithromycin (PO 15 mg/kg/day q12hr for 10 days) or Azithromycin (PO 10 mg/kg/day q24hr for 5 days), with nearly 100% success rate. In rare resistant case, tetracyclines or fluoroquinolones may be used.

Genital mycoplasma (*M. hominis* and *U. urealyticum*) are common colonizers of genitourinary tract in post-pubertal adults, rarely transmitted to newborns or children *via* sexual abuse, genital-hand-genital contact, during vaginal delivery or in presence of chorioamnionitis.

Neonatal infection with genital mycoplasma has been attributed to abortions, stillbirths, prematurity and rarely, neonatal respiratory disease.

Adolescent infection may be asymptomatic or presents with non-gonococcal urethritis in males and vaginitis, cervicitis and pelvic inflammatory disease in females.

Diagnosis of pathogenic infection is difficult due to high colonization rate in normal population.

Treatment of choice is single dose Azithromycin, indicated only in symptomatic cases with pure mycoplasma culture.

10.33 MALARIA

Malaria continues to be a major public health problem in India and has acquired new dimensions due to (a) resurgence in previous low-endemic areas, (b) increasing proportion of severe *P. falciparum* cases, and (c) emergence of drug-resistance.

India aims to *eliminate* malaria with 2030, with zero indigenous cases in the entire country, maintain malaria–free status in areas where transmission has been interrupted, and prevent re-introduction of malaria, as also recommended by WHO Global Technical Strategy for Malaria 2016–2030.

Magnitude of malaria in a community is usually measured as *annual parasite incidence* (API), i.e. number of smear-positive cases per year per 1000 population. Recent years have witnessed major changes in malarial epidemiology in India, as follows:

- Significant decline in the incidence of disease with API of 0.12 in 2021 (*vs* 2.12 in 2001).
- Predominance of falciparum (Pf) infection, accounting for ~57% of all malaria cases (2022).
- Wide regional differences, with maximum cases in Chhattisgarh, Odisha, Jharkhand and North-eastern states (2022).
- Alarming rise in drug-resistance Pf cases, specially to Chloroquine (~40%) or Pyrimethamine (~10–20%). Partial chloroquine resistance in vivax (Pv) malaria is also emerging.

Epidemiology: Human malaria is caused by four species of Plasmodium-an obligate intracellular protozoon: *P. vivax* (benign tertian malaria), *P. falciparum* (malignant tertian malaria), *P. malariae* (Quartan malaria) and *P. ovale*. In India, *P. malariae* accounts for <1% cases in Tumkar and Hassan districts of Karnataka, and *P. ovale* is extremely rare. Few cases of malaria due to *P. Knowlesi* have been reported in south-east Asia, but not in India.

Reservoir: Infected humans are the only known reservoir of infection, except probably chimpanzees in tropical Africa. Infected person is communicable only if gametocytes are present in peripheral blood, which appear on 4–5th day in Pv and 10–12th day in Pf, after onset of fever.

Transmission: Mosquito as a vector for malaria transmission was first identified in 1897 by Ronal Ross from Hyderabad, India. Malaria is transmitted by the bites of infected female *anopheline mosquitoes*, except rare cases of *congenital malaria* (transplacental infection), *transfusion malaria* (infected blood/products) or *needle*-infection in drug-users. Six species of female anopheline are known to transmit malaria. In India, maximum transmission occurs by *A. stephensi* (urban slums) or *A. culcifacies* (rural areas) and rarely by *A. minimus* (North-East states). Vector typically breeds on stagnant water, e.g. ponds, cisterns, fountains and overhead tanks.

Host factors: Malaria is common in all age-groups and in males. Since all infected mosquito-bites do not cause clinical disease, host characteristics seem to play important role, as follows:

- *Newborns* are relatively protected, due to presence of high fetal hemoglobin levels (relatively malaria resistant) and transplacental antibodies.
- *Inherent immunity* is present in some people, probably due to: (a) genetic immunity, dependent on HLA type, (b) absence of surface receptors for merozoites on RBC membrane, or (c) presence of hemoglobinopathies, e.g. sickle cell disease, etc., which resist parasitic entry, impede *in vivo* development, or facilitate their removal.
- *Acquired resistance* due to earlier attacks in endemic population. Most severe malaria occurs in non-immune persons, e.g. travelers to endemic regions.

Environmental factors relate to vector population and activity. Malaria is more prevalent in:

- Areas with suitable vector-breeding conditions, e.g. villages and urban slums, heavy rainfall regions, e.g. north-east states, construction sites and man-made breeding sites, e.g. burrow pits, garden pools and irrigation channels (*man-made malaria*).
- Warm-humid climate from July to November, due to increased vector-activity. Malaria is uncommon in hilly regions due to cold weather, unsuitable for mosquito survival.

Life-cycle of parasite completes in two hosts—*asexual phase* in man and *sexual phase in* mosquito **(Fig. 10.17)**.

Asexual phase (in man) begins with infected mosquito bite and entry of *sporozoites* in blood. Most of these sporozoites invade hepatocytes for asexual reproduction, though some are destroyed by phagocytosis in immune people. Asexual phase may be divided into:

a. ***Hepatic (pre-/exo-erythrocytic) phase:*** During incubation period, sporozoites within liver cells develop into *hepatic schizonts*, which eventually rupture to release thousands of *merozoites* (~2000–15,000 in Pv and >40,000 in Pf) in blood. In Pv infection, some schizonts remain dormant in the hepatocytes *(hypnozoites)* to mature and rupture later, leading to late relapses (*exo-erythrocytic phase*). This phase is absent in Pf infections and congenital/transfusion malaria *(no relapse)*.

b. ***Erythrocytic phase:*** Liberated merozoites from liver invade RBCs by attaching themselves on cell-surface receptors and develop intracellularly through many developmental stages, e.g. *ring stage* > *trophozoites* > *erythrocytic schizonts* and again as *merozoites*. Infected RBC ruptures to release them in peripheral blood, with reappearance of fever. Subsequent course of merozoites is:
   - Re-infection of other RBCs and re-cycling till development of adequate natural immunity. Each erythrocytic cycle takes ~42 hrs (~72 hrs in *P. malariae*), responsible for typical periodicity of fever, i.e. tertian malaria (Pv, Pf) or quartan malaria (*P. malariae*).
   - Re-entry of some merozoites (except in Pf) into hepatocytes to re-start hepatic/exo-erthrocytic phase, responsible for relapses.
   - Development into sexual forms, i.e. micro (male) or macro (female) gametocytes, for infection of other mosquitos.

Sexual phase (in mosquito) involves fusion of male and female gametocytes to form zygote in the stomach of mosquito that develops further as *sporozoites* and enters into salivary glands, ready to inoculate next human host.

Pathogenesis: Clinical differences in the severity of illness in Pv and Pf infection mainly relate to *magnitude of parasitemia*, i.e. number of RBCs infested. As many as 30–40% of RBCs may be simultaneously infected in severe Pf malaria, as compared to <5% parasitization in Pv infections. Further, Pv invades only the younger RBCs, while Pf also infects senescent erythrocytes.

Important factors in pathogenesis of malaria are:

- *Hemolysis* of parasitized RBCs, leading to febrile episodes and anemia;
- *Increased cytoadherence* of parasitized RBCs, leading to intravascular clogging and hypoxic-ischemic tissue injury. Falciparum infested erythrocytes tends to adhere to uninfected RBCs (rosetting) to promote cytoadherence, specially in severe cerebral malaria.
- *Immunological injury* with hypergammaglobulinemia, immune-complex formation and release of pro-inflammatory cytokines, (e.g. interleukins and TNF-α), which precipitate or aggravate tissue hypoxia/injury.

Immune response to malaria is slow, incomplete and not life-long, due to antigenic diversity of the parasite. However, repeated exposures tend to reduce the severity of disease due to partial immunity in older population of endemic regions.

Clinical manifestations of malaria begin after an *incubation period* of ~ 9–14 days in Pf and ~ 12–17 days in Pv infection; and depend on the magnitude of parasitized RBCs as well as immune status of host. In endemic regions, e.g. India, even 20–30% parasitemia may be asymptomatic in older cases due to acquire immunity after repeated exposures. Some important manifestations of malaria are as follows:

Classical malaria, is characterized by typical periodicity of intermittent fever. Each episode evolves through following three stages:

a. *Cold stage*, i.e. sudden chills and rigors for ~ 10–15 minutes, followed by,

b. *Hot stage*, i.e. sudden rise of temperature, lasting for 2–3 hours, followed by,

c. *Wet stage*, i.e. profuse sweating, when fever comes down by lysis.

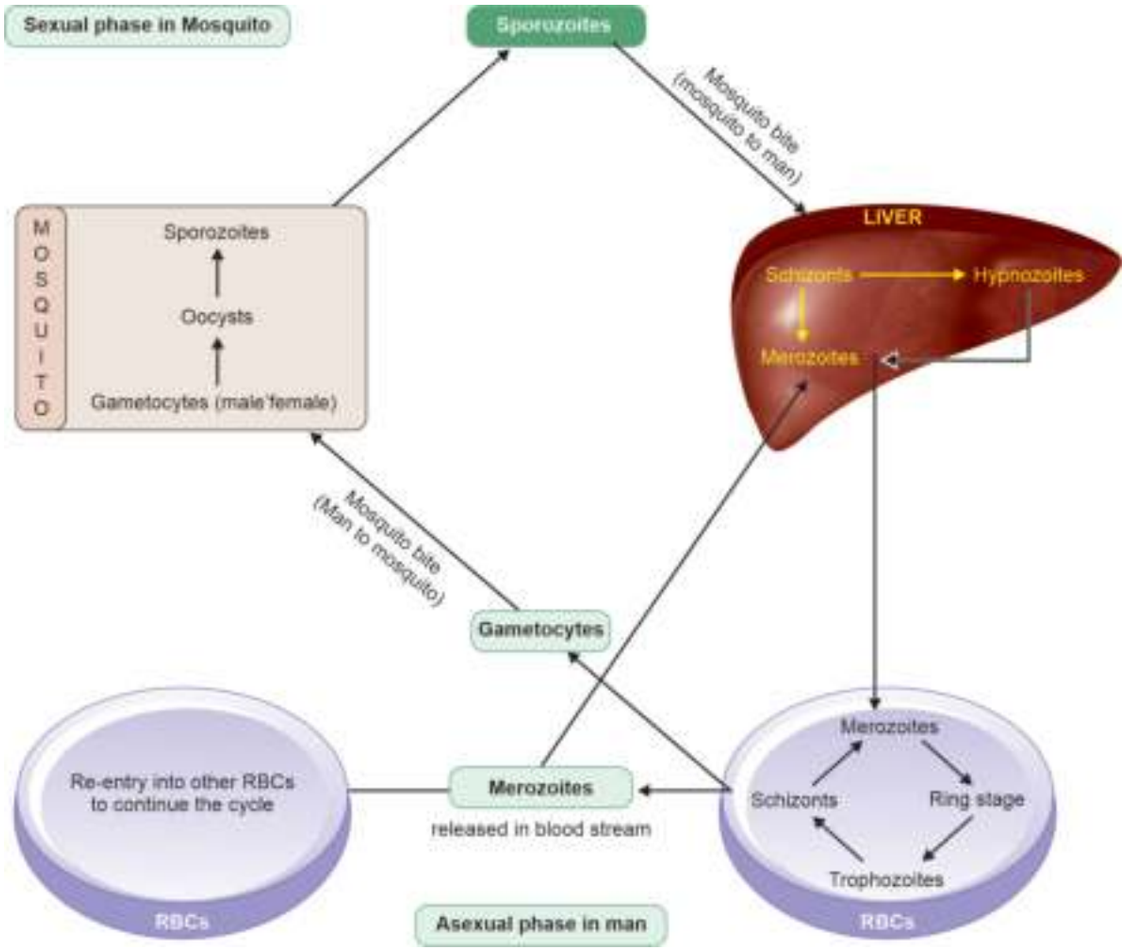

Fig. 10.17: **Life cycle of malaria parasite.**

On examination, mild splenomegaly and pallor is common.

Severe malaria is more common in non-immune population, almost always caused by Pf infection and defined as presence of any of the manifestations enumerated in **Table 10.53**. *Cerebral malaria* is the commonest and most serious presentation of severe malaria in children (Ch 18.11.4). Severe malaria due to vivax malaria is rare, but has been reported. Diagnostic criteria for severe Pv malaria are similar to those for severe Pf malaria, but with no definite parasite thresholds.

Chronic malaria is a common problem in endemic region due to relapses (in Pv infection) or recurrent infections. Armed with partial immunity, these cases often presents with intermittent bouts of mild febrile episodes but *progressive splenomegaly*.

Neonatal malaria is uncommon due to high fetal hemoglobin (relatively resistant), and may be (a) *Congenital* or transplacental, due to maternal infection in last week of gestation, or (b) *Acquired* due to mosquito bite in early neonatal period.

TABLE 10.53: WHO criteria for severe falciparum malaria (2023 update)

- Impaired consciousness (Blantyre coma score <3)
- Generalized prostration (inability to sit/stand/walk)
- Hypoglycemia (Blood sugar < 40 mg/dl)
- Recurrent seizures (≥3 in 24 hours)
- Metabolic acidosis (HCO_3 <15 or lactate >5 mmol/L)
- Severe anemia with PC >10000/µl (Hb ≤5 or Hct ≤15)
- Recurrent or prolonged bleeding
- Jaundice with PC >100000/µl (bilirubin >3 mg/dl)
- Hyperparasitemia (>10%)
- Pulmonary edema (On X-ray or SaO_2 <92%)
- Circulatory shock (SBP <70 mm Hg or CRT ≥3 sec.)
- Renal failure (S. creatinine >3 mg/dl)

PC: Parasite count, **RD:** Respiratory distress, **CRT:** Capillary refill time, **SBP:** Systolic blood pressure

These cases presents with septicemia-like manifestations, e.g. poor feeding, sluggish activity, pallor, jaundice, diarrhea/vomiting and hepatosplenomegaly. Antenatal maternal infection is also associated with intrauterine fetal death, premature labor and IUGR. Although d/d with acquired neonatal malaria is difficult,

congenital malaria is characterized by: (a) onset within 7 days of life, (b) absence of exo-erythrocytic phase with no relapses and (c) positive maternal/placental blood smear.

Diagnosis of malaria depends on the peripheral smear or a rapid diagnostic test, though collaborative hematological findings may support the diagnosis in a clinically suspected case.

- **Peripheral smear (PS):** Demonstration of ring or trophozoite stage on PS is the gold standard for diagnosis of malaria, though possible in only 50–60% cases. Smear yield is higher if—(a) PS is made during acute febrile episode and before anti-malarial therapy, (b) it is prepared from bone-marrow or splenic-aspirate, (c) special staining techniques are used, and (d) multiple smears are examined. Single negative smear does not exclude malaria. *Thick and thin smear* is most commonly used laboratory tool for demonstration of various stages of parasite **(Fig. 10.18)** that involves preparation of two smears: (a) a *thick smear* that increases chances of parasite detection due to more RBC mass, and (b) a *thin smear* to identify the species (Pv or Pf). Commonly used staining procedures include Field's stain, JSB stain and Giemsa stain **(Table 10.54)**.

  The term *parasite index* denotes percentage of parasite-laden erythrocytes, used as a marker of the disease-severity as well as therapeutic response.
- **Rapid diagnostic tests (RDTs),** based on the detection of circulating parasite antigens, are useful to detect malarial infection when microscopy is not possible or delayed. However, these tests should not be used as replacement for microscopy. Among the available RDTs, some can detect only the Pf species (monovalent) while others can also identify Pv or other species (bivalent). Two commonly used RDTs are as follows:

  Parasight-F test is a monovalent RDT, which detects histamine-rich protein (HRP-2) antigen of asexual Pf, with sensitivity of >90% in cases with parasite load of >100–500/µl. However, it may be false-negative in very low parasitemia and false-positive in post-treatment cases as HRP-2 antigen may persist for up to 4 weeks after parasite clearance on treatment. This test cannot detect Pv infection.

  Optimal test is a bivalent RDT that detects parasitic LDH enzyme, produced by all species. Sensitivity and specificity of optimal test is >95% in diagnosis of Pf as well as Pv malaria. It is capable to detect parasite load of as less as 50–100 parasites/µl and becomes negative after successful treatment.

  Sensitivity of RDT depends on the quality and storage conditions of the kit, species and load of the parasite and technique and care used during testing. RDTs may be used as a screening test, though a

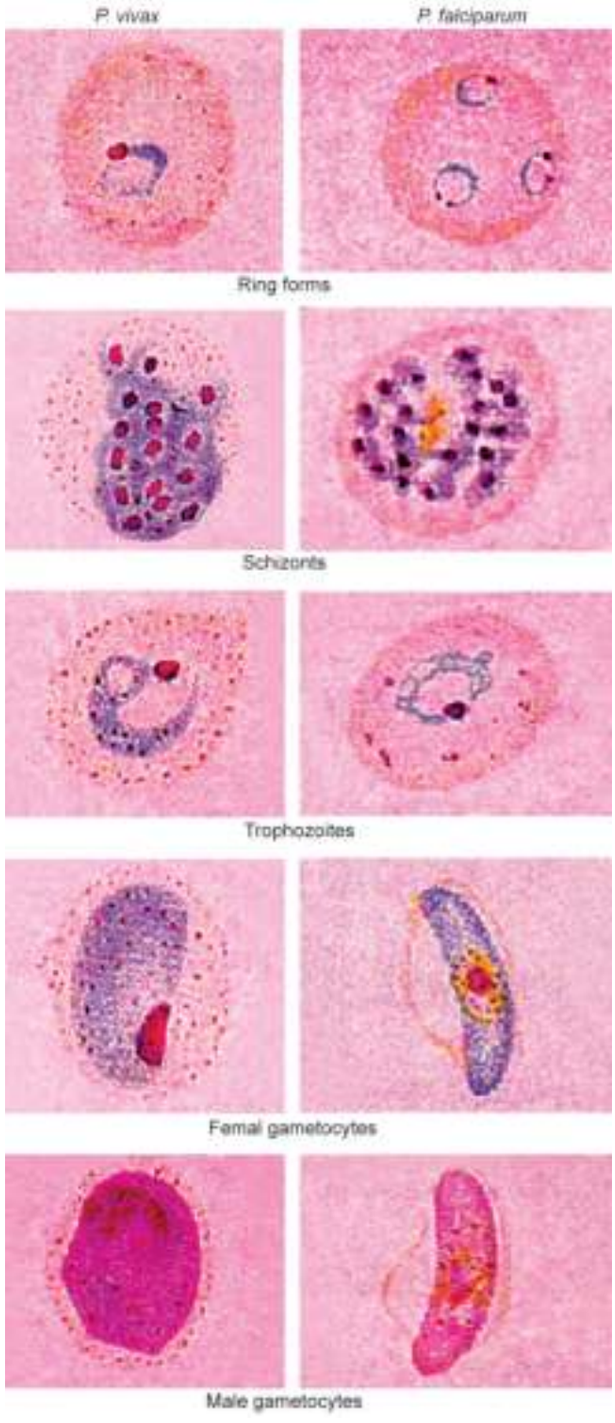

Fig. 10.18: **Peripheral smear in malaria—parasitic stages.**

TABLE 10.54: Staining methods for PS-MP

Leishman's staining:
- Cover the smear with Leishman stain (1–2 min)
- Pour equal volume of buffer water (7–10 min)
- Wash with water and dry

Giemsa staining:
- Fix the smear with acetone-free methanol (1min)
- Cover with giemsa's stain (20 min)
- Wash with water and dry

negative RDT in a strongly suspected case should always be confirmed by microscopy. RDT may not differentiate between active infection and recent effectively treated infections and should not be used to monitor the response to therapy.

- **Other diagnostic tests** of limited utility, include-special staining techniques, antibody detection tests and molecular diagnostic tests. *QBC test or Acridine-Orange staining* involves fluorescent staining of parasitic nucleic acids. It is useful to detect very low parasitemia (~2–3/µl), but species identification is difficult. *Antibody detection tests* are of little clinical significance in endemic regions due to past infection and molecular tests are confirmatory but not freely available. Other laboratory abnormalities, though not diagnostic, help in early detection of *severe malaria* and include severe anemia, thrombocytopenia and hypoglycemia.

Table 10.55 provides an overview of main epidemiological, clinical and laboratory differences between Pv and Pf malaria.

Management of malaria aims to: (a) cure the disease, (b) prevent relapses, (c) render the patient non-infective, and (d) prevent the infection. It includes specific antimalarial therapy as well as supportive measures, e.g. antipyretics, fluid-electrolyte correction, adequate nutrition and treatment of complications.

TABLE 10.55: *P. vivax vs P. falciparum* malaria

	P. vivax	***P. falciparum***
Life cycle		
No. of Merozoites[1]	<15,000	>40,000
Affected RBCs	Young	Any
Parasite index	<5%	>10–30%
EE phase[2]	Present	***Absent***
Gametocytes[3]	4–5th day	10–2th day
Clinical features		
Fever periodicity	48 hours	Usually absent
Complications	Uncommon	***Severe malaria***
Relapse	No	Yes
Smear findings		
RBC size	Enlarged	Normal
RBC stippling	Schuffner's dots[4]	Maurer's spots[5]
Ring stage/RBC	Large, 1–2 rings	Small, multiple
Schizont	Large, ameboid	Small, compact
Pigment	Golden haze	Dark brown
Gametocytes	Spherical	Cresent-shape
Response to treatment		
Drug resistance	Rare	***Common***

[1]Number of merozoites released from hepatic phase; [2]exoerthrocytic phase; [3]day of gametocyte appearance; [4]small, numerous, red dots; [5]large, <20, red dots.

No single anti-malarial agent is effective against all stages of parasite. Currently available drugs may be divided into three groups:

a. *Drugs acting on hepatic phase,* which destroy the sporozoites, prevent hepatic schizogony or prevent erythrocyte invasion by merozoites, e.g. *pyrimethamine, primaquine, proguanil.* These drugs are used to prevent the disease after exposure, i.e. *chemoprophylaxis or* to prevent relapses, i.e. *radical cure* in Pv malaria.
b. *Drugs acting on erythrocytic phase,* which inhibit erythrocytic schizogony and rupture of infected RBCs. These drugs, e.g. *chloroquine, quinine, mefloquine* merely suppress the Pv infection due to limited action on exo-erythrocytic phase; but are curative for Pf infection with no exo-erythrocytic phase. A combination of drugs effective against both erythrocytic and hepatic phase must be used for complete *clinical* as well as *radical cure* in Pv malaria, e.g. chloroquine with primaquine.
c. *Gametocidal drugs,* which destroy gametes to prevent further transmission in new vectors, e.g. *primaquine, mefloquine*, etc. Chloroquine is not gametocidal.
d. *Sporonticidal drugs* prevent maturation of parasite within the mosquito to break transmission cycle, e.g. *pyrimethamine, proguanil*, etc.
e. *Broad-spectrum antimalarial drugs*, e.g. artemisinin derivatives, effective against all forms of erythrocytic stages and gametocytes (except mature forms). However, these drugs are ineffective against extra-erythrocytic forms, sporozoites and merozoites.

Artemisinin combination therapy (ACT) has revolutionized the treatment of falciparum malaria. It involves simultaneous use of two or more schizonticidal drugs with different mode of action. One of the partners in this combination should be an artemisinin derivative due to its high killing rate (reduces parasite load 10,000 fold *versus* 100–1000 fold per cycle with other drugs), lack of serious side effects, low level of resistance and rapid elimination of the drug, which ensures that the parasites are not exposed to sub-therapeutic levels. When combined with slowly-eliminated antimalarials, e.g. lumefantrine or sulfadoxinepyrimethamine (SP), artemisinin derivatives also protect against emergence of drug resistance by drastically reducing the number of parasites exposed to these long-acting drugs.

Five ACT combinations are approved by WHO for use in children-Artesunate+Sulfadoxine-Pyrimethamine (ASP), Artesunate+Amodiaquine (AA), Artesunate+mefloquine (AM), Artemether+Lumefantrine (AL) and Dihydro-artemisinin+Piperaquine (DHP).

WHO 2023 and National Vector Borne Diseases Control Programme (NVBDC) guidelines recommends that all fever cases with suspected malaria should be investigated for confirmation, preferably with microscopy or by RDT, before initiation of the treatment. Specific chemotherapy

in malaria depends on the species of parasite, prevalent pattern of drug-resistance as well as clinical status of patient and may be broadly divided into management of—(a) uncomplicated attack, (b) drug-resistant malaria, and (c) severe malaria.

a. *Treatment of uncomplicated vivax malaria:* Chloroquine continues to be the drug of choice in all cases of uncomplicated Pv malaria, followed Primaquine for 14 days to eliminate the exo-erythrocytic phase for *radical cure* **(Table 10.56)**.

   WHO 2023 recommends Chloroquine in 3 dose-schedule (PO 10 mg/kg stat, 10 mg/kg after 24 hrs and 5 mg/kg after 48 hrs), preferable to the conventional four-dose schedule (PO 10 mg/kg stat than 5 mg/kg at 6, 24 and 48 hrs), though total dose is same, i.e. 25 mg/kg. Dose should be repeated if patient vomits within 30 minutes.

   In regions with chloroquine-resistant Pv, ACT containing Lumefantrine, mefloquine or Piperaquine (AL, AP or AM) is recommended for uncomplicated Pv malaria (WHO 2023).

   Primaquine is contraindicated in infants, pregnancy, lactation and G6PD deficiency. G6PD estimation is advisable in all cases before primaquine therapy, if possible. While 14-day Primaquine therapy is recommended for radical cure, WHO 2023 also recommends additional option of PO Primaquine 0.5 mg/kg/day for 7 days for better compliance of shorter regimen.

   G6PD deficient children may be given 0.75 mg/kg of Primaquine once a week for 6 weeks instead of usual daily dose for 14 days.

b. *Treatment of uncomplicated falciparum malaria:* Considering the high frequency of Chloroquine and Pyrimethamine resistance in India, *ACT* is the treatment of choice for uncomplicated Pf malaria.

   Of these, only two-*ASP* (for states other than north-eastern states) and *AL* (for north-eastern states) are recommended in National Drug Policy for malaria **(Table 10.56)**.

   ASP is not recommended in north-eastern states due to high incidence of Pyrimethamine resistance, in newborns due to risk of competitive bilirubin displacement by SP leading to hyperbilirubinemia, and in HIV-infected children on Cotrimoxazole prophylaxis.

   Author's note: *Author prefers AL over ASP due to: (a) lack of liquid ASP formulations, and (b) risk of missing SP in ASP combinations, as it is provided as separate tablet.*

   In all cases of Pf malaria, ACT should be followed by single dose of Primaquine (0.75 mg/kg) to destroy the gametocyte and break the transmission cycle, except in infants <6 months. G6PD testing is not required (WHO 2023).

c. *Treatment of mixed malaria* is similar to that for pf malaria, except that primaquine has to be given as PO 0.25 mg/kg/day for 14 days, as for Pv malaria **(Table 10.56)**.

d. *Treatment of severe malaria* is life-threatening and specific ant-malarial therapy in all cases including infants, should begin parenterally with any of the three drugs – artesunate, artemether or quinine for *at least first 24 hours, followed by switch-over to oral therapy as early as possible* **(Table 10.57)**.

While National Drug Policy lists Quinine, Artesunate and Artemether in the order of treatment of severe malaria, WHO 2023 recommendations favour Artesunate as the preferred choice, since it takes ~4 hours to achieve adequate quinine levels even after the loading dose. If artesunate is not available, artemether should be used in preference to quinine for severe malaria.

Children weighing <20 kg should receive a higher dose of artesunate (3 mg/kg per dose) than larger

TABLE 10.56: Treatment of uncomplicated malaria

***P. VIVAX* MALARIA**	
PO Chloroquine*	10 mg/kg on day 1 and 2, then 5 mg/kg on day 3 followed by
PO Primaquine	0.25 mg/kg × 14 days
***P. FALCIPARUM* MALARIA**	
In Rest of India (Other than NE states)	
PO Artesunate	4 mg/kg/d × 3 days and
PO PYM+SLF**	1.25 mg/kg on Day 1,
With PO Primaquine	0.75 mg/kg on Day 2
In North-eastern states:	
PO Artemether + Lumifantrine combination	
5–14 kg : 20 + 120 mg BD × 3 days	
15–24 kg : 40 + 240 mg BD × 3 days	
25–34 kg: 60 + 360 mg BD × 3 days	
>34 kg: 80 + 480 mg BD × 3 days	
With PO Primaquine	0.75 mg/kg on Day 2
MIXED MALARIA	
Same as for Pf malaria with	
PO Primaquine	0.25 mg/kg × 14 days

**Pyrimethamine + sulfadoxine, not to be used <5 months

TABLE 10.57: Treatment of severe malaria (Any one)

Quinine[1, 2]	IV 20 mg/kg (Loading), **then...**
	IV/PO 10 mg/kg 8-hrly × 7 days, **with**
	PO Doxycycline 100 mg OD × 7 days (>8 yr) **or**
	PO Clindamycin 20 mg/kg q12hr × 7 days (<8 yr)
Artesunate[3]	IV 2.4 mg/kg (at 0, 12 and 24 hours) **then...**
	IV 2.4 mg/kg OD till PO treatment is possible, **then...**
	PO area-specific ACT, full course
Artemether[4]	IM 3.2 mg/kg (Loading), **then...**
	IV 1.6 mg/kg OD till PO treatment is possible, **then...**
	PO area-specific ACT, full course

[1] Diluted in 5% DW (2 mg/ml) and infused slowly over 2–4 hours.
[2] No loading dose, if received quinine in preceding 12 hours.
[3] Dilute with 3–5 ml of 5% DW and given as bolus.
[4] IM Artemether is given as deep IM and not IV.

children and adults (2.4 mg/kg per dose) to ensure equivalent exposure to the drug.

Following initial parenteral therapy, PO Doxycycline (3.5 mg/kg OD in children >8 yrs) or PO Clindamycin (10 mg/kg BD in younger children < 8 yrs) for 7 days must be added to prevent development of resistance. However, WHO 2023 recommends switch-over to oral ACT for 3 days due to poor adherence for 7-day treatment regimens using doxycycline or clindamycin.

Intensive care with supportive therapy is also essential in these cases, including:

- Restoration of fluid and electrolyte balance, with early correction of metabolic acidosis. However, over-hydration must be avoided to prevent pulmonary edema.
- Regular monitoring of blood sugar for early detection and treatment of hypoglycemia.
- Correction of anemia with transfusions or preferably partial exchange transfusion, which also helps to reduce parasite load.
- Control of seizures with anticonvulsants, e.g. phenobarbitone or diazepam.
- Organ-specific supportive management, as required.
- Treatment of cerebral malaria, the commonest form of severe malaria is discussed in Ch 18.12.6.

Treatment failure in malaria is defined as failure of the fever and/or parasitemia to resolve or recur after treatment within 28 days, further classified as e*arly treatment failure* (no response in 3 days) or *late treatment failure* (4–28 days). Absence of parasitemia on day 28 is considered as adequate clinical and parasitological response (ACPR). All cases of treatment failure are not due to drug resistance and many may represent recrudescence or relapse due to inadequate treatment or re-infection.

Management of these cases, as per current WHO recommendation (2023) is as follows:

- Recurrence of fever or parasitemia within 28 days is more likely due to recrudescence of infection and must be treated second-line treatment, i.e. an alternative ACT known to be effective in the region.
- Recurrence of fever and parasitaemia after 28 days of treatment may be due to either recrudescence, relapse or re-infection. Distinction can be made only by PCR genotyping of parasites from the initial and the recurrent infections. Since PCR is not routinely used in patient management, all presumed treatment failures after 4 weeks of initial treatment should be considered new infections and treated with the first-line ACT. However, reuse of mefloquine within 60 days of first treatment is not recommended due to increased risk for neuropsychiatric reactions.

Prevention: Malaria control strategies in India have been revised periodically, to meet the changing epidemiology, occurrence of outbreaks, drug-resistance and insecticide resistance in vectors.

Malaria vaccines: More than thirty vaccines against Pf malaria are at pre-clinical and clinical stages of evaluation, acting on different stages of the parasite. However, RTS, S (Mosquirix®) is the only vaccine licensed on pilot basis in three sub-Saharan African countries – Ghana, Kenya and Malawi, and has shown significant reduction in prevalence as well as severity of falciparum malaria (Ch 9.2.4). An indigenous malaria vaccine, developed by Serum Institute of India, Pune has also been approved recently and, is expected to available soon.

National Vector Borne Diseases Control Programme (Malaria)

Malaria control strategies in India date back to 1953 with launching of National Malaria Control Programme, which has been subsequently modified many times, presently being the part of National Vector-borne Disease Control Programme (NVBDCP), since 2002. Important components of this program are as follows:

a. **Early diagnosis and management** of malaria cases to reduce the reservoir by:
   - *Passive surveillance*, i.e. examination of peripheral smear in all febrile cases, covering at least 10% of total population, annually.
   - *Standardized protocols for diagnosis*, including use of rapid diagnostic tests in areas where microscopy facility is not available.
   - *Standardized protocols for treatment*, including use of artemisinin-combination therapy in falciparum malaria due to high frequency of chloroquine-resistance.
   - Radical treatment of confirmed vivax malaria for 14 days.
   - *Presumptive anti-malarial therapy* is no longer recommended except in cases from endemic regions with high suspicion of malaria, provided microscopy result is not available within 24 hours and bivalent RDT is not possible. In such cases, full 3-days course of chloroquine is recommended without Primaquine, which should be used only in confirmed cases. Treatment must be modified after smear or RDT results.

b. **Chemoprophylaxis** is indicated only selective groups, e.g. military personals, travelling to high *Pf* endemic areas, along with other personal protection measures, e.g. insecticide-treated nets.
   - *Short-term chemoprophylaxis* (<6 weeks) involves PO Doxycycline 1.5 mg/kg OD from 2 days before to 4 weeks after the exposure. It is contraindicated in children <8 years or pregnant women.

  - *Longer chemoprophylaxis* (>6 weeks) is advised only in adults (not children) with PO Mefloquine 250 mg/week from 2 days before to 4 weeks after the exposure. It is contraindicated in individuals with history of convulsions, neuropsychiatric problems and cardiac conditions.

c. **Vector control** to reduce the transmission, by:
  - *Anti-adult mosquito measures*, e.g. residual spraying/fogging, with DDT, malathion, fenitrothion, etc.
  - *Anti-larval measures*, e.g. source reduction (reducing breeding sites), use of chemical larvicidals (oil, temphos) or biological agents, e.g. fishes.
  - *Personal protection measures*, e.g. nets, repellents, etc.

d. **Information, education and communication** (IEC) campaign is intensified during pre-monsoon season, i.e. June (declared as anti-malaria month).

e. **Ancillary activities,** e.g. research, training, etc.

National Framework of Malaria Elimination (2016-2030)

In line with the WHO Global Technical Strategy for Malaria 2016–2030, National Framework for Malaria Elimination 2016-2030 outlines India's strategy for elimination of the disease by 2030 with well-defined goals, strategies, targets and timelines. It aims to: (a) eliminate malaria (zero indigenous cases) throughout the entire country by 2030, (b) maintain malaria–free status in areas where malaria transmission has been interrupted, and (c) prevent re-introduction of malaria.

10.34 KALA-AZAR

Leishmaniasis denotes varied presentations of infection with multiple species of an intracellular parasite—*Leishmania;* while the term *kala-azar* refers to typical manifestations of *visceral leishmaniasis*, i.e. prolonged pyrexia, gross splenomegaly, anemia, dark pigmentation of skin and failure to thrive.

In India, leishmaniasis is still seen in four states: Bihar, Uttar Pradesh, Jharkhand and West Bengal, though number of cases have declined by over 98% in last decade and India aims to eliminate Kala-azar by 2023.

Epidemiology: Indian kala-azar is mainly caused by *L. donovani*, which is dimorphic in life cycle—aflagellate *promastigote form* in the vector and an aflagellate *amastigote form* in macrophages of human host.

Reservoir of infection is an infected human host, harboring amastigote forms within reticuloendothelial system and, intermittently in peripheral smear.

Mode of transmission is vector-borne, by a female sandfly—*phlebotomus,* which breeds in the hot-humid climate and gets infected after biting infected humans. In the vector, parasite assumes a promastigote form (*leptomonads*) to proliferate in gut and then ascends to pharynx during next 6–9 days (*extrinsic incubation period*).

Pathogenesis: After infected bite, parasite enters into macrophages to transform in amastigote form (Leishmania bodies or LD bodies) and replicates intracellularly. These infected macrophages eventually concentrate in spleen, liver and bone marrow, leading to *hyperplasia of reticuloendothelial system*-pathological hallmark of disease. Rarely, congenital and blood-borne transmission have been reported.

Clinical spectrum depend on the susceptibility and nutrition of the host as well as virulence and size of inoculums:

- ***Sub-clinical infection*** is more common than clinical disease, identified by a delayed hypersensitivity response to leishmania antigens (*Montenegro skin test*)
- ***Visceral leishmaniasis (kala-azar),*** is the commonest manifestation in children **(Fig. 10.19)** after an incubation period of 2–6 months, with (i) *Intermittent fever* without significant constitutional symptoms, (ii) *Gross splenomegaly* with hepatomegaly, (iii) Moderate to severe *anemia* and *weight loss*, and (iv) dry, rough skin with dark pigmentation (kala-azar) over forehead, face and bony prominences.

  Typical *double-rise fever* of kala-azar is uncommon in children. Long-standing cases may develop signs of *hypersplenism*, i.e. severe anemia, bleeding tendency and recurrent infections, as well as signs of *hepatocellular failure,* e.g. jaundice, edema and ascites. Untreated cases are usually fatal.
- ***Post kala-azar dermal leishmaniasis*** is rare in childhood, seen after many years of treatment and cure of visceral disease with development of multiple hypopigmented, erythematous or nodular lesions over face, back and extensor aspect of extremities, which persist for many years before disappearance.

Fig. 10.19: **Kala-azar: Clinical (cachexia with splenomegaly).**

- ***Rare presentations,*** uncommon in India, include localized or diffuse cutaneous leishmaniasis (O*riental sore*) or mucosal leishmaniasis.

Kala-azar in HIV-infected population is an opportunistic infection, presenting as reactivation of old infection with prominent GIT involvement, without significant splenohepatomegaly.

Diagnosis depends on:

- *Clinical tetrad* of gross splenomegaly, anemia, failure to thrive and skin pigmentation, with/without fever, in a case from endemic region.
- Rapid diagnostic kits based on the antibody immunoassay with >90% sensitivity and specificity
- *Demonstration of LD bodies*, in splenic aspirate (>95%) or bone marrow aspirate (60–70%) **(Fig. 10.20)**.
- *Parasitic culture* from above samples on *Novy-McNeal-Nicolle* (NNN) media, are less sensitive but allow detection of promastigote form and species identification for epidemiological studies.
- *Serological tests*, e.g. ELISA test, using K39 antigen, is ~100% sensitive and specific. Others, e.g. indirect fluorescent antibody test are sensitive but do not differentiate between active and past infection.
- *Other laboratory abnormalities* include moderate anemia, leukopenia, thrombocytopenia and hypergammaglobulinemia (> 5 gm/dl).

Aldehyde test (Napier test) is a screening test, based on development of hypergammaglobulinemia in kala-azar. Add 1–2 drops of formalin in 1 ml of patient's serum. Milky-white opacification within 30 minutes indicates positive result. Test is positive after 2–3 months of the onset of illness and turns negative by 6 months of cure.

Leishmanin test-an intradermal test to assess cutaneous reaction to a promastigote suspension (leishmanin), is of no use for diagnosis of active kala-azar, but helps to distinguish immune (>5 mm induration) from non-immune subjects for epidemiological studies.

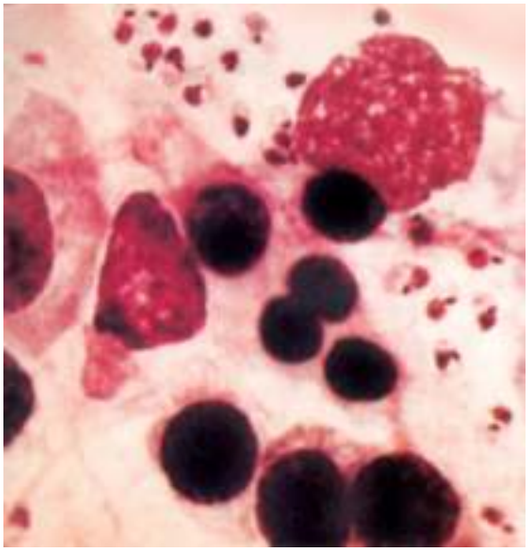

Fig. 10.20: Kala-azar: LD bodies (amastigote form of *L. donovani*).

Management of kala-azar aims to achieve clinical and parasitic cure, as well as to prevent relapses, by specific therapy and supportive measures, e.g. correction of anemia, undernutrition and intercurrent infections.

According to *operational guidelines for elimination of kala-azar in India 2015*, based on WHO recommendation, current treatment guidelines are as follows:

- Single-dose *Liposomal Amphotericin* (IV 10 mg/kg, infused over 2 hours) is the treatment of choice for all ages, including children.
- PO *Miltefosine* (2.5 mg/kg/d OD) for 28 days is an equally effective option with oral convenience, but should not be used in children <2 years, pregnant and lactating women and cases with Co-HIV infection.
- Amphotericin B deoxycholate (IV 1 mg/kg/dose over 8 hrs x 15 doses) may be used in refractory cases.
- Combination of Miltefosine (PO 2.5 mg/kg/d OD) *with* Paromomycin (IM 11 mg/kg/dose OD) for 10 days may be used, if IV liposomal amphotericin infusion is not possible.

Other drugs, e.g. sodium stibogluconate, pentamidine, etc. are no longer recommended due to treatment failures and toxicity. Oral therapy with ketoconazole or allopurinol is effective in cutaneous leishmaniasis but has no role in kala-azar.

Splenectomy is indicated only in cases with massive splenomegaly on the verge of rupture or associated hypersplenism.

All treated cases should be reassessed with splenic/marrow aspirate after 3 months to exclude late relapse, which should be treated as a fresh case.

Prevention of kala-azar depends on: (a) *controlling the source*, i.e. identification and adequate therapy of infected cases, (b) *controlling the vector* by residual insecticide sprays and sanitation measures, and (c) *personal prophylaxis* against mosquito bite by repellents and nets.

National Kala-azar Elimination Programme (2010) aims to reduce the annual incidence to < 1/10000 population at block PHC level in endemic districts and is being implemented under NVBDCP involving: (a) early diagnosis and complete case management, (b) integrated vector management and vector surveillance, (c) supervision, monitoring, surveillance and evaluation, and (d) IEC activities, with inter-sectoral convergence.

10.35 FILARIASIS

About 2/3rd of filaria cases in world are from three Asian countries, i.e. China, India and Indonesia. It is endemic

all over India, except in some northern and north-eastern states. National Health Policy (2017) aims to eliminate filaria, defined as achieving microfilaria rate of <1:10000 population in endemic regions.

Epidemiology: In India, 98% cases of filariasis are caused by *W. bancrofti*, and rest by a closely related *Brugia malayi* infection, limited to certain districts of Kerala.

Reservoir of infection is an infected man, harbouring adult worms of ~4–5 cm size in lymphatic system that live for many years. Female worm produces ~ 50,000 *microfilaria* (Mf) per day, which enter the circulation via lymphatics, usually at midnight (*nocturnal periodicity*).

Mode of transmission is a vector (Mosquito)-C*ulex fatigans* for bancroftian filariasis and *Mansonia annulifera* for brugian infection. After an infected feed, Mf exsheath in mosquito gut to develop as infective larva (10–14 days), which migrate to proboscis and injected into new human host during next bite.

After the infected bite in humans, infective larva are deposited near puncture-site and enter lymphatics, where they reside and develop as adult worm to produce Mf.

Clinical manifestations develop only in a small percentage of infected population, less common in children than adults and present as: (a) lymphatic filariasis, or (b) occult filariasis.

- ***Lymphatic filariasis*** may present as:
  - *Asymptomatic microfilaremia,* detected on night-smear examinations in endemic zones,
  - *Acute filariasis* in initial months of infection, with recurrent episodes of fever, lymphangitis, lymphadenitis, lymphedema and epididymo-orchitis, and
  - *Chronic lymphatic obstruction* due to fibrosis and block of lymphatic channels after many years, e.g. elephantiasis, hydrocele and chyluria (very rare in childhood).
- ***Occult filariasis,*** without signs of lymphatic disease, is more common in children and presents with tropical pulmonary eosinophilia or other immunological disturbances, e.g. arthritis, proteinuria, etc.

Diagnosis usually depends on:

- *Clinical features* of acute/obstructive disease in endemic area, supported by,
- *Night-smear:* Demonstration of Mf in thick peripheral smear **(Fig. 10.21)**, collected around mid-night *or* after one hour of 100 mg PO diethylcarbamazine administration (*Provocation test*);
- *Serodiagnosis* i.e demonstration of filarial antigens/antibodies, and
- *Biopsy/radiology* of affected part showing calcified, dead or living worm/s.

Fig. 10.21: Microfilaria: Peripheral smear.

TABLE 10.58: Diagnostic criteria for TPE

- Typical clinical episodes in endemic region
- Hypersensitivity indicators:
  - Absolute eosinophil count >3000 cells/mm^3
  - Elevated IgE levels (>1000 IU/ml)
  - Presence of anti-Mf antibodies
- Therapeutic response to DEC therapy

Treatment: Role of anti-filarial drugs in acute filariasis or chronic obstructive disease is controversial, as these drugs have no effect of infective larvae or ? adult worms. However, all Mf positive cases need specific therapy to reduce parasite load, as follows:

- PO *diethylcarbamazine* or DEC (6 mg/kg/d q8hr) for 14–21 days. Some workers recommend lower dose on first 2–3 days to avoid hypersensitivity reactions due to rapid death of Mf.
- PO *Ivermectin* (20–200 mg/kg) with/without PO albendazole (400 mg), as a single dose is equally effective to clear microfilaremia.

Tropical pulmonary eosinophilia is a common hypersensitivity manifestation against Mf or ? adult worms in school children of endemic regions.

Clinically these cases present with recurrent and paroxysmal asthma-like episodes of dry cough, wheeze and dyspnea; with/without mild fever, anorexia, hepatosplenomegaly and lymphadenopathy. Recurrent episodes may lead to interstitial fibrosis and chronic respiratory insufficiency.

Diagnosis rests on *a diagnostic criteria* **(Table 10.58)** among residents of an endemic region. Night smears for Mf may/may not be positive. X-ray chest may be normal except bronchovesicular prominence or reveals typical *miliary mottling*.

D/D of TPE includes other causes of paroxysmal cough with eosinophilia, e.g. asthma, Loeffler syndrome, drug allergy, fungal infections, sarcoidosis, lymphomas and rare hypereosinophilic syndromes.

Treatment involves oral DEC therapy for 21 days, which may be repeated in cases with partial response. Response is monitored clinically and by absolute eosinophil counts.

10.36 INTESTINAL PROTOZOAL INFECTIONS

Two most common intestinal protozoal infections in children include Amebiasis and Giardiasis, discussed here.

10.36.1 AMEBIASIS

Amebiasis, a common waterborne illness in India, is relatively less common in children than adults.

Epidemiology: Causative protozoan *Entamoeba histolytica* exists in two different forms—*cysts*, in contaminated water/food; and *trophozoites* in human intestines. Infection is acquired feco-orally on ingestion of parasitic cysts (not by trophozoites, which rapidly degenerate by gastric acid).

On ingestion, each cyst liberates eight trophozoites in small intestines, which are passed further to attach and penetrate colonic mucosa. Some trophozoites *encyst* again, to be excreted in stools.

Invasive trophozoites may multiply locally to produce *flask-shaped colonic ulcers* in cecum, transverse and sigmoid colon (*intestinal disease*) or enter portal circulation to invade liver (*extra-intestinal disease*).

Minimal local inflammatory response in colonic ulcers or at the site of extraintestinal disease is pathognomonic of amebic lesions.

Clinical spectrum: 90% of amebic infections are asymptomatic except intermittent passage of cysts in the stools (*carriers*). Symptomatic disease may be intestinal and extra-intestinal:

- ***Intestinal amebiasis*** manifests after 2–3 weeks of infection with gradual onset of: (a) diarrhea or dysentery with blood and mucus, (b) colicky abdominal pain or sense of fullness, (c) vague tenderness over iliac region, and (d) characteristic absence of constitutional features, e.g. high fever, toxemia, etc.

  Rare cases develop chronic colitis with recurrent bouts of dysentery and abdominal cramps, often confused with inflammatory bowel disease.
- ***Extraintestinal amebiasis*** is seen in <1% of infected cases, usually as hepatic abscess. Rarely, these abscesses may rupture in peritoneum, plural space or through the skin.

Amebic liver abscess usually involves the right lobe and may be single or multiple, filled with typical *anchovy-sauce* colored sterile pus. These cases present with—(a) fever with chills/rigors, (b) right hypogastric pain, and (c) tender hepatomegaly on deep palpation. History of intestinal disease and stool examination is negative in >50% cases.

TABLE 10.59: Common anti-amebic agents

Luminal amebicides		
Diloxanide fuorate	PO	20 mg/kg/d q8hr × 7 days
Di-iodoquinol	PO	30 mg/kg/d q8hr × 10 days
Paromomycin	PO	25–35 mg/kg/d q8hr × 7 days
Tissue amebicides		
Metronidazole*	PO	30–50 mg/kg/d q8hr × 10 days
Tinidazole	PO	50 mg/kg/d q24hr × 3 days
Secnidazole	PO	30 mg/kg single dose
Nitazoxanide	PO	100–500 mg BD × 3 days**

*or 20 mg/kg/d IV
**100 mg (1–3 yr), 200 mg (3–12 yr), 500 mg (>12 yr)

Diagnosis of *intestinal amebiasis* is confirmed by stool examination for cysts/trophozoites **(Fig. 14.2)**, while extraintestinal disease may be diagnosed by—(a) USG, (b) aspiration of suspected lesion to reveal *anchovy-sauce* pus with paucity of granulocytes, (c) indirect hemagglutination test (>1:128) with ~ 95% sensitivity.

Management: All children with *E. histolytica* in stools, even if asymptomatic, need to be treated. Metronidazole is the drug of choice for intestinal as well as extraintestinal disease, while luminal amebicides are preferred in asymptomatic case to eradicate carrier stage.

- *In symptomatic intestinal amebiasis*, a course of tissue amebicide, e.g. Metronidazole, Tinidazole or Nitazoxanide should be followed by a course of luminal amebicide, e.g. Diloxanide, paromomycin or Di-iodoquinol to ensure complete parasitic clearance **(Table 10.59)**.
- *In extra-intestinal amebiasis*, IV Metronidazole (20 mg/kg/day q12hr) is used for first few days, followed by oral therapy. Dehydroemetine or chloroquine are very rarely used in children. Amebic abscess needs to be drained only if-(a) poor therapeutic response after one week, (b) massive abscess with impending rupture.

Prevention depends on proper sanitation measures and boiling of drinking water. *Chlorination in usual doses is ineffective to destroy the parasite*. Stool examination of all cases and carriers should be repeated after 2 weeks of therapy to ensure parasitic clearance.

10.36.2 GIARDIASIS

Giardiasis is a common cause of chronic diarrhea or malabsorption in children, especially those with *poor sanitation, malnutrition, immunodeficiency states and institutionalization*, e.g. daycare centers or orphanages.

Epidemiology: *Giardia lamblia* exists in two stages—*cysts* in the environment and *trophozoites* in intestinal lumen. Infection is acquired feco-orally, after ingestion of contaminated water.

After ingestion, each cyst liberates 2–4 trophozoites, which colonize the *duodenum and proximal jejunum* (site of infestation) by attaching themselves to brush borders with their powerful sucking discs. Later, some detached trophozoites pass-down and encyst again, to appear in stools for further transmission.

Malabsorption in Giardia-infested children is attributed to—(a) mechanical damage to microvilli by trophozoite discs, causing disaccharidase deficiency, (b) pancreatic injury with reduced tryptic activity and (c) bacterial overgrowth in duodenum, causing bile-salt deconjugation.

Clinical manifestations: After incubation period of 1–2 weeks, giardiasis may manifest as:

- Asymptomatic excretion of cysts (carriers),
- Acute, explosive, watery, foul-smelling diarrhea, lasting for 3–4 days,
- Chronic malabsorption with intermittent diarrhea, steatorrhea, flatulence and failure to thrive.

Diagnosis requires demonstration of cysts or trophozoites in stools or *duodenal aspirate/biopsy*, later being the best specimen to detect asymptomatic infestation. At least 3 fresh stool samples should be examined for giardia, collected on alternate day after discontinuation of anti-parasite drugs **(Fig. 14.2)**.

Serodiagnosis of giardia antigen in stools, using monoclonal antibodies is possible, but rarely used.

Management: All cases including asymptomatic carriers need treatment with:

- PO Metronidazole (15 mg/kg/day q8hr) for 5 days, *or*
- PO Tinidazole (50 mg/kg single dose above 3 years), *or*
- PO Nitazoxanide (100 mg 1–3 yr, 200 mg 3–12 yr, 500 mg >12 yr per dose, BD × 3 days), or
- PO Albendazole (400 mg OD × 5 days, above 6 years)

Repeat stool exam is necessary to ensure eradication of infection. Persistence of infection despite repeated therapy indicates possible immunodeficiency state.

Prevention depends on improved sanitation and safe water supply. Micropore filtration (<5 mm) or boiling of drinking water is effective to eliminate/kill the cysts, but *chlorination in usual doses or ultraviolet radiation is ineffective.*

10.37 INTESTINAL WORM INFESTATIONS

Intestinal worm infestations are estimated to be present in ~20% of under-five children in India and WHO classifies India as a moderated-risk country for worm infestations. Some important worm infestations in children are as follows.

Ascariasis: Ascariasis (*round worm*) is the ubiquitous worm infestation of mainly pre-school and early-schoolchildren, specially in low-hygiene population.

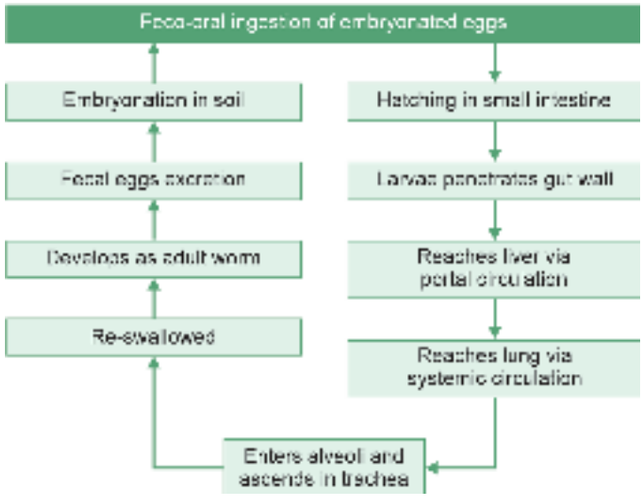

Fig. 10.22: **Life cycle of *Ascaris lumbricoidus*.**

Life-cycle: Heterosexual adult worm (*A. lumbricoidus*) lives in small intestine, with a lifespan of 1–2 years. Female worms are longer (20–30 cm) than males (12–20 cm) and lay up to 2 lac eggs/day, which are excreted in feces. These eggs embryonate in soil and turn infective after 2–3 weeks.

Infective (larva-containing) eggs are *feco-orally* transmitted to another host via soil-contaminated fingers or uncooked food items. Promiscuous defecation and use of human feces as manure are two important risk factors in transmission.

On ingestion, eggs hatch in small intestine and larva penetrate the gut wall to reach the liver and then the lungs via blood stream. In lungs, they mould twice before breaking alveolar walls to enter bronchioles, ascend to trachea and re-swallowed. On reaching the intestine second-time, these larvae develop into mature worms, lay eggs and continue the cycle **(Fig. 10.22)**.

Clinically, ascariasis is asymptomatic or present with:

- *Vague features,* e.g. abdominal discomfort, malabsorption and undernutrition in heavy infestation.
- *Mechanical obstruction,* e.g. airway obstruction during larval migration, intestinal obstruction due to mass of adult worms, or rarely, biliary obstruction by migrating worm with obstructive jaundice.
- *Immune-mediated* pulmonary manifestations, e.g. Loffler-like syndrome.
- Passage of adult worms in stools/vomitus.

Diagnosis depends on: (a) history of passing worms in stools/vomitus, *or* (b) stool microscopy (*Kato's thick smear*) to demonstrate presence of fertilized/unfertilized eggs **(Fig. 14.2)**. Presence of fertilized eggs in stool indicates bi-sexual infestation.

Treatment of choice is single oral dose of Albendazole 400 mg (200 mg < 2 yrs). Alternatives include other oral wormicidal drugs, e.g. Mebendazole (100 mg BD x 3 days)

or Ivermectin (150–200 µg/kg once). Nitazoxanide, a broad-spectrum drug may also be used orally as 100 mg BD x 3 days (400 mg BD in 4–12 years age group and 500 mg BD in adolescents).

In cases with intestinal or biliary obstruction, *Piperazine citrate* is preferred due to its neuroparalytic reaction on worms, which facilitates their expulsion. Surgical intervention may be needed in cases with severe obstruction.

Prevention: Community load of round worm may be reduced by: (a) mass deworming of pre-school children every 3–6 months, (b) hygienic sanitary/excreta-disposal practices, and (c) reduced use of human feces as manure.

Toxocariasis *(visceral* or *ocular larva migrans)* is an accidental human infestation by primarily zoonotic ascarids, i.e. *T. canis* (dogs) or *T. catis* (cats).

Life-cycle involves excretion of eggs in animal excreta > accidental feco-oral infection of children via contaminated fingers or food > hatching and larval release > gut penetration > migration to different tissues, e.g. lungs, liver, eyes, brain, etc. Toxocara larva do not develop beyond this stage in human host (*no adult worms*).

Clinically, these cases may present with: (a) *immunological reactions*, e.g. fever, hepatomegaly, urticaria, Loffler syndrome, or (b) *mechanical damage* due to migrating larvae, e.g. sudden decrease in visual acuity or blindness (*ocular larva migrans*).

Diagnosis rests on visualization of larvae in the tissues or an antibody-ELISA test (rarely available). History of frequent dog/cat exposure and eosinophilia is common.

Treatment is non-specific, including steroids for allergic manifestations, e.g. urticaria or Loffler syndrome. Antihelminthic therapy (PO Albendazole 400 mg BD × 5 days) is indicated only in symptomatic cases, along with steroids to reduce inflammatory response to antigens released from dying parasites. Longer therapy for 3–4 weeks is needed in ocular or neurological disease.

Enterobiasis: Enterobiasis (*Threadworm or Pinworm*) is the commonest worm infestation in pre-school children, which is essentially harmless except inconvenient perianal itching.

Life-cycle: Causative adult worm *E. vermicularis* is ~0.5–1 cm in size and lives in caecal region of infested human host. Gravid female migrates externally through the anus during night, to lay eggs over perianal area. These eggs mature here as infecting larvae in 6 hours and remain viable for next 20 hours.

While a new host is infected feco-orally, same host may also be re-infected by *auto-inoculation* of eggs, carried under fingernails after perianal scratching. On ingestion, these eggs hatch in stomach, larvae migrate to caecal region and mature as adult worms to continue the cycle **(Fig. 10.23)**.

Fig. 10.23: Life cycle of *E. vermicularis*.

Clinically, *nocturnal perianal pruritis* is the commonest manifestation of enterobiasis, leading to disturbed sleep. Very rarely, perianal granuloma containing live/dead worms or eggs have been reported.

Diagnosis: As eggs are generally not passed in stools, definitive diagnosis depends on demonstration of eggs **(Fig. 14.2)** in perianal region *or* adult worms in stools or at perineal region.

Best method to demonstrate enterobius eggs is to stick an adhesive cellophane tape against perianal region in early morning and examine under microscope.

Treatment of choice is single oral dose of Albendazole 400 mg (200 mg < 2 years), though alternatives include other wormicidals, e.g. Mebendazole (100 mg once) or Pyrantel Pamoate (11 mg/kg base TDS x 1 day). It is to be noted that:

- Treatment should be repeated after 2 weeks in all cases, to eradicate residual infestation, and
- All family members should be treated simultaneously, to prevent cross-infection.

Soothing creams, e.g. crotamitone, may be applied to relieve perianal itching and prevent auto-inoculation.

Prevention: Personal cleanliness with regular trimming of nails and periodic de-worming of susceptible population are important measures to prevent threadworm infestations.

Trichuriasis (Whipworm) is a common infestation in children, though rarely diagnosed due to lack of symptoms.

Life cycle: Adult worm *T. trichuria* (~ 3–4 cm) lives in cecum and ascending colon, firmly anchored to mucosa to suck ~ 0.005 ml blood/day. Infection is transmitted feco-orally, on ingestion of embryonated eggs in contaminated hands, food or water.

Clinical manifestations are rare and include: (a) vague abdominal discomfort, e.g. colic or distension, or (b) mild anemia, bloody diarrhea or rarely rectal prolapse in heavily parasitized host.

Diagnosis depends on stool examination for typical eggs **(Fig. 14.2)**.

Treatment of choice is PO Albendazole 400 mg x 3 days (200 mg < 2 years), though alternatives include PO Mebendazole 100 mg BD or Ivermectin 200 µg/kg/d, both for 3 days.

Ankylostomiasis: Ankylostomiasis (*Hookworm* infestation) is an important cause of iron deficiency anemia in Indian children, usually caused by *Ancylostoma duodenale,* and occasionally by *Necator amaricanus*.

Life cycle: Hetrosexual adult worm (5–13 mm) lives in small intestine, firmly attached to the gut mucosa with their typical hooks or teeth. Female worms produce up to 30,000 eggs/day, which are excreted in stools to develop as infective larvae in warm and damp soil.

Infection is usually acquired via *cutaneous penetration* over feet, especially in bare-foot walkers (rarely feco-oral). After skin-penetration, larvae enter the venous circulation to reach lungs, where it comes out of the vascular bed to enter in alveoli, ascend into airways and get swallowed. On reaching the small intestine, it develops into adult worms, attaches itself to intestinal walls and starts oviposition **(Fig. 10.24)**.

Bare-foot walking on infested soil, poor sanitary conditions and use of human feces as manure, are the main risk factors for hookworm infestation, which is common in rural and slum population.

Clinically, *anemia* due to intestinal blood loss by hooked attachment of adult worms is the most important manifestation of ankylostomiasis and its severity depends on worm-load. *Each adult worm is responsible for ~ 0.2–0.3 ml of blood loss per day*.

Other manifestations include: (a) non-specific GIT problems, e.g. abdominal pain, anorexia, diarrhea, and melena; (b) localized itching (*ground-itch*) at the site of skin entry*, and rarely, (c) transient stridor or pharyngitis, during airway migration of larvae.

*Typical *cutaneous larva migrans* is seen only with some zoonotic worms, e.g. A. braziliense.

Diagnosis should be suspected in cases with unexplained anemia and occult blood in stools, confirmed on stool examination for eggs **(Fig. 14.2)**.

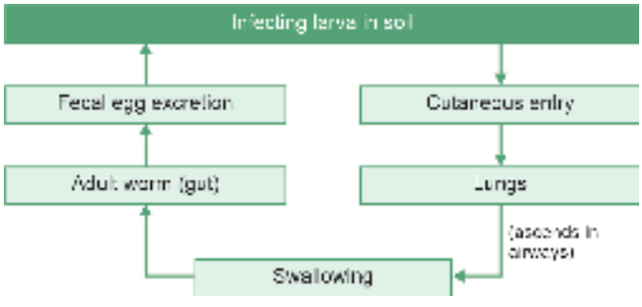

Fig. 10.24: **Life cycle of Hookworm *(A. duodenale)***.

Treatment of choice includes single oral dose of *Albendazole* 400 mg (200 mg < 2 years), though alternatives include other oral wormicidal agents, e.g. Mebendazole 100 mg BD x 3 days or Pyrantal pamoate 11mg/kg/day OD for 3 days. Repeated doses may be required for complete eradication.

In addition, these patients also need correction of anemia by oral iron therapy or rarely blood transfusions.

Prevention depends on community measures, e.g. (a) periodic deworming, (b) avoidance of bare-foot walking, (c) improvement of sanitation and excreta disposal, and (d) reduced use of fecal manure.

Strongyloidosis *(S. stercolaris)* is an uncommon infestation, acquired via skin penetration by infective larvae in feces-contaminated soil.

Life-cycle is similar to hookworm, except that eggs often hatch *in vivo* during intestinal passage and infective larvae re-enters the circulation by penetrating intestine walls or perianal skin (*auto-inoculation)*.

Clinically, it is asymptomatic or present with: (a) perianal itching due to auto-inoculation (*larva currens)*, (b) Loeffler's-like syndrome with eosionophilia due to larval migration through lungs, (c) malabsorption syndrome in heavy infestations, and (d) rarely, *disseminated strongyloidosis*—a septicemia-like illness in severely malnourished or immunocompromised children.

Diagnosis depends on examination of stools or duodenal aspirate for characteristic larvae.

Treatment: PO Ivermectin (200 µg/kg/d) for 1–2 days is the drug of choice. PO Thiabendazole 50 mg/kg/d q12hr is an alternative, specially in disseminated disease.

Cestodal (Tapeworm) infestations: Human cestodal (tapeworm) infestations present in two forms—(a) *intestinal infestation* by adult worms, and (b) *tissue infestations* by invasive stages, e.g. hydatid cyst and neurocysticercosis.

a. ***Intestinal tapeworm infestations*** are less common in children than in adults, caused by *Taenia solium* (Pork tapeworm), *T. saginata* (Beef tapeworm), *Diphyllobothrium latum* (Fish tapeworm) and *Hymenolepis nana* (Dwarf tapeworm).

Life-cycle: These infestations are acquired by ingestion of—(a) parasitic eggs, present in contaminated soil/water or over the body of intermediate hosts; *or* (b) uncooked beef, pork or fish, containing invasive stages of parasite.

Adult tapeworms are present only in human intestines and have long, segmented (*proglottids*) bodies of variable length (fish tapeworm is longest, 10–20 meters). On maturation, caudal gravid segments detach intermittently to pass in stools and release eggs in the soil.

Although entire life-cycle may be completed in humans alone (except *D. latum**), animals, e.g. dogs, pigs, cattle, etc. are frequently infected by ingestion of egg-contaminated soil *or* invasive-stage-contaminated flesh of infected animals, to contribute in propagation of disease (*Co-hosts*).

**D. latum* requires hatching of eggs in fresh water and subsequent passage of embryo through two intermediate hosts, i.e. *copepods*—small crustaceans, which swallow the eggs/larvae and *fishes* that eat these crustaceans, before re-infecting humans on ingestion of uncooked fish.

Clinically, intestinal tapeworm infestation is asymptomatic or presents with vague abdominal complaints, except *D. latum infestation, which may cause megaloblastic anemia* by inhibiting vitamin B12 absorption and utilizing it for own metabolism.

Diagnosis depends on presence of proglottids (on naked eye) or eggs (on microscopy), in stools *or* rectal swabs.

Treatment of choice for all intestinal tapeworms is single oral dose of Praziquantel (25 mg/kg) or Niclosamide (50 mg/kg). PO Nitazoxanide 100 mg BD x 3 d (400 mg BD in 4–12 years age group and 500 mg BD in adolescent and adults) may also be used. Simultaneous treatment with polyethylene glycol can increase fecal yield of scolices.

Prevention involves adequate sanitation, proper excreta disposal and avoidance of eating uncooked meat/fish.

b. ***Hydatid cyst*** is caused by intermediate (invasive) form of *Echinococcus granulosus*-a zoonotic tapeworm in dogs or other canines.

Pathogenesis: Humans are accidentally infected by ingestion of the intermediate forms of parasite, present in contaminated water/food or over fecal-contaminated body of infected dogs. Ingested intermediate forms penetrate the gut-wall, carried via lymphatics/blood to liver, lung, bones, etc., and develop into gradually enlarging cysts.

Structurally, these cysts are surrounded by a tough fibrous capsule of host tissue, lined by inner layers of parasitic origin and contain thousands of parasites (*protoscolices*) along with cystic fluid.

Clinically, lung cysts are more common in children, while liver cysts are commoner in adults. Hydatid cysts may be asymptomatic or present with mass effect, i.e. (a) hepatomegaly with palpable mass and pain in liver cysts, (b) cough, hemoptysis and chest pain in lung cysts, and (c) pathological fractures in bone cysts.

Complications include: (a) cyst rupture (spontaneous or during surgery) which may lead to sudden anaphylaxis and/or formation of secondary cysts, and (b) pressure on other structures, e.g. biliary tree with obstructive jaundice.

Diagnosis depends on: (a) *ultrasonography*, i.e. cystic lesion with internal membranes and floating echogenic cyst material (*Hydatid sand*), and (b) *Casoni's skin test*, to detect hypersensitivity against crude or partially purified antigen. It may be false-negative in 50% cases and false-positive in other tissue helminthes, e.g. neurocysticercosis or schistosomiasis.

Treatment depends on the size and site of cyst and includes:

- *Conventional surgical removal* of cyst as a whole (except outer fibrous wall) for large and complicated cysts,
- *PAIR technique*, i.e. USG or CT guided ***p***ercutaneous ***a***spiration > ***i***nstillation of hypertonic saline or other scolicidal agent > ***r***e-aspiration after 15 minutes. PAIR is contraindicated in pregnancy or bile containing cysts.
- *Medical therapy* for multiple, small, deep-seated cysts, with albendazole (PO 7.5 mg/kg BD) for 1–6 months. Medical therapy is also indicated when surgery is contraindicated or one week before and one month after PAIR.

c. ***Neurocysticercosis*** (NCC) is the commonest parasitic infection of CNS, caused by the invasive intermediate stage of *T. solium* (pork tapeworm), with formation of asymptomatic or symptomatic cysts in the brain (*see* Ch 18.12.9 for details).

Trematodal (Fluke) infestations are uncommon in Indian children and characterized by their typical life-cycle involving two hosts-man for sexual phase and snails for asexual phase.

According to preferential tissue-habitat, trematodal infestations are also termed *Blood flukes,* (*Schistosoma hematobium*) *Liver flukes* (*Fasciola hepatica, Clonorchis sinensis*) and *Lung flukes* (*Paragonimus westermani*).

Schistosomiasis is the commonest trematodal infestation, acquired via *cutaneous penetration* by the infective larvae, i.e. *cercariae,* present in contaminated water bodies and on aquatic plants. Post-entry, cercariae migrates via subcutaneous tissue, lungs and liver; and develops as adult worms (sexual stage) that reside in the venous plexus surrounding ureters and urinary bladder.

Oviposition occurs intravascularly and eggs are intermittently excreted in urine, after rupture of invaded capillaries. Further development from egg to infective larvae (asexual stage) occurs only in *fresh-water snails* (intermediate host), to continue the cycle.

Clinically, these cases present with—(a) local pruritic rash at the portal of entry (*Swimmer's itch*), (b) acute febrile illness with eosinophilia after 4–8 weeks of infection (*Katayama fever*), or (c) chronic granulomatous injury at the site of parasitic deposition, e.g. periureteic/perivesicular venous plexus, leading to hematuria.

Diagnosis depends on urine examination for schistosome eggs.

Treatment of choice is PO Praziquantel 20 mg/kg, total two doses at 12-hour interval.

10.38 NOSOCOMIAL INFECTIONS

Nosocomial infections, defined as *infections acquired during or as a result of hospitalization* are major cause of morbidity and mortality in hospitalized children. Generally, *All new infections, manifesting after 48 hours of hospitalization are considered as nosocomial*, unless proved otherwise.

Incidence of nosocomial infections in general hospital wards is estimated to be ~ 3–5%, but may be as high as >40–50% in post-operative wards, intensive care units, high-risk patients, and after prolonged hospitalization.

Epidemiology of nosocomial infections varies from hospital to hospital and even within the hospital from ward to wards.

Sources: Hospital flora is full of pathogenic and seemingly innocuous organisms that keeps on changing time to time. Nosocomial infections may originate from:

- *Inanimate objects*, e.g. (a) hospital floorings, walls, furnitures, fixtures, linens, etc. (b) water supply and sanitation closets, (c) resuscitation or other equipment, e.g. catheters, nebulizers, ventilators, etc., or (d) shared use sources, e.g. suction apparatus, oxygen bottles/tubings, dressings, antiseptic solutions, etc. *or*
- *Animate objects*, e.g. (a) asymptomatic/symptomatic hospital persons, visitors and other patients and (b) patient's own flora, i.e. *auto-inoculation* during aspiration and IV lines.

Mode of infection: Nosocomial infections may be acquired via multiple routes, e.g.

- *Direct contact* with unsterilized equipments or infected hands of hospital personnel,
- *Inhalation* of suspended organisms, i.e. droplet infections,
- *Ingestion* of contaminated hospital-food and medicines,
- *Vector-borne* spread from flies and mosquitoes,
- *Auto-inoculation* from own flora, e.g. aspiration or IV lines.

High-risk factors: Although all patients in a hospital ward are exposed to nearly similar risk for colonization with hospital pathogens, some are more susceptible to develop nosocomial infections than others **(Table 10.60)**. Apart from these host-related factors, infection control practices, antibiotic policy and waste-management policies of the hospital are important determinants of nosocomial infections.

Clinico-microbial profile: Nosocomial infections may be caused by any normal or opportunistic organisms (OIs) present in the hospital environment, depending on the source. Common nosocomial infections in children are as follows:

TABLE 10.60: High-risk host factors for Nosocomial infections

- Newborns and young infants
- Immunocompromized states
- Critically sick, debilitated or unconscious child
- Surgical, oncological or burn cases
- Invasive devices, e.g. vascular catheters
- Prolonged antibiotic therapy
- Prolonged hospitalization

- ***Respiratory tract infections*** account for 25–30% of nosocomial infections, more common in cases with airway interventions (oxygen, nebulizers, ventilators, intubation/tracheostomy) *or* high-riskof aspiration (debilitated or unconscious children). Most of them are caused by *Staph. aureus* and *Pseudomonas.*
- ***Urinary tract infections*** are common in general wards (40–45%), specially prevalent in cases with indwelling urinary catheters, genitourinary surgery and urinary retention/incontinence, these infections are usually caused by *gram negative bacilli,* e.g. Klebsiella; coagulase negative staphylococci (CONS); and enterococci, etc.
- ***Surgical wounds and burn infections*** (5–7%) are common in cases with poor wound drainage or infected dressings. These infections are usually caused by *Staph. aureus, Pseudomonas and CONS*; though enterococcal and anaerobic infections are common in feces-contaminated wounds.
- ***Vascular-catheter related infections*** (~3–5%) are more likely with central vascular lines, prolonged peripheral IV therapy and total parenteral nutrition. Risk of bacteremia/septicemia in these cases is directly related to duration of cannulation. Microbial agents in catheter-related infections are usually derived from normal skin flora, e.g. *CONS, anaerobes and Staph. aureus*, although candidemia is also common after prolonged cannulations.
- ***Gastrointestinal infections,*** e.g. enterocolitis (~8–10%) are common in patients with prolonged antibiotic therapy (*Candida, C. defficile*) or hospital-diet (*Salmonella*).
- ***Skin infections*** of nosocomial etiology are common at IV or monitor-probe sites. Most of them are *staphylococcal* in origin (*Staph. aureus* or CONS), though candidal infections may develop at macerated skin sites, e.g. back-sores.
- ***Immunocompromised hosts*** are specially susceptible for *candidal and anaerobic infections*, as well as serious bacterial infections due to *Staph. aureus* and Pseudomonas.
- ***Transfusion-related infections*** develop immediately after receipt of blood/products, e.g. sepsis, malaria; or after many months/years, e.g. HIV, HBV, etc.

Prevention of NIs is one of the most important aspects in management of intensive care. Each hospital should have—(a) written hospital *infection control policy*, (b) efficient *surveillance system* to identify changing microbial profile, antibiotic-sensitivity patterns and new nosocomial outbreaks, and (c) periodically review of *antibiotic policy*, consistent with changing hospital flora. Important components of hospital-infection control measures include:

- Maintenance of environmental hygiene
  - General cleanliness, e.g. regular vacuum cleaning or wet-floor mopping with antiseptics.
  - Adequate sunlight and wind-movements. Air-conditioner filters should be cleaned regularly.
  - Restricted use of curtains and decorative items.
  - Periodic fumigations, specially if an outbreak is suspected.
  - Proper bio-medial waste disposal.
- Prevention of cross-infection
  - Strict handwashing (discussed below).
  - Minimum handling of patients.
  - Isolation of highly septic/infectious cases.
  - *Barrier nursing* for immunocompromised host.
  - No overcrowding (restricted visitors).
  - Use of mask, gloves, etc., whenever indicated.
- Prevention of device-related infections
  - Use of disposable instruments/devices.
  - Proper sterilization of equipments.
  - Frequent change of invasive catheters.
  - Regular cleaning of suction and oxygen bottles.
- Rational use of antibiotics
- ***Regular surveillance*** for:
  - Hospital flora (cultures from various sites).
  - Microbial profile to decide antibiotic policy.
  - Early detection and control of NIs outbreaks.
- ***Health education*** of hospital staff
- ***Minimum hospitalization,*** as far as possible.

Handwashing is the most effective control measure against nosocomial infections. Important steps **(Fig. 10.25)** for proper handwash include:

a. Remove the watch and jewellery,
b. Wash with soap and running water, with special attention to inter-digital areas,
c. Minimum duration of wash – 3 minutes before the first handling and 30 seconds in-between the patients,
d. Dry under automatic hand drier or with disposable sterile napkins.

Use of antiseptic solutions, e.g. alcohol, cetrimide, chlorhexidine or iodine solutions, etc. for handwash is no way superior to simple soap and running water wash, though may be practiced in special circumstances.

Outbreak control measures in a suspected outbreak of NI include:

Fig. 10.25: Correct handwashing technique.

- Confirming the outbreak by review of records.
- Identification of index case and contacts.
- Barrier or *cohort nursing* for suspected cases.
- Search for the source of infection* and remedial measures.
- General measures, e.g. fumigation and post-fumigation swab-cultures from various sites.
- Continuous surveillance to further cases.

*Search for the source involves environmental cultures, cultures from probable inanimate sources, e.g. suction bottles; as well as nasopharyngeal cultures from health-care personal.

Biomedical Waste Disposal

Biomedical waste is defined as '*any waste, generated during the diagnosis, treatment, or immunization of human beings and animals as well as during related research activities*'.

Nearly 75–90% of this waste is comparable to any domestic waste, without any additional health-risk.

However, remaining 10–25%, containing biological tissues and secretions, drugs, sharp devices, etc.

TABLE 10.61: Essentials of bio-medical waste disposal

Color code	*Type of waste*	*Container*	*Method of disposal*
Yellow	Biological waste*	Plastic bag	Incineration *or* deep burial
Red	Reusable, non-sharp waste	P. bag/sterile container	Autoclaving, chemical, microwave
Blue	Sharp waste	Puncture-proof container	Shredding > disinfection > recycling
Black	Drugs and chemicals	Plastic bag	Land-burial

*Blood, tissues and laboratory samples

Is potentially harmful and needs to be disposed carefully. Important steps in biomedical waste disposal (as per GOI rules, 1998) include:

- ***Segregation*** of the waste at ward-level, in suitable *color-coded* containers **(Table 10.61)**.
- ***Transport*** to disposal sites by proper means, e.g. covered trucks without spillage.
- ***Proper method of disposal,*** e.g. incineration, dumping, burning, etc.

CHAPTER

11

Genetic Disorders

Kshitija R Patil, Mukesh Agrawal

Since the discovery of the principles of inheritance (*Gregor Mendel*, 1865), genetic composition of a cell is considered as the blueprint of life. Genetic disorders are estimated to affect ~4–5% of all live births, though exact prevalence is considerably higher as many genetically defective conceptions die *in utero* or remain undetected throughout the life.

Modern genetics is a rapidly expanding science in the man's quest to understand the origin of human disease. Recent advances, including new methods in molecular diagnosis and gene manipulation have revolutionized the scope of prevention and treatment of genetic disorders.

11.1 BASIC CONSIDERATIONS

Human genome: Each human somatic cell contains two copies of the entire genetic program, i.e. g*enome*, *each* encoded in 3 million base pairs of DNA. However, less than 2% of human DNA is functionally active, rest being *junk or redundant DNA,* for which exact function are not yet known. Most, but not all, of the DNA is contained in the nucleus, rest being in mitochondria or scattered in cytoplasm.

DNA: DNA (deoxyribonucleic acid) is a double-stranded chemical structure, resembling a long and twisted rope ladder, i.e. *helix*. Each *side* of this ladder is made up of pentose sugar and phosphate molecules and each *step* comprises a pair of nitrogenous bases, termed base pairs (bp).

Human DNA contains four nitrogenous bases—two purines, i.e. Adenine (A) and Guanine (G); and two pyrimidines, i.e. Cytosine (C) and Thymine (T). Of these, *A* always pairs with *T*, and *C* with *G* **(Fig. 11.1)**. The order of this *bp* arrangement varies from the site to site on a DNA strand, denoted as *DNA sequence.* DNA sequence at a specific DNA locus determines its role in genetic functions.

Chromosome: Entire DNA material in the somatic human cell nucleus is packaged in 23 pairs of chromosomes (n = 46), including 22 pairs of somatic chromosomes

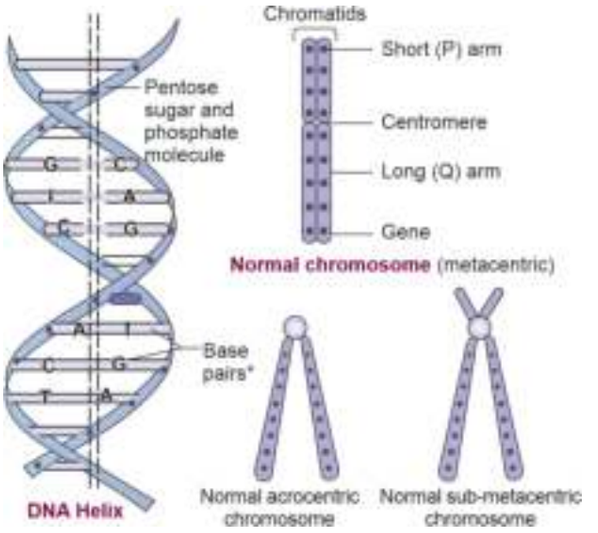

Fig. 11.1: Basic structure of DNA and chromosomes
*C: cytosine; T: Thymine; A: Adenine; G: Guanine

(*autosomes*) and a pair of sex chromosomes (XX in females and XY in males). A baby receives one chromosome of each autosomal pair from different parents, one sex chromosome from father (X or Y) and another sex chromosome (X) from mother. Unlike somatic cells with paired chromosomes, (i.e. *diploid cells*), germ cells, e.g. sperms or eggs contain only 23 unpaired chromosomes, (i.e. *haploid cells*).

Morphologically, somatic chromosomes are of variable size and numbered according to its size in decreasing order-the largest being chromosome 1 and the smallest being chromosome 21. Sex chromosomes are not numbered, identified by their size and morphology. X is a large submetacentric chromosome, while Y is a small acrocentric chromosome.

Each chromosome consists of two identical thin strands (sister *chromatids*), with a short arm (p), long arm (q) and joined together by a centromere **(Fig. 11.1)**. According to the location of centromere, chromosomes are also classified as *metacentric* (central centromere), *submetacentric* (centromere towards the short arm) and *acrocentric* (centromere at one end).

Gene: Gene is a functional unit of DNA, which codes for various proteins required for to govern various functions of the body. Each gene has a *unique* bp sequence, size, and location on a specific chromosome.

While over 1,00,000 genes are encoded in human DNA, all are not biologically active and some are active only in a particular cell, e.g. globin genes in RBCs. However, biologically inactive genes are not necessarily inert and some of them play important roles in modulation of the functions of biologically-active genes.

Genes with similar function, (e.g. globin chain synthesis) tend to cluster on a particular region of chromosome and may be switched-off and switched-on, at various stages of life. For example, γ-globin gene, which determines synthesis of fetal Hb *in utero* is turned-off at birth, when β-globin gene is activated to produce adult Hb.

Each gene regulates synthesis of specific proteins and contains two functionally different regions, i.e. *exons*—which code its biological activity, and *introns*—which are either functionally inert or act as regulator of exons.

As one chromosome in each pair is derived from different parents, every gene on one chromosome has a counterpart gene at the identical location (*homologous loci*) on other chromosome of the pair, together termed as ***alleles*.** Allelic genes are *analogous*, i.e. affect the same biological characteristics, but not necessarily *identical*. An individual is termed *homozygous*, if both alleles of a genetic pair carry identical biological information (normal or abnormal) and *heterozygous*, if they are non-identical.

Penetrance and expressivity: All genetic traits (*genotype*) do not necessarily manifest externally (*phenotype)* due to many factors including variable penetrance and expressivity of the Gene.

- *Penetrance* refers to the percentage of individuals with a specific genotype express in terms of corresponding phenotype, e.g. 80% penetrance means that 8 out of the 10 individuals carrying that particular gene manifest its effects.
- *Expressivity* refers to the degree that a particular genotype is expressed as phenotype in different persons, e.g. different severity of the disease despite same genetic defect.

Further, a gene may also not manifest due to presence of another dominant gene for same character (allele) on the other chromosome from different parental source, e.g. in autosomal or x-linked recessive inheritance, discussed later.

Transfer of genetic information for parental to daughter cells occurs during the cell division via transfer of DNA as chromosomes and constituent genes. Process of cell division may be divided into two types—*meiosis* and *mitosis*.

Meiosis is a two-step process that ultimately ends in formation of *haploid* germ cell. Subsequent fusion of two haploid germ cells from different parents restores normal diploid number in zygote, from which the new life begins.

Mitosis is characterized by replication of chromosomes before the cell division, so as to form two genetically identical, i.e. *diploid* daughter cells.

Mutation: All biological functions of a living cell are mediated by amino acids or proteins, e.g. enzymes. Genes are prime regulators of specific amino acid synthesis, essential for corresponding cell function.

Mutation (or variant), refers to a *heritable change in the DNA sequence of the gene,* which may or may not affect the structure and function of corresponding protein. Mutations may be of three types: (a) *point mutations* or substitutions replacing single nucleotide from another; (b) *deletions* involving loss of one or more nucleotides in the gene; and (c) *insertions*, i.e. addition of one or more nucleotide in the gene. Each mutation may be benign, pathogenic or of unknown significance, based on the effect on phenotype. While germline mutations usually cause monogenic disorders, somatic cell mutations may cause cancers.

Sequence variations without any obvious disease-causing effect are termed as *Polymorphism*.

Mutations may occur naturally as *chance* errors in DNA replication during chromosomal division or may be due to external teratogens, e.g. ionizing radiation or chemical exposures.

11.2 MODES OF GENETIC INHERITANCE

According to the mode of transmission and inheritance, Genetic disorders may be classified into various types, as follows **(Table 11.1)**:

1. Chromosomal Disorders

Chromosomal abnormalities are either numerical or structural and may be inherited from parents or arise *de novo* during gametogenesis by following mechanisms:

TABLE 11.1: Classification of genetic disorders

- **Chromosomal disorders**
  - Numerical abnormalities
  - Structural abnormalities
- **Single gene (Mendelian) disorders**
  - Autosomal recessive or dominant
  - X-linked recessive or dominant
  - Y-linked inheritance (non-pathogenic)
- **Multifactorial or polygenic disorders**
- **Mitochondrial disorders**
- **Alternate modes of inheritance**
  - Genomic imprinting
  - Uniparental disomy
  - Mosaicism
- **Somatic cell disorders**

- *Meiotic nondisjunction*, i.e. failure of a pair of chromosome to separate during meiosis. Consequently, one germ cell contains both members of chromosome pair (trisomy), while other lacks both (monosomy). *Advanced maternal age* is a major risk factor for meiotic nondisjunction.
- *Anaphase lag*, i.e. failure of one chromosome of a pair to move towards the opposite pole of dividing cell during anaphase of cell division *despite separation*, is another important source of numerical chromosomal abnormalities.
- *Mitotic nondisjunction (mosaicism)*, i.e. failure of the separation of a pair of chromosome in diploid zygote, during initial cell divisions after fertilization. Consequently some of the individual cells are trisomic, while rest are monosomic. Mosaic defects tend to be less severe or sub-clinical.

Numerical chromosomal abnormalities include the number of chromosomes being other than the haploid number (23) of germ cells or diploid number (46) of somatic cells. *Aneuploidy*, the commonest numerical abnormality, refers to number of chromosomes being other than in *multiples* of haploidy, due to more chromosome/s (47XY/XX or Down syndrome) or less chromosome/s (44XO, Turner syndrome). Other numerical abnormalities include *Euploidy* and *Polyploidy* **(Table 11.2)**.

Structural chromosomal abnormalities include (a) ***Deletion,*** i.e. loss of a DNA segment, (b) ***Translocation,*** i.e. separation of a DNA segment from one chromosome and re-attachment on another chromosome, and (c) ***Inversion,*** i.e. separation of a DNA segment from one chromosome and its re-attachment on the same chromosome but in reverse order. Mutual exchange of DNA segments between two chromosomes is termed as *Reciprocal translocation.* However, *inversion* or *reciprocal translocation* rarely manifest clinically, due to no loss of DNA segment **(Fig. 11.2)**.

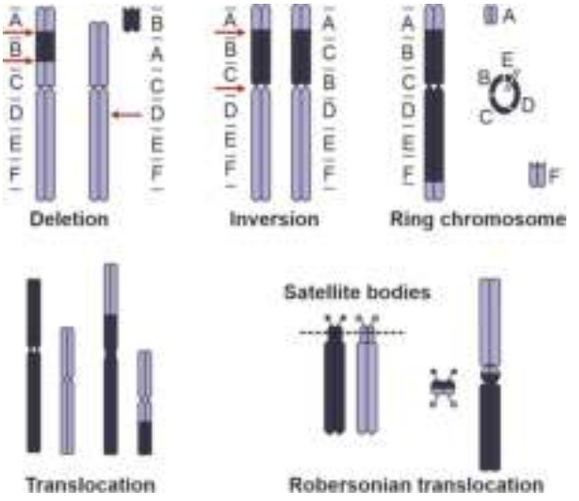

Fig. 11.2: Common structural abnormalities of chromosomes.

Robertsonian translocation is a specific translocation defect involving fusion of two acrocentric chromosomes near their centromere with loss of short arms, leading to reduction in total chromosomal numbers, (e.g. 45). Though the short arms of acrocentric chromosomes have no known function and carriers of Robertsonian translocations are phenotypically normal, they are at-risk for abortions.

Microdeletions, i.e. deletions, which are not visible on routine karyotyping and need special prophase studies for diagnosis, are being increasing recognized in association with various genetic disorders, e.g. Prader-Willi syndrome, William syndrome, Alagille syndrome, etc. Some important chromosomal disorders have been discussed in Ch 11.3.

Loss or gain of smaller regions of a chromosome, known as *copy number variations* (CNV), usually involve more than one gene and are implicated in many human diseases.

TABLE 11.2: Glossary of chromosomal abnormalities

Normal karyotypes
- ***Haploidy:*** Cells with 23 chromosomes, e.g., germ cells
- ***Diploidy:*** Cells with 46 chromosomes, e.g. somatic cells

Numerical abnormalities
- ***Euploidy:*** Number of chromosomes in multiple of haploidy (46, 69,...)
- ***Polyploidy:*** Euploidy with chromosomal numbers > diploidy (69, 92,..)
- ***Aneuploidy:*** Number of chromosomes not in multiples of haploidy.
- ***Trisomy:*** Presence of extra chromosome (47 XY/XX, Down syndrome)
- ***Monosomy:*** Absence of one chromosome (45 XO, Turner syndrome)

Structural abnormalities*:
- ***Deletion:*** Loss of a chromosome segment (Cri du chat syndrome)
- ***Translocation:*** Inter-chromosome transfer of DNA segment
- ***Inversion:*** Detachment of DNA segment > re-attachment in reverse order

*also see Fig. 11.2

2. Single Gene (Monogenic) Disorders

As stated earlier, each gene has an analogous allele at the identical location on other chromosome of the pair affecting same biological characteristics, but may or may not be identical (*homozygous vs heterozygous).*

In heterozygous state, generally one gene of the allelic pair determines biological activity (*dominant* gene), while other remains suppressed (*recessive* gene) and manifests only in absence of dominant allele. Thus, disorders encoded on dominant genes manifest even in a heterozygous state, while disorders of recessive genes

are asymptomatic in heterozygous state (suppressed by normal allele) and manifests only in homozygous state.

As the genes present on X-chromosome of a male (XY) do not have their corresponding allele *(hemizygous state)*, an X-linked recessive gene manifests only in males and remains suppressed in heterozygous females (XX).

Thus, single gene disorders may be broadly divided into 4 categories—(a) autosomal dominant, (b) autosomal recessive, (c) X-linked recessive, and (d) X-linked dominant disorders. *Y-linked genetic abnormalities* are rare and present with minor phenotype features in males, inherited from fathers, e.g. hairy pinna, frontal baldness, webbed toes, porcupine skin, etc.

Autosomal dominant (AD) disorders, i.e. defects encoded on the dominant gene on autosomal chromosome, are characterized by following features **(Fig. 11.3)**:

- *Clinical manifestation in heterozygous state,* as the defect is encoded on the dominant gene of the pair. Homozygous states are rare for ADDs and present with more severe disease.
- *No silent carriers,* as all genetically abnormal members of the family manifest clinically, unless the gene has not manifested due to incomplete penetrance.
- *Vertical inheritance,* i.e. history of similar disease in one of the parents (or previous generations), unless the genetic error is a new *de novo* mutation.
- *Usual risk of recurrence* during each pregnancy being 50%, when one parent is heterozygous and another is normal. In rare cases, it may be even higher if one parent is homozygous (100%) or both parents are heterozygous (75%).
- *Both sexes are equally affected,* as the defective gene is present on the autosomes.
- *Most ADDs are non-lethal* and hence, more common than recessive defects due to survival of affected individuals till reproductive age.

Common examples of ADD are achondroplasia, neurofibromatosis, Marfan syndrome, hereditary spherocytosis, etc.

Autosomal recessive (AR) disorders, i.e. defects encoded on the recessive gene of autosomal chromosome, are characterized by following features **(Fig. 11.4)**.

- *Clinical manifestations only in homozygous state*, due to absence of corresponding dominant gene to suppress mutant gene activity.
- *Silent carrier state in heterozygous individuals*, due to suppression of abnormal gene by corresponding dominant gene. However, some carriers may have borderline abnormalities.
- *Horizontal inheritance*, i.e. all members of same generation are genetically affected, when a heterozygous carrier mates with another heterozygous carrier. However, some of them manifest with disease (if homozygous), while rest become carriers (if heterozygous). Parental history of similar disease is absent in these cases, who are heterozygous carriers.
- *Usual risk of recurrence* in subsequent pregnancy is 25% for homozygous disease and 50% for heterozygous carriers, if both parents are carriers. All children of a homozygous patient (very rare) are carriers, if the other partner is normal.
- *Consanguinity* is an important risk factor for ARDs, as the members of same family tree are more likely to be heterozygous carriers, than the general population.
- *Both sexes are equally affected,* as the defective gene is present on the autosomes.
- ARDs are frequently lethal and hence, relatively rare due to unlikely survival of a diseased case till reproductive age.

Common examples of ARDs are severe forms of inborn errors of metabolisms, hemoglobinopathies and skeletal dysplasias, etc.

X-linked recessive (XLR) disorders denote a defect of recessive gene located on X chromosome, characterized by following features **(Fig. 11.5)**:

- *Clinical manifestations only in males* (XY), due to absence of corresponding dominant gene to suppress the abnormal recessive gene. Females (XX) are not affected due to presence of normal dominant gene, *except* in very rare instances of 45, X genotype (Turner syndrome), X autosome translocation, skewed X inactivation, fresh mutations or a diseased male mating a carrier female. However, carrier females may have mild and silent biochemical defects, e.g. low factor VIII activity in hemophilia.

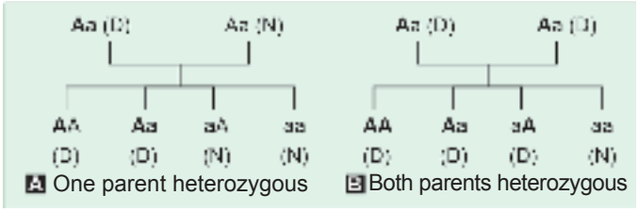

Fig. 11.3: Autosomal dominant inheritance.
Bold 'A' denotes abnormal dominant gene
N: normal, **D:** diseased

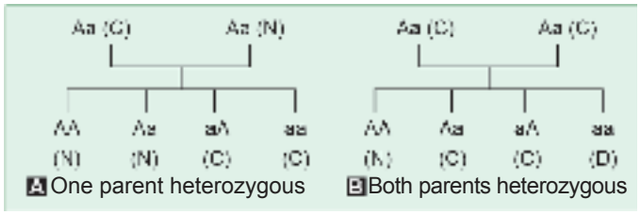

Fig. 11.4: Autosomal recessive inheritance.
Bold 'a' denotes abnormal recessive gene
N: normal; **D:** diseased; **C:** carrier

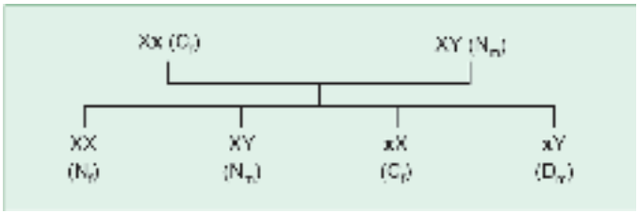

Fig. 11.5: **X-linked recessive inheritance.**
N: normal, **D:** diseased, **C:** carrier
Genes in bold letters denote abnormal gene, subscripted letters m and f denote male and female.

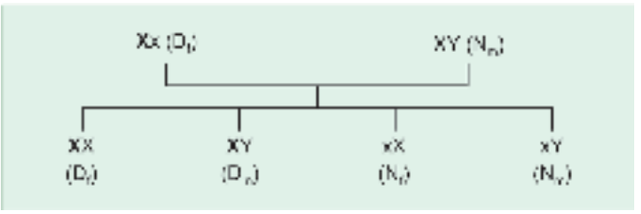

Fig. 11.6: **X-linked dominant inheritance.**
N: normal; **D:** diseased
Genes in bold letters denote abnormal gene, subscripted letters m and f denote male and female.

- *Carrier state only in females* (XX), as males are always affected by disease.
- *Oblique transmission*, i.e. only males on maternal side, (e.g. maternal uncles) are affected with disease, while mother is an asymptomatic carrier and father is normal.
- *Usual risk of recurrence* during next pregnancy is 50% for disease in males or carrier state in females, when mother is a carrier.

Common examples of XLRs are hemophilia, Duchenne muscular dystrophy, color blindness, G6PD deficiency, etc.

X-linked dominant (XDD) disorders are uncommon and characterized by **(Fig. 11.6)**:

- *Clinical manifestations in both sexes*, as females are also affected due to dominant nature of abnormal gene.
- *Risk of recurrence* is 50% if mother in heterozygous and father is normal. However, all female offsprings of a hemizygous father are affected.
- *Disease tends to be less severe in females*? due to modifying effect of corresponding normal allele, thus creating excess of females in XLD families.
- As males are more severely affected, defective gene is usually acquired from maternal side.

Common examples of XLDs are familial hypophosphatemic rickets, incontinentia pigmenti, orofacial digital syndrome, nephrogenic diabetes, etc.

3. Polygenic and Multifactorial Disorders

Often confused together, these two terms have different connotations. While *polygenic disorders* represent a "defect regulated by additive or interactive effect of two or more genes", *multifactorial disorders* refer to a "*genetically determined susceptibility of certain individuals to various environmental factors*". Various normal human traits, e.g. height, as well as abnormal disorders are multifactorial in origin. In these cases, contribution of genes is termed *heritability*.

While exact genetic error in most MFDs is usually not clear, some have strong association with certain specific HLA types, e.g. diabetes (DR3/4), spondyloarthropathy (B27), etc.

TABLE 11.3: Recurrence risk in multifactorial disorders

	General incidence (1000 live births)	*Recurrence risk* (%)*
Neural tube defects	4–5	5%
Cardiac malformations	6–8	3–4%
Cleft lip and palate	2	4–5%
Cleft palate alone	0.5	2–6%
Pyloric stenosis	2–3	3%
Cong. talipes equinovarus	3–4	2–8%
Cong. dislocation of hip	3–4	3–4%
Hirschsprung disease	0.1	6%

*If previous sibling is affected, with normal parents.

Risk of recurrence (RR) in MFDs, in absence of well-defined genetic basis, is usually estimated on the basis of epidemiological observations **(Table 11.3)**. Some general observations are as follows:

- RR in most MFDs is ~2–10% among first-degree relatives, and gradually declines in more distant relatives.
- RR rises by 2–3 folds, when more than one family members, e.g. one parent and one sibling or two siblings are affected (d/d single gene disorders, where it is same for each pregnancy).
- RR is higher in common and severe disorders, as compared to rare or benign defects.
- In disorders with sex-predilection, RR is higher if the index case belongs to rarely affected sex, e.g. in Infantile hypertrophic pyloric stenosis, which is common in males, RR is higher for offspring of an affected mother than of affected father.
- Unlike single gene defects, presence of similar MFD disorder in identical twins (concordance) is never 100%, usually being 21–63%.

4. Mitochondrial Disorders

Mitochondria contain ~16,000 bps of DNA, arranged in small circular segments (mitochondrial chromosomes). Mutations in mitochondrial genome are responsible for many genetic disorders, e.g. Leber hereditary optic neuropathy, MELAS (*M*itochondrial myopathy

*E*ncephalopathy, *L*actic acidosis and *S*troke), Leigh syndrome and MERRF (myoclonic epilepsy with ragged-red fibers). Mitochondrial disorders are characterized by:

- Involvement of specific tissues, e.g. brain, muscles and eyes.
- Exclusive inheritance from mothers, as sperms do not contain mitochondrial component. However unlike X-linked disorders, offsprings of both sexes are affected in these disorders.

5. Non-traditional Modes of Inheritance

Non-traditional modes of inheritance include some genetic traits, which are not determined by an equal genetic contribution from both parents or do not follow conventional modes of inheritance discussed earlier. Some important disorders of this nature are as follows:

Uniparental disomy (UPD) denotes a mode of inheritance in which *both chromosomes (or part of a chromosome) of a pair are inherited from same parent*. Most important effect of UPD may be increased risk of manifesting autosomal recessive disorders, due to transfer of two identical chromosomes carrying mutant genes from a heterozygous parent. UPD has been observed in many recessive disorders, e.g. cystic fibrosis or other defects, e.g. Prader-Willi syndrome and Russell-Silver syndrome.

Genomic imprinting refers to the *differences in the phenotype expression of a genetic defect, depending on the parent of origin* for implicated gene/chromosome. For example, deletion of paternally-derived 15th chromosome presents with *Prader-Willi syndrome*, while similar deletion of maternal-derived chromosome manifests as *Angelman syndrome*.

Mosaicism refers to an *individual with two different cell lines*, derived from a single zygote (mitotic non-disjunction). Over 2% of conceptions are estimated to have mosaic chromosomal abnormality in first trimester. Mosaic defects tend to be less severe and often allow the survival in otherwise lethal chromosomal defects due to presence of normal cell lines. Mosaicism may be divided into:

- *Chromosomal mosaicism*, e.g. Down syndrome (46/47), Turner syndrome (45,X/46XX);
- *Single gene mosaicism*, limited to certain genes, e.g. McCune-Albright syndrome, and
- *Germ-line mosaicism*, i.e. presence of mosaicism in germ cells. Unlike other types, germ-line mosaicism is inherited from parents and hence, may affect more than one offspring of mosaic parents, e.g. in Duchenne muscular dystrophy or osteogenesis imperfecta.

Chimerism refers to an individual with at least two or more cell lines, often originating from fusion of many different zygotes (d/d Mosaicism with single zygote).

6. Somatic Cell Disorders

The term '*somatic cell disorders*' refers to a new genetic mutation during mitotic cell division in the somatic cells, after differentiation of gonads. These mutations are limited to a single cell line and *not transmitted* to the next generation. Although each individual is likely to have many somatic mutations, most of them are silent and never detected. Two important examples of somatic mutations are *cancers* due to mutation in oncogenes, and *autoimmune disorders* due to mutation in genes regulating T-cell selection.

11.3 CHROMOSOMAL DISORDERS

Chromosomal abnormalities are present in ~0.4% of live births and ~50–60% of aborted fetus and include numerical as well as structural abnormalities. These abnormalities may be inherited from parents or arise *de novo* during gametogenesis.

When to suspect? Unlike singe gene disorders, Chromosomal disorders do not follow a specific pattern of inheritance and hence, family history is of limited significance in diagnosis. Physical dysmorphism is the hallmark of most chromosomal disorders, though **Table 11.4** enlists some common indicators of chromosomal disorders. Diagnosis is often based on constellation of clinical features many good databases are available to assist in the search for diagnostic possibilities.

Laboratory diagnosis of chromosomal disorders includes *study of chromosomal number and morphology*, using following methods:

- **Conventional karyotyping** may be performed on any living cells, e.g. lymphocytes, biopsies, aspirates, etc. or even the chorionic villi and amniotic fluid for prenatal diagnosis. Since the chromosomal profile is best appreciable during metaphase of mitotic division, karyotyping involves cell cultures to stimulate the mitotic division, arrest the division in metaphase by adding *colchicine*. dispersing these multiplying chromosomes by bathing the sample in hypotonic solution and then Staining with conventional stains, e.g. G-banding (Giemsa stain). In these stained slides, each chromosome is identified under microscope due to its unique light and dark banding patterns.

TABLE 11.4: Clinical indicators of chromosomal disorders

- **Family history of…**
  - Similar morphology/disease with unexplained etiology
  - Recurrent fetal or neonatal deaths or malformations
- **Physical characteristics**
  - External dysmorphic features
  - Multiple congenital malformations
  - Developmental delay/Intellectual disability
  - Ambiguous genitalia or sexual infantilism
  - Abnormal stature or deformities
  - Unusual cancers
- **Prenatal biochemical/USG abnormalities**
  - Abnormal USG
  - Abnormal biochemical markers

Conventional karyotyping require long time (2–3 weeks) for results and can identify numerical and structural chromosomal abnormalities, but only up to 5 Mb resolution.

- **Molecular cytogenetic studies,** e.g. Fluorescent *in situ* hybridization (FISH), quantitative Polymerase chain reaction (qPCR) and Multiplex ligation dependent probe amplification (MLPA) use target-specific fluorescent probes or markers against the suspected chromosome/s or regions. Results are available rapidly within 24 hours *but only* for the defect/s in that specific chromosome/s or regions. These tests are very useful where clinical suspicion limits the diagnostic possibilities, e.g. identification of aneuploidies for prenatal diagnosis and microdeletions.
- **Chromosomal microarray** has revolutionized the diagnosis of chromosomal disorders, based on the principle of complementary DNA hybridization to screen entire genome for differences from the known pattern, termed as copy number variations (CNVs), i.e. deletions or duplications. This test does not require living cell, results are available in few days and defects can be identified with a fine resolution of as low as 10–20 kb. However, microarray does not detect balanced translocations which do not alter CNVs and point mutations, deletions or duplications at the single gene level.

Chromosomal microarray is useful when there is a need to screen for many defects due to lack of a specific genetic diagnosis, e.g. unexplained intellectual disability, autistic spectrum disorders and multiple congenital anomalies.

Barr body (BB): In females, one of the two X chromosomes is randomly inactivated during early embryogenesis *(Lyon hypothesis)*, which may be seen as a clump of heterochromatin adjacent to the nuclear membrane (termed *Barr body)*. Males have only one X chromosome and hence no Barr body. Thus, the *number of BB is one less than the number of X chromosomes*. Detection of a Barr body in buccal smear is a quick method to identify the genetic sex in ambiguous genitalia (Female: one BB, Male: no BB) *or* disorders with abnormal X numbers, e.g. Turner syndrome (45 XO; no BB), 47 XXY female (2 BB), etc. However, these results are often misleading and no longer used in practice.

Some common chromosomal disorders are discussed as follows:

11.3.1 DOWN SYNDROME

Down syndrome (DS) is the commonest chromosomal aneuploidy in live-births, characterized by a typical phenotype and triplicate copy of entire chromosome 21 or its critical segment (DCR).

Incidence of DS in general population is ~1:600–800 live births, though the true incidence is much higher as ~50% of affected conceptions are spontaneously aborted. *Advanced maternal age is the most important risk factor for DS*, with an estimated risk of ~1:1000 below 30 years, ~1:350 by 35 years and ~1:100 after 40 years.

Cytogenetically, DS may be divided into two types- (a) *regular trisomy (~95%)*, i.e. presence of entire extra chromosome (47,XX/XY,+21); (b) *translocations (~5%)*, i.e. presence of 3 copies of DCR, but with normal chromosomal number (46, XX/XY).

- ***Regular trisomy*** is the commonest cause of DS in children born to elderly mothers, due to non-disjunction of 21st chromosome during meiotic phase in 94% cases or during mitotic phase in 1%. *In 95% cases of regular trisomy, the extra chromosome is derived from mother.*

  Non-disjunction in mitotic phase leads to *mosaicism*, in <1% cases witth presence of two different cell lines, one normal and another with trisomy.
- ***Translocations,*** i.e. the transfer of additional DCR *by transfer* on other acrocentric chromosomes (Robertsonian translocation), e.g. 14, 15, or 13 (usually t14;21), may arise *de novo* or inherited from a balanced carrier parent. Most are maternally inherited and only 20% are paternal. Maternal age is irrelevant and *most cases of DS born to younger mothers are translocations.*

Clinical phenotype of DS spans from presence of a few dysmorphic features to full-blown picture including developmental delay, hypotonia and systemic defects **(Fig. 11.7)**.

Common systemic problems present since birth include congenital heart diseases in ~40% (commonest being atrioventricular septal defect), gastrointestinal malformation, e.g. duodenal atresia in ~12%, hypothyroidism in ~15–50% and hearing defects in ~40–60%, while some others may arise after few years, e.g. atlanto-axial joint instability in ~10–30% and leukemia or other lymphoprolierative disorders in later life **(Table 11.5)**.

Fig. 11.7: Down syndrome: Facial appearance and simian crease (Inset).

TABLE 11.5: Clinical features in Down syndrome

- **External dysmorphism**
  - **Head:** Brachycephaly or flat occiput, microcephaly, Delayed closure of fontanels
  - **Eyes:** Upward slanting palpebral fissures, hypertelorism, Epicanthic folds, brushfield spots, cataract, refractive errors
  - **Nose:** Small and depressed nasal bridge, flat face
  - **Ears:** Small/dysplastic ears, deafness
  - **Oral cavity:** Dental hypoplasia, furrowed protruding tongue, high-arched palate
  - **Neck:** Short neck** with loose posterior folds in infancy
  - **Hands/feet:** Short/broad hands, clinodactyly**, sandal
  - gap (↑ gap between 1st and 2nd toe)
  - **Dermatoglyphics:** Simian crease** and others*, plantar (Kennedy) crease between 1st and 2nd toe
  - **Skin:** Dry, hyperkeratotic skin, fine sparse hairs, Cutis marmorata
  - **Genitals:** Cryptorchidism, micropenis
- **Generalized hypotonia with hyperextensible joints** hypotonia**, poor Moro's reflex**, hyper-extensible joints**
- **Developmental delay**
- **Systemic abnormalities**
  - **CVS:** Endocardial cushion defects, other CHDs
  - **GIT:** Obstructive lesions, e.g. duodenal atresia, Imperforate anus, Hirschsprung disease
  - **Respiratory:** Obstructive sleep apnea syndrome, hypoplastic lung, pulmonary hypertension
  - **Endocrinal:** Cong hypothyroidism, short stature, Infertility
  - **Hematological:** Leukemia, leukamoid reactions
  - **Skeletal:** Hypoplastic pelvis**, atlanto-axial instability
  - **Others:** Visual errors, deafness

*wide 'ATD' angle, distal triradius, ulnar loop ridge patterns
included in ***Halls criteria* for Down syndrome

TABLE 11.6: Periodic screening in Down syndrome

Karyotyping	*Birth/first contact*
Growth assessment	0, 6 mo, then... Annually till 18 years
Hearing assessment	0, 6 mo, 18–24 months, then... Annually till 6 years, then alternate year till 18 years
Eye evaluation	Birth, 2,4,6 yr, then.. Alternate years till 18 years
Thyroid profile	0, 6 ,12 mo, then annually every year
ECG/ECHO	Birth/ First contact
Dental evaluation	Annually from 1 year onwards
Complete blood count	0, 1 year then annually till 5 years

TABLE 11.7: Recurrence risk for Down syndrome

Normal parental karyotype
- Maternal age <35 years 1%
- Maternal age >35 years 1% more than age-related risk

Abnormal parental karyotype *(balanced translocation)*
- Mother as a carrier 10–15%
- Father as a carrier 5%
- T 21:21 (either parent) 100%

Despite developmental delay, these babies are friendly, playful and enjoy music. Motor development is slower than social development due to hypotonia, which tends to improve with age.

While many cases survive till adulthood and lead relatively independent life after learning the self-help skills, ~50% die in early childhood or need recurrent hospitalizations due to congenital heart diseases and recurrent aspiration (palatopharyngeal incoordination).

Diagnosis is largely clinical, though karyotyping is indicated in all cases to confirm the diagnosis, mode of inheritance and genetic counseling.

Management aims to: (a) improve the quality of life, (b) detect and treat systemic conditions, and (c) genetic counseling; and includes:

- *Confirmation of diagnosis* by karyotyping. If it is due to translocation, cytogenetic studies of parents are also necessary to detect balanced carriers and assess the risk for next conception.
- *Screening for systemic abnormalities*, e.g. congenital heart diseases, hypothyroidism and hearing/vision defects is essential at birth and then periodically, as many defects become apparent only in later life. IAP has recommended a time schedule for periodic follow-up for important medical issues till 18 years of age in all cases of DS **(Table 11.6)**.
- *General care* to ensure adequate nutrition, immunization, and growth and development monitoring.
- *Interventional programs*, e.g. physiotherapy, occupational therapy and self-help learning to achieve maximum functional independence.
- *Psychological support* to family.
- *Medical therapies*, i.e. megavitamins, selenium, piracetam, dimethyl sulfoxide, etc. have been tried in DS but with no proven value. However, associated illnesses, e.g. hypothyroidism should be promptly treated. Surgical intervention is indicated for major structural malformations. Cosmetic surgery for facial dysmorphism is justifiable in selected cases to increase social acceptance.

Genetic counseling is the most important component of management in DS and involves:

- **Assessment of recurrence risk** in future pregnancy: Recurrence risk for Down syndrome varies with maternal age and parental cytogenetic profile **(Table 11.7)**.
- **Prenatal screening** based on biochemical and USG markers **(Table 11.8)** is indicated in high-risk mothers, e.g. advanced age, previous affected child and abnormal parental karyotype, as follows:
  - ***First trimester screening*** (11–13 weeks) usually rests on: (i) reduced Pregnancy associated plasma

TABLE 11.8: Prenatal screening of Down syndrome

Screening tests	*Sensitivity*
First trimester screening (11–13 wk)	
• NT + Double marker test *(Serum free β-hCG and PAPP-A)*	85–95%
• NT + Double marker test + other USG markers*	93–96%
Second trimester screening (15–22 wk)	
• Triple marker test *(Serum AFP, free β-hCG, uE3)*	65–70%
• Quadruple marker test: *(Serum AFP, free β-hCG, uE3, inhibin A)*	70–75%
Confirmatory cytogenetic tests *(QF-PCR, Karyotype or FISH)*	
Chorionic villous sampling (11–13 weeks)	
Amniocentesis (17–23 weeks)	
Chordocentesis (>18 weeks)	

NT: Nuchal translucency; **hCG:** Human chorionic gonadotrophin; **PAPP-A:** Pregnancy-associated plasma protein-A; **AFP:** Alpha fetoprotein; **uE_3:** Unconjugated estriol; **QF-PCR:** Quantitative - fluorescent polymerase chain reaction
* See text

protein-A (PAPP-A) levels, (ii) elevated human chorionic gonadotropin (HCG) levels and (iii) increased nuchal thickness > 4 mm (echo-free space between skin and dorsal cervical spine).

Non-invasive prenatal screening (NIPS) is a new screening test in high-risk cases to analyse free fetal DNA in maternal plasma at ~10th week of gestation. It can detect aneuploidies of chromosome 21 with 99% sensitivity but false-positive results are possible and must be confirmed with cytogenetic studies.

– ***Second trimester screening*** (14–16 weeks) involves triple/quadruple marker test and includes presence of a combination of biochemical abnormalities in mother: (i) reduced-fetoproteins levels, (ii) reduced unconjugated estradiol levels, (iii) elevated human chorionic gonadotropin levels and (iv) increased inhibin levels in *Quadruple marker test*. A positive test indicates >50% risk of DS. Presence of certain USG abnormalities, e.g. heart disease or duodenal atresia also indicate need to exclude DS.

Important prenatal USG markers of DS include (*Two or more of following*): (a) increased nuchal translucency, (b) absent or hypoplastic nasal bone, (c) presence of soft markers like pyelectasis, echogenic bowel, echogenic intracardiac focus, single umbilical artery, choroid plexus cyst, short femur, etc., (d) structural abnormalities, e.g. duodenal atresia, cardiac defect, and (e) adjunct features like clinodactyly.

- **Confirmation of prenatal diagnosis,** by cytogenetic studies on suitable antenatal samples is possible in high-risk cases as early as 11–13 weeks by chorionic villous sampling, 17–23 weeks by amniocentesis and 18 weeks on cordocentesis. While conventional karyotyping takes ~2 weeks, PCR-based tests are available to give results in 2–3 days.
- **Parental counseling:** DS is a shattering diagnosis for parents and they should be informed as soon as possible after the confirmation in simple terms about: (a) confirmation of diagnosis, (b) possibilities of associated problems in present and in future, (c) need for regular follow-up to detect and mange these problems, (d) expected level and pace of development and achievement of life-skills, (e) risk of recurrence and options for prenatal diagnosis during next conception.

  They must also be counselled about immediate risks for life due to congenital anomalies. If any, morbidities which can arise in future and precautions required to minimize them. It needs to be emphasized that most cases of DS are trainable and can live near normal adult life with family support. Parents must be answered truthfully but compassionately for their apprehensions and may also be connected to support groups. Issues, e.g. schooling, menstrual hygiene etc may be discussed in future dates.

Other important somatic chromosomal disorders are as follows:

Trisomy 18 (Edward syndrome) is seen in ~1:6000 births, characterized by low birth weight, microcephaly, rocker-bottom feet, joint contractures/deformities overlapping fingers, developmental delay and cardiac/renal malformations. 95% of these cases die in infancy.

Trisomy 13 (Patau syndrome) is seen in ~1:10,000 births, characterized by *multiple midline defects*, e.g. facial defects (hypotelorism, bulbous nose, cleft palate, deformed ears, microphthalmia), cerebral malformations (microcephaly, encephalocele or holoprosencephaly), chest deformities (hypoplastic ribs, congenital heart diseases) and genital abnormalities (hypospadias). Polydactyly with overlapping fingers and visceral malformations are common and most cases die soon after birth.

Cri-du-chat syndrome, i.e. *deletion of short arm of 5th chromosome* (5p-), is characterized by typical cat-like cry, hypotonia, microcephaly with moon-like facies and mental retardation.

Microdeletion syndrome are characterized by multiple and small chromosomal deletions, missed on routine karyotyping studies.

Many microdeletion syndromes are being identified with newer diagnostic methods, commonest being *William syndrome* (typical *elfin* facies with supravalvular aortic stenosis), *Prader-Willi syndrome* (obesity, short stature, hypotonia), *Rubinstein-Taybi syndrome* (microcephaly, beaked nose with low philtrum, broad and long thumbs/toes), *DiGeorge syndrome* (first brachial

arch defects, e.g. thymus aplasia, hypocalcemia due to hypoparathyroidism, ear defects and congenital heart diseases) and *Alagille syndrome* (intrahepatic biliary atresia).

Chromosomal breakage syndromes: Some chromosome sites are known to show abnormal tendency for separation, breakage or attenuation, either spontaneously or under environmental stress, e.g. UV radiations (*Fragile sites)*. Many genetic disorders have been identified with fragile chromosomes, e.g. *Fanconi anemia*, *Bloom syndrome* (skin malignancies with mental retardation), *ataxia telangiectasia*, etc., as well as higher risk of malignancies.

11.3.2 TURNER SYNDROME

Turner syndrome is the commonest sex chromosome disorder *in females*, characterized by a spectrum of phenotype abnormalities and complete or partial absence of one X chromosome.

Incidence of Turner syndrome in female live-births is ~ 1:2500, though the turner genotype (45, XO) is present in 1–2% of conceptions, of which 95% are spontaneously aborted in first trimester. It is a sporadic defect with *negligible risk of recurrence* and maternal age is not a risk factor.

Cytogenetically, Turner syndrome may be divided into- (a) *classical karyotype* (50%), i.e. complete absence of one X chromosomes in all cell lines (45, XO), (b) *Mosaicism*, i.e. presence of two cell lines (45, XO/46, XX), and (c) rare structural defects, e.g. deletion of the p or q arm of X chromosome.

As the genes regulating ovarian function and growth (*SHOX* gene) are present on X chromosome, its complete absence leads to characteristic phenotype of Turner syndrome with short stature and gondal dysgenesis (streak ovaries). However, mosaic cases tend to have milder phenotype and better survival. Deletion of the *p* arm presents with typical phenotype, while deletion of the *q* arm is associated with only gonadal dysgenesis without somatic signs.

Clinical spectrum of Turner syndrome is highly variable **(Table 11.9)** and diagnosis is usually missed at birth. *Presence of lymphedema over dorsum of hands/feet and loose skin folds on the nape of neck are two important signs of Turner syndrome in newborns.*

Most cases present later with short stature, small triangular face, anomalous ears, short-webbed neck **(Fig. 11.8)**, wide chest, cubitus valgus with wide carrying angle at elbow, learning disabilities and delayed onset of puberty or menarche.

Congenital heart diseases, specially coarctation of aorta and renal anomalies are common. Hypothyroidism occurs in 15–30% adults with Turner syndrome. Stature may be normal in cases with mosaicism, who may present with secondary amenorrhea.

TABLE 11.9: Clinical features of Turner syndrome

- **Short stature**
- **External dysmorphism**
  - *Face:* Triangular facies, abnormal ears, cataracts
  - *Neck:* Short, webbed neck, low hairline
  - *Chest:* Broad chest with inter-nipple distance
  - *Limbs:* Carpel/pedal edema, cubitus valgus*
  - *Skin:* Nevi, recurrent keloids, dysplastic nails
- **Learning disabilities**
- **Systemic defects**
  - CVS: Coarctation of aorta, bicuspid aortic valve, AS
  - Renal: Horseshoe shaped or ectopic kidney
  - Skeletal: Scoliosis, made-lung deformity, CDH
  - Endocrine: Diabetes mellitus, obesity
- **Sexual infantilism (Gonadal dysgenesis)**
  - Delayed puberty
  - Amenorrhea/sterility

*Wide carrying angle at elbow >110°

Fig. 11.8: Turner syndrome: Webbed neck, widely spaced nipples and cubitus valgus.

Diagnosis is usually made during evaluation for short stature or delayed puberty in girls. Presence of streak ovaries on USG (and absence of germ cells on biopsy) is highly suggestive of Turner syndrome.

Diagnosis needs to be confirmed by karyotyping from peripheral lymphocytes or skin fibroblasts. *Buccal smear to detect absence of Barr body* is unreliable to exclude Turner syndrome, as it may fail to detect mosaicism and structural defects.

Other investigations are necessary in Turner syndrome to detect or exclude systemic defects, e.g. echocardiography, abdominal USG, audiometry and serum FSH/LH levels.

Prenatal diagnosis: As recurrence is extremely rare, prenatal diagnosis is indicated only in cases with some antenatal USG markers, e.g. cystic hygroma, lymphedema, hydrops fetalis, left-sided heart defects

and higher fetal heart rate, using cytogenetic studies from chorionic villus sampling or amniocentesis.

Management aims to maximize growth potential and early diagnosis/treatment of medical complications, with:

- *Parental counseling*, regarding its implications on growth and reproductive failure.
- *Periodic evaluation* for growth/development, hypertension, vision/hearing impairment, thyroid functions, etc.
- *Psychosocial support*.
- *Hormone replacement therapy* with growth hormone with/without an androgen, e.g. oxandrolone, is indicated when growth velocity falters and continued till bone age exceeds 14 years. In addition, Estrogen replacement with conjugated estrogen (0.3 mg/day) or ethinylestradiol (5–10 µg/day) is indicated at 14 years for 3–6 months, followed by cyclical estrogen/progesterone therapy to maintain menstrual cycle.
- *Prophylactic gonadectomy* in cases with streak gonads, to prevent risk of malignancy.
- *Assisted reproduction* options must be explained to an adult case, as infertility is almost universal.

Noonan syndrome, a variant of Turner syndrome is usually seen in males. These cases usually share some common phenotypic features with Turner syndrome, e.g. short stature and neck-webbing, hence sometimes referred in the past as "*male Turner syndrome*" or "*female pseudo Turner*". However, it is a single gene disorder affecting the RAS MAPK pathway (Rasopathy) and karyotype is essentially normal.

11.3.3 KLINEFELTER SYNDROME

Klinefelter syndrome is the commonest sex chromosome disorder *in males*, characterized by presence of extra X chromosome/s, though many of them remain undetected throughout the life.

Incidence of Klinefelter syndrome is ~1:1000 male live-births, being higher in children/adults with mental retardation or psychiatric problems.

Cytogenetically, commonest karyotype is presence of an extra X chromosome (47,XXY), due to meiotic nondisjunction. Advanced maternal age is a risk factor and extra X chromosome is of maternal origin in ~60% cases. Other variants include Mosaicism (46,XY/47,XXY) or more than one extra X (48, XXXY, 49,XXXXY, etc.).

Clinical spectrum is highly variable, with no well-defined somatic phenotype and many cases are indistinguishable from normal males. Mosaic individuals tend to have milder phenotype and better prognosis. Severity of the disorder increases with increasing number of X chromosomes.

TABLE 11.10: Features of Klinefelter syndrome

- **Abnormal development**
  - Delayed speech and language development
  - Scholastic failure and learning disabilities
- **Behavioral/psychological problems**
  - Shy/passive behavior with social isolation
  - Aggressive or anti-social behavior
- **Abnormal sexual functions**
  - Cryptorchidism, micropenis, hypospadias
  - Delayed puberty, poor virilization
  - Azoospermia and infertility
- **Somatic abnormalities**
  - Tall and thin stature (Eunuchoid features)
  - Cranio-facial abnormalities*

*mongoloid slant, epicanthic folds, large mouth, large/malformed ears and flat/wide nasal bridge

Most cases are normal in pre-pubertal period with delayed onset of puberty and gynecomastia being earliest presentation. Other important indicators include: (a) tall stature with long legs, (b) intellectual disability, (c) behavioral problems, and (d) abnormal sexual development, e.g. small testes, micropenis, etc. **(Table 11.10)**.

Diagnosis needs confirmation by cytogenetic studies, though presence of one or more *Barr bodies* (normally absent in males) have been used as a screening test.

Gonadal biopsy reveals reduction/absence of germ cells with hyalinization of seminiferous tubules. Gonadotropin levels (FSH/LH) are normal till early puberty, but subsequently, testosterone levels are lower and estradiol levels are higher than the age-related values.

Management includes: (a) early intervention programs for speech/language dysfunction and learning disabilities, (b) psychotherapy, and (c) hormone replacement therapy with testosterone enanthate, from 11–12 years onwards to facilitate virilization.

Other important sex chromosome disorders are:

47 XYY male, is a common (1:1,000 live births) but usually an asymptomatic chromosomal defect, with no striking phenotype abnormalities, except relatively tall stature and mild behavioral problems.

Fragile X syndrome is one of the commonest causes of mental retardation in males, characterized by presence of an abnormally fragile site on long arm of X chromosome (usually Xq27.3) due to unstable DNA sequence (allelic expansion of the trinucleotide sequence CGG located in the 5′ untranslated region of FMR1 gene). Typical phenotype includes: (a) macrosomia, i.e. large body size, (b) characteristic facies with long face, macrognathia and prominent ears, (c) macroorchidism, and (d) intellectual disability with stereotyped behavior and speech. Females are less severely affected than males, though present with premature ovarian failure.

11.4 EVALUATION OF GENETIC DISORDERS

All familial disorders are not necessarily genetically inherited (may be due to common environmental factors, e.g. malnutrition or infection) and similarly, all inherited disorders are not familial (may be due to new mutations).

Diagnostic evaluation for a genetic disorder is usually indicated on the basis of strong family history *or* clinical suspicion and aims to: (a) confirm the diagnosis in the index case, (b) detection of carrier state in parents/siblings of index case; and (c) prenatal diagnosis in a suspected high-risk fetus.

Elaborate laboratory investigations are indicated only in selected cases with strong possibility of a known or unknown genetic defect.

This section deals with three important steps in genetic diagnosis: (a) suspecting the genetic disease, (b) clinical evaluation in these cases; and (c) laboratory workup in selected cases.

Step I. Suspecting the genetic disease: Family history and unexplained clinical features **(Table 11.11)** are most important clues to a genetic disease, although note that:

- *A negative family history does not exclude genetic defect* and the index case may be the only affected member of family, as recurrence risk is only 25–50% in single gene disorders and even lesser in multifactorial disorders or new mutations.
- *A genetic defect may have variable expression*, ranging from typical textbook description to very mild disease or physical stigmata.
- *Similar phenotype may develop due to different genetic errors*, e.g. arachnodactyly is seen in Marfan syndrome as well as homocystinuria.

TABLE 11.11: Indicators of genetic disease

a. Family history of…
- Similar disease with unexplained etiology
- Known genetic defect or carrier state
- Recurrent fetal/neonatal deaths

b. Clinical indicators (unexplained)
- Critically sick newborn/infant
- Failure to thrive
- Persistent vomiting
- *Visceromegaly:* Hepatomegaly, etc.
- Developmental delay/Intellectual disability
- *Neurological:* Seizures, coma, hypotonia, etc.
- Respiratory distress
- *Hepatic:* Icterus, Gallstones
- *Hematological:* Cytopenia, clotting defects
- *Renal:* Chronic kidney disease, stones
- Hearing/vision defects
- *Dysmorphism:* Abnormal skin, hair, eyes, genitals
- Skeletal dysplasia

c. Biochemical abnormalties (unexplained)
- Abnormal urinary odor/color
- Intractable acidosis/ketosis
- Hyperammonimia
- Hypoglycemia or dyselectrolytemia

- *All genetic defects do not necessarily manifest at birth*-some may present even beyond childhood or may not present at all due to variable *penetrance*.

Step II. Clinical evaluation: Clinical evaluation in a suspected genetic disorder aims to confirm the diagnosis or the need for further laboratory work-up. Some important aspects of clinical evaluation in these cases are as follows:

- **Consanguinity**, i.e. mating between close-relatives, is a major risk factor for unmasking of autosomal recessive defect with risk being directly proportional to strength of consanguinity, as follows:
  - *First-degree consanguinity*, i.e. relationship between siblings or parent-offsprings.
  - *Second-degree consanguinity*, i.e. relationship between uncle-niece, aunt-nephew or step-siblings.
  - *Third-degree consanguinity*, i.e. relationship between first cousins.
- **Pedigree charting:** Pedigree charting is one of the most important tool to recognize genetic defects and their mode of inheritance, which requires careful history as well as examination of living relatives for at least *three* generations of index case (Proband or Propositus).

  Common symbols used for pedigree construction are given in **Fig. 11.9B**. By convention, all members of same generation (living or dead) are placed in one horizontal line, with male members on the left side. Each generation is also denoted by roman numerals on left side. **Fig. 11.9A** has given a sample pedigree of an autosomal recessive disorders
- **Constellation of clinical signs:** Genetic frequently present with a constellation of clinical features, rather than an isolated abnormality. Many disorders are identifiable by combination of these features (syndrome). **Table 11.12** enlists some useful pointers (handles) towards genetic disorders. For easier syndromic search, it is advisable to use an uncommon handle as starting point, as features, e.g. mental retardation, simian crease, failure to thrive, etc. are *too* non-specific to facilitate a single diagnosis.

  Various databases like *Online Mendelian Inheritance in Man* (OMIM) or *Phenomizer* can be used to conduct search.

Step III. Laboratory evaluation: Laboratory evaluation of genetic disorders is often costly and indicated only in selected cases with strong possibility of a these defects, with choice depending on the probable clinical diagnosis.

Diagnostic investigations in genetic disorders may be broadly divided into (a) *molecular genetic studies* for suspected genetic disorders, and (b) Biochemical *(enzymatic) studies* for suspected inborn errors of metabolism. In addition, some overlapping cases may also need cytogenetic studies to rule out chromosomal disorders, discussed in Ch 11.3.

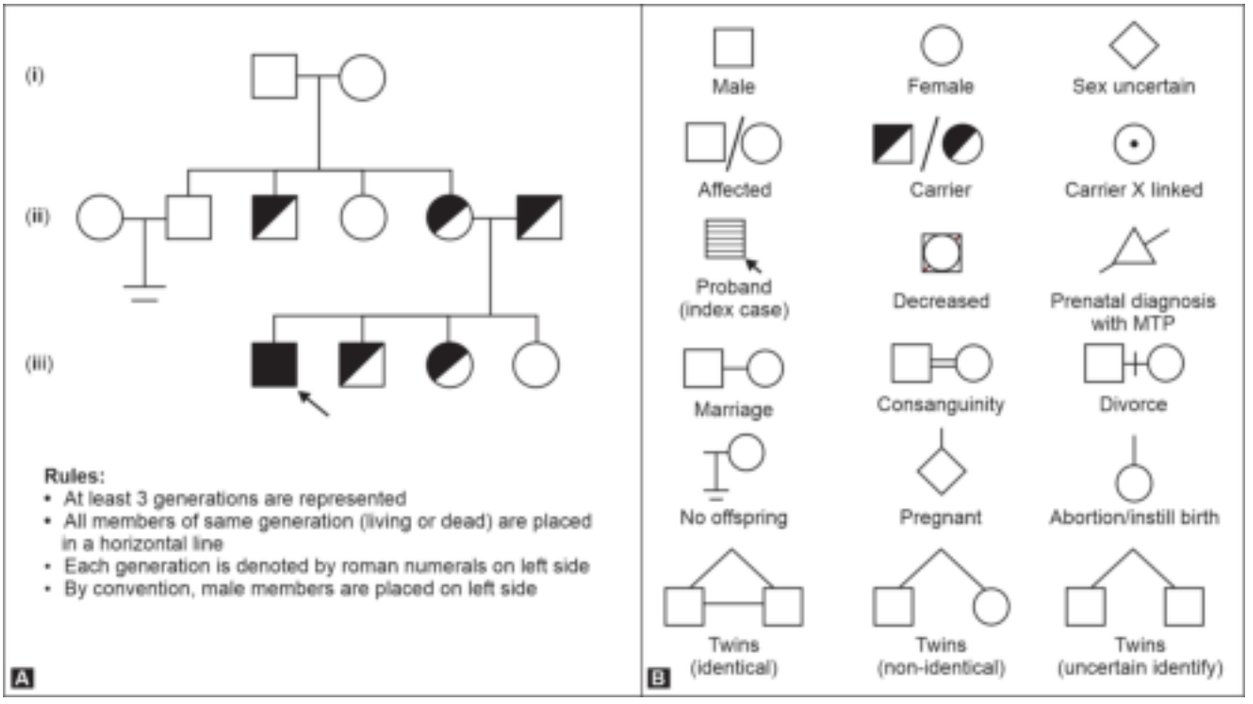

Fig. 11.9A and B: **Pedigree charting: (A) Representative pedigree chart (B) with commonly used symbols.**

TABLE 11.12: Suitable clinical handles (starting points) for genetic diagnosis

Dysmorphic features
- *Stature:* Tall/short/disproportionate stature
- *Head:* Microcephaly, craniosynostosis
- *Eyes:* Cataracts, coloboma, retinitis
- *Ears:* Deafness, deformed ear, preauricular tags
- *Mouth:* Cleft lip/palate, large tongue
- *Neck:* Webbing, masses
- *Limbs:* Poly/syndactyly, dermatoglyphics
- *Back:* Spina bifida
- *Genitals:* Ambiguous genitals, micropenis
- *Skin/hair:* Dyspigmented skin patch/hair

Systemic abnormalities
- Organomegaly, e.g. hepatosplenomegaly
- Major malformations, e.g. CHD, gut atresias
- Skeletal abnormalities

Biochemical abnormalities
- Abnormal urinary odor
- Acidosis, hyperammonimia
- Recurrent/persistent icterus, hypoglycemia

Molecular genetic testing for single/multiple gene defects involve study of the specific DNA sequence from a sample of blood or other body fluids/tissues. These tests are also valuable to detect carrier states for single gene disorders. Some common molecular genetic tests include:

- ***Amplification methods*** to clone the sequence of interest in a DNA fragment using polymerase chain reaction (PCR) and form multiple copies, which can then be examined by specific probes or primers. Results are available within few hours and commonly used for genetic studies when very small quantities of DNA are available as well as to detect viral/bacterial DNA in infectious disorders.

  Many variants of PCR tests are available at present including Real time PCR, Multiplex PCR, Nested PCR or Reverse transcriptase PCR (RT-PCR), the last one to amplify RNA.
- ***Hybridization methods*** using DNA probes tagged with radioactive or fluorescent markers, to attach to the complementary sequence in subject's DNA. These hybridized probes can be later detected by various methods, e.g. FISH, MPLA, southern blotting, etc.
- ***Sequencing methods*** to compare the sequence of whole or part of the DNA from patient with reference population to detect genetic alterations and include two common methods – Sanger sequencing and Next generation sequencing (NGS).

Next generation sequencing (NGS): Only 1% of human DNA is used for protein coding (Exons), the rest being in non-coding regions (Introns), though it may regulate functions of Exons. NGS has emerged as the most powerful tool for diagnosis of monogenic disorders, which includes: (a) *targeted panel testing* of selected regions, (b) *exome sequencing* of whole coding regions (ES), and (c) *whole genome sequencing* (WGS) of coding as well as non-coding regions.

NGS involves fragmentation of the DNA sample into multiple fragments followed by capture of selected or entire DNA fragment for sequencing. This sequence,

when compared with reference population, may reveal many differences (variants), which may or may not be of pathogenic significance and need correlation with clinical phenotypes for interpretation.

NGS is usually preferred test in cases with overlapping or probably new phenotypes, for which precise genetic defect is difficult to specify with multiple possibilities.

Biochemical studies are indirect but most frequently used methods to detect *genetic disorders* for which the actual enzymatic defect is known to cause the disease. These tests can be applied in the index case, prospective carrier or in the fetus for prenatal diagnosis and include: *(a) primary enzyme assays*, e.g. hexosaminidase-A in Tay-Sachs disease; *(b) non-enzymatic protein assays*, e.g. fVIII assay for hemophilia; *(c) secondary biochemical abnormality tests*, e.g. CPK levels for Duchenne muscular dystrophy or Hb electrophoresis in hemoglobinopathies.

Many biochemical tests, though not diagnostic of a specific genetic disorder or IEM *per se*, help in short-listing the differential diagnosis in these defects, e.g. hyperammonemia, acidosis, hypoglycemia, etc. Relevance of these tests in diagnosis of IEM has been discussed in chapter of IEM.

11.5 MANAGEMENT OF GENETIC DISORDERS

Management of genetic disorders includes three important components: (a) treatment of the index cases, (b) genetic counseling to prevent recurrence in subsequent pregnancy, (c) prenatal diagnosis for appropriate decision.

11.5.1 TREATMENT OF INDEX CASE

Genetic disorders cannot be cured and treatment is largely supportive, including physiotherapy, blood transfusions, e.g. haemolytic anemia, surgical treatment of malformations, incl. However, recent therapeutic advances in the management of these rare diseases have be able to prevent the severe morbidity or at least slow down the progression of disease, with following measures:

- **Dietary manipulations** to reduce the intake of substances which cannot be adequately metabolized in a genetic defect, specially if they are potentially toxic, e.g. removal of galactose (milk) from diet in galactosemia.
- **Enhancing urinary excretion** of toxic metabolites by drugs, e.g. sodium benzoate in urea cycle defects, penicillamine in Wilson disease or desferrioxamine in thalassemia.
- **Enzyme inducers** and coenzymes to augment deficient enzymes in certain defects, e.g. phenobarbitone for Crigler-Najjar syndrome. Desmopression in haemophilia. Administration of mega doses of vitamins have been successful in some defects to bypass enzymatic block, e.g. biotin in biotinidase deficiency, pyridoxine in homocystinuria
- **Enzyme replacement therapy (ERT)** is available for many lysosomal disorders at present, e.g. Gaucher disease, Niemann-Pick disease, Hurler syndrome and some other mucopolysaccharidoses, Pompe disease, Fabry disease, etc., though at a prohibit cost. Factor VIII therapy in hemophilia is another example of enzyme replacement therapy.
- **Avoidance of precipitating factors:** Symptoms of many IEMs are precipitated by prolonged fasting, heavy exercise, sun-exposure or exposure to certain drugs, e.g. primaquine in G6PD deficiency or Barbiturates in porphyria, which can be avoided.
- **Removal of disease organ,** e.g. splenectomy in hereditary spherocytosis of thyroidectomy in multiple endocrinal dysplasia.
- **RNA Modulators,** i.e. antisense oligonucleotides (ASO) therapy, e.g. Nusinersen (Spinal muscular dystrophy), Eteplirsen (Duchenne muscular dystrophy), etc.
- **Stem-cell transplant** is the ultimate therapy for many genetic defects, e.g. thalassemia major, Hurler syndrome and some primary immunodeficiencies. Liver transplant may be useful in many urea cycle defects.
- **Molecular targeted therapy** is available for certain disorders, e.g. Ivacaftor or Lumacaftor for cystic fibrosis, Nusinersen or risdiplam for spinal muscular atrophy and exon-skipping drugs for Duchenne muscular dystrophy and Imatinib for chronic myeloid leukemia.
- **Gene therapy** is possible for some disorders, e.g. SMA, Metachromatic leukodystrophy and some cancers, discussed as below.

Gene therapy aims '*to replace an identified abnormal gene with a normal gene*, i.e. *recombinant DNA, to modify or manipulate cell function and correct the genetic defect*.' It is emerging as an exciting option to cure many single gene defects and multifactorial disorders, e.g. cancers. However, medical and ethical issues support use of gene therapy only in rare and serious life-threatening disorders, for which no effective therapy are known.

Gene therapy involves: (a) isolation of recipient's plasmid, (b) selection of normal donor/recombinant gene for replacement from established gene libraries, (c) insertion of the normal gene into recipient's plasmid, (d) facilitating the multiplication of recombinant plasmid to yield multiple copies of new gene and (e) delivery of the recombinant DNA to the target cell nucleus. Direct insertion of a gene into cultured mammalian cells is also possible, if the candidate gene is introduced along with its promoter.

Depending on the type of recipient cell, gene therapy may be divided into: (a) *somatic cell therapy*, i.e. transfer of recombinant DNA into somatic cells, e.g. muscle cells

TABLE 11.13: Common disorders for gene therapy

- Spinal Muscular atrophy (Zolgensma)
- β-thalassemia (Zynteglo)
- Hemophilia A (Hemgenix)
- Retinal dystrophy (Luxturna)
- cerebral Adrenoleukodystrophy (Skysona)
- Adenosine deaminase deficiency (ADA)
- Alpha-1 antitrypsin deficiency (A1AT)
- Cystic fibrosis (CFTR)
- Familial hypercholesterolemia (LDL receptor)
- Gaucher's Disease (acid β glucosidase)
- Phenylketonuria (PAH)
- Neuroblastoma (IL-2)

in Duchenne muscular dystrophy or bone marrow for thalassemia; and (b) *germ-line therapy*, i.e. transfer of recombinant DNA into germ cells for transmission to future generations. Germ-line therapy, is considered as unethical for human use, though has been successfully adopted for obtaining α-glucosidase enzyme from rabbit milk for treatment of *Pompe's* disease.

Various *delivery systems* are used to insert donor gene into the recipient's plasmid including *physical methods*, e.g. gene-gun technology, *viral vectors*, e.g. retroviruses, adenoviruses and *non-viral vectors*, e.g. liposomes, DNA-ligand complexes and vaccines.

Gene therapy has shown promising results in many disorders and has been approved by USFDA for over 30 conditions **(Table 11.13)**.

11.5.2 GENETIC COUNSELING

Genetic counseling may be defined as *"a communication process between appropriately trained person/s and the parents/prospective parents, regarding the occurrence or the risk of occurrence of a genetic disorder in a family"*.

Aims: It aims to enable family members to:

- *Comprehend the medical facts* regarding genetic defect in the index case, e.g. diagnosis, probable course and available management,
- *Appreciate the hereditary aspects and risk of recurrence* in specified relatives,
- *Understand the options* to deal with the risk of recurrence,
- *Choose the appropriate course of action*, according to risk-estimates, family-goals, ethical and religious standards (and act accordingly),
- *Make the best possible adjustment* to the existing disorder or risk of recurrence.

Genetic counselling assists the family to make informed decision and should not be used as a forum to enforce the counselor's views and opinions.

Indications: Genetic counseling is usually advisable in settings with:

- Family history of a genetic disease or a carrier state in parents, offspring or close-relatives.
- Obstetrical history of recurrent abortions, stillbirths or neonatal deaths
- High-risk pregnancies for genetic disease, e.g. consanguinity or advanced parental age.
- Identified high-risk families during screening programs, e.g. biochemical/radiological screening for Down syndrome or population screening for hemoglobinopathies.

Prerequisites: It is essential to ensure that:

- Provisional diagnosis of the index case is established to calculate the expected risk of recurrence.
- Results of carrier screening are available, if possible.
- Counsellor is well-trained in communication skills and well-informed about current knowledge on probable diagnosis/differential diagnosis.
- Session is conducted in complete confidentiality and relaxed atmosphere to ensure adequate parental comprehension.

Components: Important components of genetic counseling include:

- *Assessing the comprehension* capacity and knowledge of cosult and (parents), regarding probable genetic defect/s.
- *Providing essential information about the specific problem* in comprehensible terms, specially related to its natural course, need for diagnostic procedures, cost and usefulness of therapeutic interventions and quality/span of life. Use of appropriate audiovisual aids, e.g. pedigree charts, facilitates parental understanding, who may also be provided with addresses of support groups and relevant books or websites.
- *Explaining the probable risk of recurrence*, in terms of percentages and fractions. While it is possible to provide exact risk estimates in single gene disorders, a range or magnitude of risk (high, low or negligible) should be clearly stated, based on the current knowledge, if the diagnosis is uncertain *or* precise risk is unknown, e.g. in chromosomal disorders.
- *Offering the options regarding future conceptions*, e.g. feasibility of preventive interventions, (e.g. folic acid supplementation in neural tube defects), prenatal diagnosis/therapy with costs and risks/benefits of procedures, and alternate options, e.g. termination of an affected fetus, gene therapy, assisted reproduction or adoption. These options should be explained in unbiased and non-directive manner, avoiding recommendation of a particular option. It is emphasized that counsellor merely facilitates the decision process by parents but should never take a decision on their behalf or suggest an option, even if pressurized to do so.
- *Follow-up visits* to allow parents enough time to accept/understand the problem and decide future course of action.

11.5.3 PRENATAL DIAGNOSIS

Prenatal diagnosis of a suspected genetic/hereditary disease or congenital malformation is an important component of genetic counseling, referral to suitable centers for delivery and further management, as well as to prepare the family for the expected or unexpected outcomes. Recent developments in understanding of human genome, molecular biology, fetal/gene therapy and assisted reproduction have further enhanced the value of prenatal diagnosis.

Indications for prenatal diagnosis usually include:

- Advanced maternal age (>35 years) at delivery
- Obstetric history of recurrent abortions/stillbirths or neonatal deaths
- History of a potentially genetic disease or malformation in previous child
- History of a genetic disease, carrier state or abnormal karyotype in parents
- Abnormal maternal serum markers during antenatal screening
- Antenatal history of exposure to potential teratogens, e.g. infections, drugs, irradiations, etc.
- Abnormal prenatal USG/anomaly scans.

Prerequisites: Prenatal diagnosis is a costly and time consuming procedure, with inherent risks of diagnostic interventions. Hence, it should be offered only in selected cases, when:

- Accurate diagnosis of index case is available and parents have been identified with abnormal carrier state or chromosomal abnormality,
- Estimated risk of recurrence is fairly high and expected fetal disorder is sufficiently severe, to justify the need and risk for prenatal diagnosis.
- Available prenatal diagnostic tests for suspected defect are fairly sensitive and specific.
- No satisfactory postnatal treatment is available for suspected defect *or* delayed diagnosis is likely to worsen the outcome.
- Option of pregnancy termination or fetal/gene therapy is acceptable to the couple in case of abnormal result.
- Family has made an informed decision to accept risks/benefits of such intervention and consented in writing.

Techniques: Prenatal diagnostic tests may be broadly divided into: (a) screening tests, and (b) specific diagnostic tests **(Table 11.6)**.

Screening tests are simple and cost-effective interventions to identify high-risk mothers in need of further investigations and should form the part of regular antenatal workup. Pre-conception carrier state for many recessive disorders may be identified by selected screening investigations in high-risk mothers, e.g. serum CPK levels for Duchenne muscular dystrophy, HbA_2 levels for thalassemia, etc. Important prenatal screening tests **(Table 11.14)** are as follows:

TABLE 11.14: Prenatal diagnostic tests

Maternal studies

- Prenatal USG studies
  - Level 1 and 2 anomaly scans
  - Early transvaginal scans
  - Late malformation scans
- Biochemical
  - Triple marker test
  - Quadruple marker test
- Non-invasive prenatal screening
- *Others:* TORCH screen, Hb electrophoresis

Fetal studies

- Cytogenetic and molecular diagnostic tests
  - Chorionic villous biopsy (~11–13 weeks)
  - Amniocentesis (~17–23 weeks)
  - Cordocentesis,(> 18 weeks)
- Biochemical enzyme assays
- *Others:* Fetoscopy, fetal echocardiography

- ***Prenatal ultrasonography*** is the most commonly used prenatal screening test to detect major/minor structural malformations *in utero*, as well as to assist in collection of samples for advanced cytogenetic studies.

  Routine transabdominal USG screening is recommended at 11–13 weeks (Level 1 anomaly scan) and again at 18–20 weeks (Level 2 anomaly scan) of gestation in all antenatal mothers. However, additional USGs are advised in high-risk pregnancies, as follows:

  Early transvaginal scans to detect markers of chromosomal defects, e.g. first trimester markers, e.g. cystic hygroma, hydrops fetalis, nuchal translucency, growth retardation and fetal heart rate abnormalities; and second trimester markers, e.g. nuchal thickening, echogenic bowel, short extremities, pyelectasis, intracardiac echogenic foci, brain ventriculomegaly, clinodactyly, etc.

  Late scans (20–24 week) to detect malformations, which may be missed on routine USG at 18–20 weeks, e.g. small bowel atresia, esophageal atresia, diaphragmatic hernia, renal tract anomalies and achondroplasia. Disorders, e.g. skeletal dysplasia may be identified, using intrauterine nomograms and growth curves on serial scans from second trimester onwards.

  3-D USG scans are also available to detect minor fetal malformations, e.g. cleft palate, single vertebral defects.
- ***Maternal biochemical markers:*** Conventional protocols for biochemical screening at 11–13 weeks gestation include *Triple marker test* at 11–13 weeks of gestation (α-fetoprotein, total or free β-human chorionic gondotropin and unconjugated estriol levels) and Quadruple marker test at 14–16 weeks (Triple markers + inhibin levels), to predict fetal chromosomal defect, e.g. Down syndrome (Ch 11.3.1).

- ***Non-invasive prenatal screening*** (NIPS) is a new screening test in high-risk cases to analyse free fetal DNA in maternal plasma at ~10th week of gestation. It can detect aneuploidies of chromosome 21 with 99% sensitivity but false-positive results are possible and must be confirmed with cytogenetic studies.

Specific genetic studies in fetus are indicated only in a selected subset of high-risk mothers, as identified on routine screening tests *or* with known risk of genetic disease. While most of them are expensive and require invasive sample collections with inherent risk of procedure, information obtained is often precise enough to confirm or exclude a suspected defect. These tests include karyotyping, molecular diagnosis and enzyme studies in fetal samples to confirm or exclude suspected genetic defect.

Choice of the method to collect these samples depends on the gestational age at the time of proposed prenatal diagnosis and usually include chorionic villous biopsy at ~11–13 weeks, amniocentesis at ~17–23 weeks and cordocentesis, at >18 weeks. Fetoscopy is most traumatic and rarely used, except to obtain samples of fetal tissues, e.g. liver or skin for enzymatic studies.

All these techniques except fetoscopy, are fairly safe in expert hands with estimated risk of fetal loss as 0.1–0.2%. Fetoscopy is associated with >5% risk of abortion. However, some fetomaternal hemorrhage is inevitable with these procedures and hence, administration of Rh immunoglobulin is indicated in all Rh –ve mothers taken up for these studies.

11.6 INBORN ERRORS OF METABOLISM

The term "Inborn errors of metabolism" refers to a broad group of *genetic defects with qualitative or quantitative deficiency in one or more enzymes or their co-factors, involved in synthesis, transport, storage, metabolism or degradation of various biochemical compounds in body*.

Consequently, these enzymatic defects may lead to: (a) deficiency of final metabolite product, (b) accumulation of proximal substrate in metabolic pathway, or (c) activation of alternate metabolic pathways with formation of abnormal metabolites.

More than 300 of such disorders are known, with an estimated incidence of 3–4/1000 births, though many of them are asymptomatic or never diagnosed. According to the predominant metabolic defect, these disorders may be broadly classified as disorders of: (a) amino acid metabolism, (b) fat metabolism, (c) carbohydrate metabolism, (d) nucleic acid metabolism, and (e) miscellaneous errors **(Table 11.15)**.

TABLE 11.15: Classification of inborn errors of metabolism (IEM)

- **Amino acid metabolism**
  - Aminoacidurias
  - Urea cycle defects
  - Organic acidemias
- **Carbohydrate metabolism**
  - Glycogen storage disorders (GSDs)
  - Galactosemia and fructose intolerance
  - IEMs with lactic acidosis
  - Glycoproteinoses
  - Mucopolysaccharoidoses (MPS)
- **Fat metabolism**
  - Mitochondrial fatty acid oxidation defects
  - Peroxisomal disorders
  - Lipoprotein metabolism/transport defects
  - Lipid storage disorders (lipidoses)
- **Nucleic acid metabolism**
  - Purine metabolism, e.g. Lesch-Nyhan syndrome
  - Pyrimidine metabolism, e.g. Orotic aciduria
  - Gout
- **Miscellaneous disorders**
  - Heme metabolism, e.g. porphyria
  - Trace element metabolism, e.g. Wilson disease
  - Others, e.g. α-1 antitrypsin deficiency

When to Suspect an IEM

Clinical spectrum of IEMs is extremely wide, depending on the type and severity of specific enzyme defect and ranges from completely asymptomatic patients to severe and lethal disease in neonatal period. Generally, these babies are normal at birth as toxic metabolites are cleared by placenta.

IEMs, which manifest in neonatal period, are usually severe and frequently lethal. High index of suspicion is essential for early diagnosis of these defects as presentations are usually non-specific and easily confused with more common problems, e.g. infections, hypoxia, etc. Important clinical indicators of IEM are given in **Table 11.11**.

History of consanguinity in parents or similar illness in previous sibling with/without death is an important warning for IEMs in newborns or early infancy. However, most of the fatal IEMs are autosomal recessive and similar family history may not be obvious.

IEMs, which manifest after neonatal period, are usually milder variants of autosomal recessive defects or transmitted by dominant inheritance. Family history of similar or unexplained illness is often present in these cases.

Laboratory Diagnosis in IEM

Precise diagnosis is essential for appropriate genetic counseling. However, considering the costs involved, a step-wise approach is advised in laboratory workup of these cases involving certain baseline investigations before specific tests. In illnesses with intermittent presentation, all biochemical investigations should be done during the symptomatic phase, as these tests may be false-negative during normal phase. Important investigations in IEMs include:

a. ***Baseline investigations*** in all cases:
   - *Blood:* Complete hemogram, sugar, ammonia, electrolytes, liver enzymes, bicarbonates, lactate and pyruvate levels and arterial blood gases.
   - *Urine:* Color, odor, pH, reducing sugar, ketones, ferric chloride test.
   - *Others:* CSF, nerve conduction studies, etc.

b. ***Specific investigations*** for suspected cause:
   - *Biochemical* estimations of metabolic substrates, e.g. phenylalanine.
   - *Tissue biopsies*, e.g. liver, muscle, bone marrow or skin biopsy for storage disorders.
   - *Specific enzyme assays* in blood or other tissues.

c. ***Molecular diagnosis*** for exact genetic defect in the index case and suspected carriers, as discussed in previous chapter using amplification, e.g. PCR or sequencing tests, e.g. NGS (Ch 11.4).

d. ***Prenatal diagnosis*** by enzyme studies or molecular tests in chorionic villous biopsy or cultured amniotic cells (Ch 11.5).

In morbidly sick children with suspected IEM, it is advised to collect following samples for later studies and genetic counseling: (a) clinical photograph, (b) relevant X-rays, (c) 5–10 ml of blood in heparin and EDTA vials, (d) urine sample, (e) CSF sample, (f) skin, liver, muscle and bone marrow biopsy. All these samples should be adequately stored and transported for further studies.

Some important IEMs from the Indian perspective, are discussed here in greater details.

11.6.1 DISORDERS OF AMINO ACID METABOLISM

Proteins are complex organic nitrogenous compounds made up of smaller units-*amino acids,* which are part of almost all enzymes required for human metabolism. Common IEMs of amino acid metabolism are as follows:

Phenylketonuria: Phenylalanine is an essential amino acid, which is degraded into tyrosine, if not utilized. PKU is the commonest IEM, due to deficiency of enzyme *phenylalanine hydroxylase* (*classical PKU*) or its cofactor *tetrahydrobiopterin* (*malignant PKU*), essential for this degradation. Consequently, un-degraded phenylalanine accumulates in blood and tissues or gets converted into phenylpyruvic acid or phenylethylamine by alternate pathways, which are excreted in urine. Excess phenylalanine prevents utilization of other amino acids by developing brain, leading to progressive neurological damage.

Clinically, children with *classic PKU*, which accounts for >98% cases, are normal at birth and usually manifest at 2–3 months with—(a) progressive mental retardation, (b) neurological features, e.g. irritability, seizures and hypertonia (c) fair complexion with blond hair, blue eyes and occasionally eczema due to tyrosine deficiency, which is essential for melanin production, and (d) mousy odor in urine due to excretion of alternate phenylalanine products.

Diagnosis depends on—(a) plasma phenylalanine levels >2 mg/dl, with (b) altered plasma phenylalanine: tyrosine ratio (>1:3). Urinary excretion of alternate metabolites may be used for screening as *Guthrie test* or *Ferric chloride test* (Add few drops of 1% ferric chloride to fresh urine, which turns deep green due to presence of phenylpyruvic acid). Molecular diagnosis is confirmatory.

Neonatal screening for PKU is widely practiced in many countries, involves whole-blood phenylalanine assay after 48–72 hours of birth by a semi-quantitative bacterial inhibition assay on dried blood spot. Diagnosis should be confirmed by quantitative plasma chromatography as transient hyperalaninemia is not uncommon in newborns.

Treatment aims to reduce phenylalanine/metabolites levels to minimize brain damage. Controlled dietary restriction of phenylalanine using commercial formula, is the key of successful management, which should begin within 1–2 weeks of life and continued till at least 8–10 years.

During dietary restriction, plasma phenylalanine levels should be closely monitored to maintain between 3–15 mg/dl, as over-restriction may lead to deficiency. Adequate dietary intake of tyrosine is essential as its endogenous synthesis is impaired in PKU.

Pregnant mothers with untreated PKU are at risk for (a) spontaneous abortions, (b) babies with mental retardation, microcephaly, agenesis of corpus callosum and heart defects. Prospective mothers should begin low phenylalanine diet before conception to maintain plasma phenylalanine levels <10 mg/dl.

Malignant PKU, carries poor prognosis with rapid neurological deterioration within few months of life. Apart from dietary phenylalanine restriction, some cases may benefit with co-factor BH4 supplementation and/or therapy with neurotransmitter precursors, e.g. L-dopa or 5-HT, to prevent neurological damage.

Tyrosinemia: Tyrosine is a precursor of many important human proteins, e.g. dopamine, norepinephrine, epinephrine, melanin and thyroxine. *Hypertyrosinemia* is seen in many inherited enzyme defects or acquired disorders, e.g. liver failure, scurvy and hypothyroidism.

Clinically, Hereditary tyrosinemia (Tyrosinemia type I) is an autosomal recessive deficiency of *Fumarylacetoacetate hydrolase enzyme*, which presents with:

- Failure to thrive and developmental retardation,
- *Acute hepatic crisis* with fever, vomiting, jaundice, hypoglycemia, hemorrhagic tendencies and a *cabbage like odor* due to accumulated methionine metabolites. Crises are often precipitated by intercurrent infections and resolve spontaneously or progress to cirrhosis or hepatic carcinoma in survivors.

- *Episodic acute peripheral neuropathy*, also triggered by intercurrent infections, presents with severe leg pain, hypertonia and motor weakness. These episodes may recover within a week or terminate into respiratory failure and death.
- *Fanconi-like syndrome* due to renal tubular dysfunction with metabolic acidosis, hyperphosphaturia with nephrocalcinosis and hypophosphatemia with vitamin D resistant rickets.

Early onset cases usually die by 2 years, while others may survive till 8–10 years before death due to cirrhosis or hepatic tumors.

Diagnosis must be suspected on presence of succinylacetoacetate and succinylacetone in serum and urine, confirmed by molecular test by sanger or next generation sequencing. *Prenatal diagnosis* by NGS or enzyme assay in chorionic villous biopsy or succinylacetone levels in amniotic fluid is possible.

Treatment includes dietary restriction of tyrosine and phenylalanine to retard progression of disease, though liver transplant as early as possible is the only effective therapy. An alternate enzyme inhibitor Nitisinone or NTBC (PO 1 mg/day), an inhibitor of the upstream enzyme 4-HPP,) is the mainstay of treatment to prevents toxic metabolite formation. However, as it does not restrict tyrosine formation, diet restriction is mandatory. Liver transplant is recommended only in case of acute liver failure and hepatocellular carcinoma.

Tyrosinemia type II (oculocutaneous tyrosinemia) presents with mental retardation, self-mutilating behavior and herpetiform corneal ulcers in *infancy* due to tyrosine deposition; and palmar/planter punctuate hyperkeratosis in *older children*, which responds well to dietary restriction.

Transient tyrosinemia of newborn is usually seen in preterms on high-protein diet, due to delayed maturation of enzyme *4-hydroxy phenylpyruvate dioxygenase.* Most cases are asymptomatic but some may develop lethargy, poor feeding, decreased motor activity due to high phenylalanine levels. While most cases recver spontaneously in 3–4 weeks, symptomatic cases need dietary protein restriction and vitamin C supplementation (200–400 mg/d).

Albinism denotes a group of genetic disorders with defective biosynthesis and distribution of melanin due to enzyme *tyrosinase* deficiency, despite normal number of melanocytes. Melanin is mainly synthesized in skin, hair follicles and eye (choroids/iris), from tyrosine by a melanocyte organelle—*melanosomes*.

Clinically, Albinism may be *generalized* or *localized*, though all variants have some degree of hypopigmentation of hair and skin, with/without eye involvement. Hypopigmented skin tends to burn on exposure to sunlight, hair are white and silky and those with ocular involvement have translucent/pinkish or bluish sclera with photophobia, diminished visual acuity and strabismus. Blindness and skin cancers are common in severe albinism.

Management depends on severity and includes: (a) avoidance of sun exposure and use of sun-protection creams, (b) ophthalmic support with anti-glare lenses, (c) vocational support, and (d) genetic counseling.

Important variants of albinism include:

- ***Oculocutaneous albinism type I*** (OCA-1), is the most severe form with complete lack of pigment in skin/hair and eyes since birth, though some pigmentation may occur with advancing age.
- ***Oculocutaneous albinism type II*** (OCA-2), the commonest type with partial tyrosinase activity, presents at birth with some pigmentation of skin/eyes and yellowish hair and continue to collect pigment throughout the life.
- ***Ocular albinism*** is limited to eyes with near-normal skin/hair pigmentation and hair bulb tyrosinase activity. Most cases are X-linked.
- ***Partial albinism*** may also be associated with immunodeficiency states, e.g. *Chédiak-Higashi syndrome* (with neutropenia and increased susceptibility to infection), and *Hermansky-Pudlak syndrome* (with platelet dysfunction and bleeding tendencies).
- ***Localized albinism***, limited to a small part of skin/hair, is usually auotosomal dominant and may be present at birth or develop over time. Two important syndromes associated with localized albinism are – *Piebaldism* with white forelock at birth with/out white macules over face, trunk and limbs; and *Waardenburg syndrome* with white forelock, heterochromia iridis and sensorineural deafness.

Homocystinuria, an autosomal recessive disorder of methionine metabolism, is the second commonest error of amino acid metabolism. **Classic homocystinuria**, the commonest variant, denotes deficiency of enzyme *cystathionine β-synthetase*, which leads to accumulation of homocystine (an intermediate metabolite) and methionine (dietary amino acid) in various body fluids and tissues.

Clinically, these cases are asymptomatic in infancy and usually manifest at 3–4 years of age with:

- *Ocular complications*, e.g. ectopia lentis with consequent myopia, iridodonesis, glaucoma, cataracts and retinal detachment/optic atrophy;
- *Skeletal manifestations* with generalized osteoporosis and marfanoid features, e.g. tall and thin stature, arachnodactyly, scoliosis, pectus excavatum, genu valgum, etc.;
- *Neurological manifestations*, e.g. mental retardation and psychiatric/behavioral disorders; and
- *Susceptibility to thromboembolic episodes*, e.g. cerebrovascular strokes, renovascular hypertension, pulmonary embolism, etc.

Diagnosis rests on elevated levels of homocystine (>100 µmol/L) and methionine (>50 µmol/L) in plasma as well as in urine. It is confirmed by enzyme assay or molecular testing in liver biopsy specimen. *Cyanide nitroprusside test* is a simple screening test in these cases to detect presence of homocystine in urine.

Prenatal diagnosis is possible by enzyme assay in cultured amniotic cells or chorionic villi. Whole blood methionine estimation is used for *neonatal screening*.

Treatment with high doses of Pyridoxine (200–1000 mg/d) is effective in ~40% cases and should be continued throughout the life, along with dietary methionine restriction and cysteine, folate and B_{12} supplementation

Non-responsive cases may benefit with betaine therapy (trimethylglycine 100 mg/kg/day q12hr), which stimulates reconversion of homocystine into methionine.

Hartnup disease, an autosomal recessive disorder with mutation in *SLC6A19* gene causing *defective transport of various neutral amino acids*, specially tryptophan, across the gut mucosa and renal tubules is not uncommon but usually asymptomatic. Clinical manifestations are usually attributable to: (a) nicotinamide deficiency—an end-product of tryptophan metabolism, and (b) accumulation and bacterial decomposition of unabsorbed amino acids in gut, which are then absorbed and excreted in urine as indole derivatives.

Clinically, these cases present with:

- *Cutaneous photosensitivity* with pellagra-like rash or chronic eczema, and
- Intermittent episodes of cerebellar ataxia and psychiatric disturbances.

Symptoms are usually exacerbated after diarrhea or low-protein diet. Long, spontaneous remissions are common.

Diagnosis rests on: (a) selective aminoaciduria with normal excretion of non-neutral amino acids, e.g. arginine, proline or hydroxyproline, and (b) heavy urinary excretion of indole derivatives, e.g. indican. Indicanuria, on oxidation into indigo-blue after air exposure, leads to *blue staining of diapers**. Plasma levels of tryptophan and other neutral amino acids are usually normal due to alternative modes of absorption.

**Blue-diaper syndrome is a familial disorder with indicanuria, hypercalcemia and nephrocalcinosis.*

Treatment includes high protein diet to replenish urinary loss of amino acids along with nicotinamide supplements (50–300 mg/day) in symptomatic cases and avoidance of sun-exposure.

Alkaptonuria, the *first identified IEM*, is a rare autosomal recessive disorder with deficiency of *homogentisic acid oxidase* enzyme, essential for degradation of *homogentisic acid*-an intermediate metabolite of tyrosine metabolism. Consequent accumulation of homogentisic acid in tissues leads to black pigmentation and destruction of connective tissues (*ochronosis*) and increased excretion in urine, which turns black on oxidation.

Clinically, these cases are essentially asymptomatic in childhood except black discoloration of urine on standing, specially if it is alkaline.

Most cases manifest in adults with: (a) *ochronosis*, i.e. black pigmentation of sclera and ear/nose cartilage, (b) progressively degenerative arthritis, specially involving spine and large joints. Nephrolithiasis due to renal pigment deposits may develop in later stages.

Diagnosis is based on elevated levels of homogentisic acid in urine and bi-allelic pathogenic variant in *HGD* gene. Homogentisic acid is a strong antioxidant and its presence in urine is indicated by *black reaction with Benedict* or *Fehling agent*. (d/d black urine include phenol poisoning and melanotic tumors)

Treatment is non-specific, though vitamin C therapy (PO 1 gm/d) and Nitisinone (PO 1 mg/day) may delay ochronosis and degenerative arthritic changes. NTBC has shown to slow progression of disease and is approved for treatment in some European countries. Physiotherapy is recommended to promote strength and flexibility.

Organic acidemia or aciduria, is a group of amino-acidopathies due to enzymatic defects in catabolism of *three* essential branched-chain amino acids, i.e. *valine, leucine* and *isoleucine*. Most of these disorders present in neonatal period with persistent metabolic acidosis and neurological dysfunction, with/without hyperammonemia.

Organic acidosis with wide anion gap (>15 mEq/L) is the hallmark of these disorders, though many other inborn errors with metabolic acidosis **(Table 11.16)** must be excluded in differential diagnosis.

Maple syrup urine disease (MSUD) is a rare autosomal recessive defect in decarboxylation of these branched chain amino acids due to deficiency of a complex enzyme system—*branched-chain-ketoacid dehydrogenase*. Consequent accumulation of intermediate metabolites in body fluids and their excretion in urine leads to metabolic acidosis, neurological manifestations and a typical *maple syrup-like odor in urine.*

TABLE 11.16: IEMs with metabolic acidosis

a. Carbohydrate defects (Hyperketotic acidosis)
- Disorders of gluconeogenesis, e.g. GSD
- Disorders of pyruvate metabolism
- Ketotic hypoglycemia

b. Fatty-acid oxidation defects (Hypoketotic acidosis)
- Medium chain aceyl CoA dehyrogenase deficiency
- Carnitine deficiency
- Biotinidase deficiency

c. Amino acid defects (Organic acidemia)
- Branched-chain organic acidurias
- *Others:* Hyperlysinemia

Clinically, classic MSUD manifests within first week of life with poor feeding, vomiting and tachypnea; and rapidly progress to develop neurological features, i.e. coma, seizures and alternate periods of hypotonia and hypertonia (*extensor spasms*). Most cases die in infancy due to severe ketoacidosis and cerebral edema, while mental retardation and neurological deficit is common among survivors.

Other variants present with intermittent ketoacidosis and neurological manifestations during stress, e.g. infections; or a mild late-onset disease beyond infancy with mental retardation, seizures and typical urinary odor.

Diagnosis must be suspected in a case with typical urinary odor, metabolic acidosis, hypoglycemia and ketonuria with *navy blue color on ferric chloride test*. A useful screening test is the development of yellowish precipitate on addition of dinitrophenylhydrazine in urine. Confirmation requires NGS and aminoacidogram to show marked elevation of branched amino acids.

Treatment includes: (a) life-long dietary restriction of branched-chain amino acids, especially leucine by using BCAA free formula. Supplementation with isoleucine and valine may be required; (b) exchange transfusion or hemodialysis to eliminate accumulated organic acids in acute phase, and (c) prevention of catabolic states, i.e. infections, which may precipitate the crisis. Thiamine supplementation may be beneficial in some mild cases. Liver transplantation is the definitive treatment.

Disorders of branched chain amino acids, other than MSUD, e.g. *Methylmalonic aciduria (MMA)*, *Isovaleric academia (IVA)*, and *Propionic aciduria* (PA) present with similar manifestations, i.e. metabolic ketoacidosis and neurological manifestations in early infancy and need to be differentiated on plasma aminoacidgram and Gas Chromatography Mass Spectrometry (GCMS) *urine in isovaleric acidemia has typical 'sweaty feet' odor.*

Management includes supplemental vitamin B_{12} to those MMA cases who are known to be vitamin B_{12} responsive; restricting natural protein, particularly of propiogenic amino acid precursors, while maintaining a high-calorie diet. Carnitine supplementation is required to improve the excretion of propionic acid in PA. Metronidazole is given to reduce the propionate producing gut bacteria. Liver transplant is the definitive management.

Urea cycle defects (hyperammonemia): Ammonia, a highly neurotoxic substance, is regularly produced on catabolism of various amino acids and rapidly degraded in liver by *Krebs-Henseleit* cycle to urea for excretion.

Hyperammonemia is seen in many *inherited defects*, e.g. (a) urea cycle defects and (b) organic acidemias, etc.; or *acquired hepato-cellular disorders*, e.g. (c) acute hepatic failure, (d) Reye syndrome, and (e) portal vein obstruction.

Urea cycle defects include inherited deficiency in one of the five major Krebs-cycle enzymes, namely *carbamyl phosphate synthetase* (CPS), *ornithine transcarbamylase* (OTC), *argininosuccinate synthetase* (AS), *argininosuccinate lyase* (AL) and *arginase*; leading to hyperammonemia and neurological features. All of them are autosomal recessive except OTC deficiency, which is commonest among all urea-cycle defects and inherited as X-linked dominant.

Clinical manifestations of urea cycle defects vary according to the type and severity of enzyme defects, broadly divided into:

a. *Severe neonatal hyperammonemia* (>1000 µmol/L) due to complete urea-cycle enzyme defects, presents within few hours/days of birth with poor feeding, vomiting, hypotonia and tachypnea; rapidly progressing to coma, intractable seizures and death, if untreated.
b. *Moderate neonatal hyperammonemia* (200–400 µmol/L) due to partial urea-cycle enzyme defects or organic acidemias, presents in newborns with mild features, e.g. unexplained lethargy and poor feeding.
c. *Late-onset hyperammonemia* is asymptomatic till the baby is on low-protein breast milk, only to manifest after introduction of high-protein weaning foods or infections. These cases present with intermittent episodes of vomiting, lethargy, seizures and coma, often misdiagnosed as recurrent Reye syndrome. Plasma ammonia levels are high (200–500 µmol/L), but only during episodes.
d. *Transient neonatal hyperammonemia*, an unexplained hyperammonemic state is usually seen in preterms, which is either asymptomatic or manifests soon after birth with features mentioned in 'a' above. Most cases recover spontaneously after 6–8 weeks, unless die during acute crisis.

Diagnosis depends on high index of suspicion (often misdiagnosed as neonatal septicemia) and presence of hyperammonemia >200 µmol/L. Identification of specific urea-cycle enzyme defects depends on amino acid profile in plasma or urine.

Treatment of acute hyperammonemic states include:

- Complete elimination of proteins in diet, except an IV mixture of essential amino acids as 0.25 gm/kg/day;
- Adequate provision of calories as IV dextrose and lipids, to prevent endogenous protein breakdown;
- Gut sterilization with lactulose therapy to reduce intestinal ammonia production by bacterial activity;
- Urinary elimination of ammonia in excretable conjugate forms with sodium benzoate and arginine (PO 250–500 mg/kg/day). Arginine is not used in arginase deficiency.
- Hemodialysis or hemofiltration in severe cases.

On recovery, these cases should continue on low protein diet (<1 gm/kg/d) and chemical conjugates, e.g. sodium benzoate, sodium phenylacetate etc (orally, in abovementioned doses), along with avoidance of catabolic states, e.g. infections and heavy meals.

11.6.2 DISORDERS OF LIPID METABOLISM

Disorders of fat metabolism may be broadly divided into five categories: (a) mitochondrial fatty acid oxidation defects, (b) peroxisomal disorders, (c) lipoprotein disorders, (d) lipid storage disorders or lipidoses, and (e) mucolipidoses.

A. Mitochondrial Fatty Acid Oxidation Defects

Mitochondrial oxidation of fatty acids is an essential energy-producing pathway, specially during starvation and exercise. In skeletal and cardiac muscles, fatty acids are completely oxidized into CO_2 and water. In liver, ketones (acetoacetate and β-hydroxybutyrate) are end-products of fatty acid oxidation, which serves as fuel for peripheral tissues, e.g. brain.

Many genetic defects of mitochondrial fatty acid oxidation, all autosomal recessive, are known. Almost all are characterized by acute hypoglycemic coma on starvation with/without other features, e.g. cardiomyopathy, muscular weakness or rhabdomyolysis. As these cases manifest only on fasting, they are usually misdiagnosed as Reye syndrome or sudden infant death syndrome. *Absence of urinary ketones despite hypoglycaemia is a diagnostic clue in these cases.*

Medium chain acyl-CoA dehydrogenase deficiency is the commonest fatty acid oxidation defect, presenting between 6 months and 3 years of life, with acute episodes of vomiting, coma, seizures, hepatomegaly and, hypoketotic hypoglycemia after prolonged fasting (12–16 hours).

Acute episodes should be rapidly treated with IV dextrose to prevent lipolysis, while further attacks can be prevented by avoiding prolonged starvation, use of corn starch 2gm/kg/day, medium chain triglyceride (MCT) oil, and overall low fat diet. Attacks become less frequent with advancing age. Cardiomyopathy and muscle weakness is absent.

Carnitine deficiency: Carnintine is a critical cofactor in transport of fatty acids across the mitochondrial membrane, specially in heart and muscles. It is synthesized from lysine in humans as well as also present in red meat and dairy products. Carnitine deficiency is either *primary* (dietary) or *secondary* due to increased excretion in fatty acid oxidation defects.

Clinically, these cases may present with *fasting hypoketotic hypoglycemia* in infancy and early childhood, though most common presentation is cardiomyopathy and generalized muscle weakness at 2–4 years of age. Some cases may present with acute rhabdomyolysis, myoglobinuria and renal failure. Low plasma carnitine levels are diagnostic and treatment includes oral carnitine supplements (50–100 mg/kg/d q8hr).

Biotinidase deficiency: Biotin is an essential cofactor for many carobxylase enzymes involved in organic acid metabolism. Biotinidase enzyme frees the biotin from carboxylase enzymes for re-use, after metabolic reaction. Inherited biotinidase deficiency limits re-use of biotin and increases its dietary requirement, not fulfilled by intake.

Clinically, these cases present in neonatal period or infancy with: (a) *neurological manifestations*, e.g. seizures and hypotonia, (b) *skin manifestations*, e.g. alopecia and skin rash, (c) *metabolic acidosis* due to excessive urinary excretion of unmetabolised organic acids, and (d) *immunodeficiency* states. Megavitamin therapy with high doses of biotin (10–40 mg/d) is highly effective.

B. Peroxisomal Disorders

Peroxisomes are subcellular organelles, present in all cells except mature erythrocytes, where very-long-chain fatty acids are oxidized. Peroxisomal disorders include a genetically heterogeneous disorders due to-either defective formation of peroxisomes (multiple enzyme defects) or defective function of one of enzymes located within them (single enzyme defects).

Peroxisome biogenesis disorder is a collective term for three overlapping clinical syndromes due to defective peroxisome formation—*Zellweger syndrome, neonatal adrenoleukodystrophy and infantile Refsum disease*, in order of decreasing severity.

- *Zellweger syndrome* is usually fatal in infancy and presents with—(a) mongoloid facial features, (b) generalized hypotonia, (c) neonatal seizures, and (d) ocular abnormalities.
- *Neonatal adrenoleukodystrophy* usually presents in late infancy with developmental regression, seizures, and visual/hearing impairment.
- *Infantile Refsum disease* presents in early childhood with ataxic gait, mental retardation, sensorineural deafness, pigmentary retinal degeneration and facial dysmorphism.

Diagnosis of these disorders is mainly clinical, supported by plasma assays for very-long-fatty acids.

Treatment is largely supportive including physical and occupational therapy, hearing aids, etc.

C. Lipoprotein Disorders

Lipoprotein disorders are more important in adults due to association with atherosclerosis and consequent morbidity. Abetalipoproteinemia is the most important lipoprotein disorder in children.

Abetalipoproteinemia is rare inherited disorder of fat malabsorption, due to autosomal recessive deficiency of β-lipoproteins, essential for chylomicron formation.

Clinically, it is characterized by: (a) failure to thrive, (b) steatorrhea, (c) neurological manifestations due to vitamin E deficiency and spinocerebellar degeneration, e.g. ataxia, spastic gait, loss of position/vibration

senses and absent deep tendon reflexes, and (d) ocular manifestations, e.g. atypical retinitis pigmentosa. While malabsorption presents since early childhood, neurological and retinal changes appear beyond first decade of life.

Diagnosis rests on: (a) presence of *acanthocytes* in peripheral smear and (b) extremely low cholesterol (<50 mg/dl), LDL and VLDL levels.

Treatment is non-specific, including supplementation of fat-soluble vitamins and dietary restriction of long chain fats.

D. Lipid Storage Disorders (Lipidoses)

Glycosphingolipids are essential components of cell membranes which are regularly degraded in lysosomes by lysosomal enzymes. Genetic errors in the formation of lysosomes or its hydrolytic enzymes, transport of degradation material in/out of the lysosomes or excessive destruction of lysosomal enzymes, present with diverse disorders. *Common lysosomal disorders include—lipid storage disorders, mucopolysaccharidosis and glycoproteinosis.*

Lipid storage disorders denote a heterogeneous group of genetically inherited defects in activity of these enzymes, leading abnormal intra-lysosomal accumulation of related lipids and variable clinical presentations. Storage within the neuronal cells present with neurodegenerative disorders (Ch 18.15) while visceral storage can lead to organomegaly, skeletal deformities and other manifestations.

All lipid storage disorders are autosomal recessive, except Fabry disease, which is X-linked recessive. Some important lipidoses are as follows:

Gaucher disease (GD) is the commonest lysosomal storage disorder and lipidosis, most prevalent in Ashkenazi Jews. It is a multisystem disease, due to deficiency of a lysosomal enzyme *glucocerebrosidase*, leading to intracellular accumulation of undegraded glycolipid *glucosylceramide* in reticuloendothelial system.

Clinically, Three variants are known:

- *Type I (adult non-neuropathic form*), accounts for 99% cases and presents at any age beyond early childhood with: (a) *progressive massive splenomegaly* with/without hepatomegaly and signs of hypersplenism, (b) *skeletal involvement* with bone pains and pathological fractures in ~ 20–50%, due to bone marrow expansion from foamy lipid-filled cells. Neurological manifestations are absent.
- *Type II (acute neuropathic)* presents in infancy with: (a) rapidly progressive neurodegenerative course with severe developmental retardation and hypertonia, (b) failure to thrive, and (c) extensive visceral involvement with organomegaly. Most patients die by 2 years due to respiratory complications.
- *Type III (chronic neuronopathic)* with intermediate course, presents at 1–3 years of age with slow progression of neurological and visceral involvement These cases may survive till 10–15 years.

Diagnosis: Presence of *Gaucher cells*, i.e. large foamy PAS +ve cells with characteristic *wrinkled paper appearance* due to intracytoplasmic inclusions, in reticuloendothelial system, e.g. bone marrow/splenic puncture *or* liver biopsy is a pathological hallmark of Gaucher disease. However, Gaucher cells may also be seen in myeloma and graulocytic leukemia.

In this era of advanced diagnostic techniques, invasive tests are avoided and diagnosis is confirmed by enzyme assay *glucocerbrosidase* in leukocytes or skin fibroblasts, which also helps in carrier detection. *Prenatal diagnosis* by enzyme assay or DNA analysis in aminocytes/chorionic villous cells is possible, though targeted variant testing is preferred for accuracy.

Treatment is largely symptomatic with splenectomy and blood transfusions, if necessary. Bone marrow transplant is curative but with high morbidity and mortality.

- ***Enzyme replacement therapy*** with recombinant β-*glucocerebrosidase* (imiglucerase, velaglucerase or Taliglucerase) is the standard of care for Gaucher type I and III, given life-long IV 30–60 IU/kg alternate week. It is not recommended in type II as it does not cross the blood brain barrier.
- ***Substrate reduction therapy*** with oral Eliglustat or Miglstat to reduce production of fatty material may be useful in mild adult cases, if ERT is not possible.

Splenectomy is to be avoided except in extreme circumstances like splenic rupture. Supportive care like blood transfusions will be required. Bone marrow transplant has high morbidity and mortality.

Niemann-Pick disease a rare lipidosis with six known subtypes, of which two (type A and B) are most important in children, both due to deficiency of enzyme *sphingomyelinase* and consequent intralysosomal accumulation of sphingomyelin and other lipids.

- ***Type A*** presents at ~6 months of age with: (a) failure to thrive, (b) hepatosplenomegaly with lymphadenopathy, and (c) progressive neurodegeneration, i.e. spasticity and development delay.
- ***Type B*** presents beyond infancy with progressive hepatosplenomegaly and pulmonary involvement with diffuse nodular infiltrations on X-ray. Neurological manifestations are absent with normal intelligence. Severely affected children may develop significant pulmonary compromise or cirrhosis.

Diagnosis rests on presence of characteristic foamy *Niemann-pick cells* in bone marrow, confirmed by acid sphingomyelinase enzyme assay in leukocytes or cultured fibroblasts. *Prenatal diagnosis* is possible but carrier detection is unreliable on enzyme studies and

needs genetic workup. Cherry red spot is seen on fundus examination.

Treatment is largely supportive and non-specific. ERT is not yet available though Miglustat is approved for substrate reduction in some countries. Enzyme replacement therapy (Olipudase alfa) is available for type B or type A/B disease.

Gangliosidoses is a group of autosomal recessive disorders of *ganglioside* (a normal lipid in cell membrane) catabolism due to various enzyme defects, leading to its excess accumulation within the neuronal cells. These defects are broadly classified into two major groups—GM_1 *gangliosidoses* (β-galactosidase-1 deficiency) GM_2 *gangliosidoses* (Hexosaminidase deficiency); both presenting as neurodegenerative illnesses with variable age and severity of presentation (Ch 18.15).

Metachromatic leukodystrophy (MLD) due to *Arylsulfatase-A deficiency* and consequent accumulation of *cerebroside sulfate* within the myelin sheaths is the commonest neurodegenerative disorder in India (Ch 18.15).

Krabbe disease due to *Galactocerebrosidase* deficiency with accumulation of *galactosylceramide*, is a rare but fatal disorder, presenting in infancy as neurodegenerative disease with optic atrophy, and death by 2–3 years.

Fabry disease (*α-galactosidase deficiency*) is the only X-linked recessive lipidoses, presenting in late childhood with: (a) multiple angiokeratomas with hypohidrosis and corneal/lenticular opacities, (b) acroparesthesias, i.e. *fabry crises* with episodes of severe burning pain in hands/feet, and (c) vascular disorders of kidney (proteinuria, azotemia), heart (myocardial ischemia, hypertension) and brain (strokes).

Enzyme replacement therapy (IV Agalsidase beta or alfa) is available.

Farber disease (*ceramidase deficiency*) begins by the end of infancy with painful joint swellings and nodule formation, followed by failure to thrive, hoarseness due to vocal nodules, and moderate neurodegeneration in some cases. Most of them die in second decade of life.

Wolman disease (*acid lipase deficiency*) presents in first week of life with failure to thrive, vomiting, steatorrhea, hepatosplenomegaly and hyperlipidemia. Adrenal calcification is pathognomonic. Most cases die by 6 months. Enzyme replacement therapy with sebelipase alfa has been recently approved for this disorder. Otherwise bone marrow transplant was the conventional mode of therapy.

E. Mucolipidoses

Mucolipidoses is a group of two rare autosomal recessive disorders with defective transport of lysosomal enzymes and consequent cellular deficiency of all lysosomal enzymes—**I-cell disease** and **pseudo-Hurler polydystrophy**. Clinical manifestation of both resemble Hurler syndrome (MPS-I), except absence of mucopolysaccharoiduria.

11.6.3 DISORDERS OF CARBOHYDRATE METABOLISM

Dietary glucose, consumed as *disaccharides*, i.e. sucrose, lactose and maltose or *polysaccharides*, e.g. starch, is the principle substrate for energy (ATP) generation via the processes of *glycolysis* (glucose > pyruvate) or *mitochondrial oxidation* (pyruvate > CO_2 and water). Unutilized glucose is stored as *glycogen* in liver and muscles, which may be reconverted into glucose *by glycogenolysis* during high requirements, e.g. exercise. Thus, maintenance of euglycemic state is principally a function of balance between free glucose and stored glycogen. Galactose and Fructose, other energy-producing monosaccharides, are of limited significance. Galactose, derived from milk products as *Lactase* (glucose + galactose), is an important component of many glycolipids, glycoproteins and glycosaminoglycans. *Neoglucogenesis*, i.e. *de novo* glucose synthesis from other sources, e.g. fats, also contribute to euglycemic state.

Disorders of carbohydrate metabolism may be broadly divided into: (a) defects in glycogen degradation, i.e. glycogen storage disorders, (b) disorders of galactose or fructose metabolism, e.g. galactosemia, (c) disorders of glucose utilization, e.g. pyruvate metabolic defects, mitochondrial oxidation defects, etc., and (d) disorders of neoglucogenesis. The last two groups predominantly presents with lactic acidosis.

Glycogen storage disorders (GSD) include heterogeneous group of inborn errors in carbohydrate metabolism, all characterized by *abnormal accumulation of normal or altered glycogen* in various tissues, due to various enzymatic defects in synthesis or degradation of glycogen.

More than 14 forms of GSDs are known so far, classified numerically in order of identification *or* the principle organs of involvement, e.g. liver (Ia, Ib, III, VI, VI, VII, IX, XI, 0), muscles (V, VII), or both (II, III). All GSDs are autosomal recessive, except IXb, which is X-linked recessive. Some important forms are as follows:

Type I (von Gierke disease) is the commonest GSD with two variants (a and b) which usually present in early infancy with: (a) gross hepatomegaly and renal enlargement, (b) doll-like facies with short stature, (c) normal mental development, and (d) recurrent hypoglycemia or lactic acidosis, specially on fasting. Bleeding tendencies are common due to platelet function defects. Type Ib variant is also associated with recurrent infections due to neutropenia or neutrophil function defects.

Diagnosis rests on clinical suspicion, abnormal plasma glucose, lactate and lipid values and no rise of glucose

levels after glucagon administration. Diagnosis rests on next generation sequencing. Liver biopsy for enzyme assay is avoided, being an invasive procedure.

Treatment aims to maintain normoglycemia by frequent feedings or continuous gavage and introduction of uncooked corn starch in diet as a source of slow-release glucose (1.5–2.5 gm/kg every 4–6 hours), along with supportive and symptomatic measures. Supporting measures include control of acidosis, infections and bleeding tendencies, allopurinol therapy for hyperuricemia and regular vitamin/mineral supplementation. Untreated cases may die in infancy during hypoglycemia/acidotic episodes, survivors may improve with age, though some develop gout, uric acid nephropathy and hepatic adenomas in adulthood. Patients of GSD1b with neutropenia may require G CSF injections.

Type II (Pompe disease) is a lysosomal disorder with lysosomal storage of glycogen in muscles due to acid alpha-glucosidase deficiency.

Clinically, it presents with two phenotypes of generalized myopathy, with different age of onset and severity:

a. *Infantile form* presents in neonatal period with: (a) generalized hypotonia or '*floppy baby*' with feeding difficulties, and (b) cardiomegaly and CCF due to progressive hypertrophic cardiomyopathy. Most cases die in infancy due to aspiration or respiratory failure.
b. *Juvenile form* presents with delayed motor development or difficult walking in late childhood, followed by gradual progressive proximal muscle weakness, swallowing difficulties and respiratory failure. Most cases die in second decade.
c. *Adult form* is a very slowly progressive proximal myopathy, manifesting beyond 2–3rd decade of life, without cardiac involvement.

Diagnosis is suspected on elevated CPK and LDH levels with EMG showing myopathic features. Muscle biopsy shows presence of glycogen positive vacuoles, though can be avoided by using NGS or demonstration of reduced enzyme activity on DBS. *Prenatal diagnosis* using amniocytes or chorionic villi is possible by targeted variant testing

Treatment includes enzyme replacement therapy (IV Alglucosidase alfa) every 2 weeks, along with supportive cardiac care and physiotherapy.

Other uncommon GSDs include:

- **Type III (Debrancher deficiency)** has two variants—type IIIa, involving liver and muscles both, and type IIIb, with only liver involvement. *Clinically,* it manifests in early childhood with milder features of GSD type I, i.e. hepatomegaly, hypoglycaemic spells and growth failure but *without renal enlargement* (d/d type I). Liver disease tends to improve with age, while muscular weakness and wasting appears and worsens after puberty. Diagnosis rests on next generation sequencing.
- **Type IV (Anderson disease)** presents in infancy with failure to thrive, hepatosplenomegaly and progressive cirrhosis with chronic liver failure and portal hypertension that leads to death by 5 years. Diagnosis rests on next generation sequencing.
- **Type V (McArdle disease)** presents in late childhood/adults with muscle cramps and myoglobinuria after strenuous exercise due to rhabdomyolysis. *Ischemic exercise test*, i.e. no rise in blood lactate but elevated ammonia levels after exercise is a useful screening test for muscle glycogenoses.
- **Type VII (Tarui disease)** has similar presentation as in type V, except—(a) earlier onset with more severe cramps and myoglobinuria, not preventable with high glucose diet, (b) evidence of continued compensated hemolysis with high bilirubin and reticulocyte count,
- **Type VI (Hers disease)** presents with hepatomegaly and growth retardation in early childhood but runs a benign course and improves by puberty without treatment.
- **Type XI (Fanconi-Bickel syndrome)** presents like type IA along with hyperlipidemia, hyperuricemia and renal dysfunction.
- **Phosphoryl kinase deficiency** is clinically heterogeneous group of GSDs, (previously classified as type VIa, VIII-X), where enzyme defects may be limited to liver, muscle or both.

Galactosemia: Galactose, derived from milk and other dairy products, is converted into Glucose-6 phosphate, before utilization as metabolic fuel *or* in synthesis of other galactosides, enzymatic defects in this galactose metabolism lead to excessive accumulation of galactose and its metabolites in various tissues, galactosuria and hypoglycemia, collectively termed as galactosemia. Three major types, all autosomal recessive, are known.

Classical galactosemia denotes deficiency of Galactose-1-phoshate uridyltransferase (GALT) leading to accumulation of Galactose-1 phosphate and its metabolites, toxic to liver and other organs.

Clinically, baby is normal at birth and manifestations begin after 3–4 days of breast feeding with intractable vomiting, diarrhea and failure to thrive. Unconjugated hyperbilirubinemia is common and untreated cases may develop chronic liver disease, cataracts and renal tubular acidosis.

Diagnosis rests on elevated RBC Galactose-1 Phosphate levels (>10 mg/dl) and reduced enzyme activity (<1%) on molecular studies. However, a positive Benedict test in urine but negative urine dipstick test suggesting presence og non-glucose reducing substances is a useful screening test. Universal galactosemia screening in newborns is practiced in many countries.

Treatment involves strict elimination of galactose, i.e. milk/milk products from diet, which may reverse growth failure, cataracts and hepatic dysfunction and prevent further damage. However, mental retardation, if already developed, is irreversible. A soy-based formula may be used for infant feeding

Galactokinase deficiency, a mild variant of galactosemia, is usually asymptomatic except cataracts in older children and biochemical galactosemia/galactosuria. Mental retardation is absent. Diagnosis depends on erythrocyte enzyme assay and rearing on galactose-free diet may prevent/regress cataracts.

Lactic acidosis is a common presentation of many metabolic disorders involving—(a) *glucose utilization*, e.g. pyruvate metabolic defects, mitochondrial respiratory chain defects, etc., and (b) *neoglucogenesis*. While serum pyruvate levels are increased in disorders of neoglucogenesis or pyruvate metabolism, they are normal in mitochondrial oxidation defects.

Lactic acidosis is also seen in many fatty acid oxidation defects (with abnormal serum acylcarnitine profile) and organic acidurias (with presence of unusual organic acids in urine), as well as in acquired states, e.g. hypoxemia.

11.6.4 MUCOPOLYSACCHARIDES

Mucopolysaccharides or *glycosaminoglycans* (GAGs) are major constituents of connective tissue, including chondroitin sulfates, dermatan sulfate, heparan sulfate, keratan sulfate, hyaluronic acid and heparin.

Mucopolysaccharoidoses (MPS) are inherited defects in degradation of these GAGs, due to deficiency of specific lysosomal enzymes, leading to excess accumulation and consequent urinary excretion of various GAGs. Over 10 variants of MPS are known, each with a specific lysosomal enzyme defect, clinical presentation and severity **(Table 11.17)**. All of them are autosomal recessive, except Hunter syndrome, which is X-linked recessive. Some important types of MPS are discussed here:

Hurler syndrome (MPS IH) is the most severe and prototype manifestation of MPS with multiple organ involvement.

Clinically, These babies are normal at birth and usually manifest at 6 months-2 years of age with:

- *Short stature and coarse facial features* with prominent forehead, cloudy cornea, flat-broad nose, thick lips and large tongue **(Fig. 11.10)**;
- *Developmental delay* with poor language development and hearing loss;
- *Hepatosplenomegaly* with protuberant abdomen and frequent umbilical/inguinal hernias;

  Multiple bony deformities (dysostosis multiplex) include large, thick calvarium, dolichocephalic skull with shallow orbits, enlarged and deformed sella turcica, broad-spatulate '*oar shaped*' ribs, anterior hypoplasia (*beaking*) of lumbar vertebrae with kyphosis, short and wide bullet shaped phalanges and deformed pelvis with short femoral head and coxa valga. Long bones have wide diaphyses, irregular metaphyses and poorly developed epiphyses.
- *Others*, e.g. acute cardiomyopathy and communicating hydrocephalus in some cases.

TABLE 11.17: Classification of mucopolysaccharidoses

No.	*G) Name*	*Enzyme def.*	*Stored GAG*	*Face**	*MR*	*HSM*	*CC*	*Bone***
I H	Hurler	α-L-iduronidase	DS, HS	+	+	+	+	+
I S	Scheie	α-L-iduronidase	DS, HS	–	–	–	+	
I H/S	Hurler/Scheie	α-L-iduronidase	DS, HS					
II	Hunter	Iduronate sulfatase	DS, HS	+	+	+	–	+
IIIa	Sanfilippo A	Heparan-N-sulfatase	HS	–	+	–	–	–
	Sanfilippo B	α-N-Acetyl	HS	–	+	–	–	–
		Glucosaminidase						
	Sanfilippo C	Acetyl CoA-α	HS	–	+	–	–	–
		Glucosaminidase						
		acetyltransferase						
	Sanfilippo D	N-acetylgalactosamine	HS	–	+	–	–	–
		-6 sufatase						
IVa	Morquio A	Galactose-6-sulfatase	KS	–	–	–	+	+
	Morquio B	β-galactosidase	KS					
VI	Maroteaux-Lamy	N-acetylgalactosamine-	DS	–	–	–	+	+
		4 sulfatase						
VII	Sly	β-glucuronidase	DS, HS	–	–	+	–	+
IX	–	Hyaluronidase	Hyaluronan	–	–	–	–	–

DS: Dermatan sulphate; **HS:** Heparan sulphate; **KS:** Keratan sulphate; **HSM:** Hepatosplenomegaly; **MR:** Mental retardation; **CC:** Corneal clouding
*Abnormal facial appearance. **Dysostosis multiplex.

Fig. 11.10: Hurler syndrome: (A) Clinical appearance, note corneal clouding (inset); (B) beaking of the vertebrae (arrow).

Most cases develop recurrent respiratory infections, noisy breathing or obstructive airway disease due to facial deformities and die by 10 years.

Diagnosis rests on clinical and radiological findings with urinary excretion of *dermatan and heparin sulfate*. Definitive diagnosis requires molecular testing though specific enzyme assay in serum leukocytes or skin fibroblasts may be used. Prenatal diagnosis is possible using amniocytes or chorionic villous cells.

Treatment is supportive with control of cardio-respiratory complications, orthopedic corrections and hearing support. Although bone marrow transplant in severe phenotypes has shown significant clinical improvement in somatic features, skeletal, ocular and mental abnormalities are irreversible.

Enzyme replacement therapy (IV Laronidase every 2 weeks) reduces the GAG excretion and causes subjective improvement in respiratory symptoms. However, there is not much improvement in skeletal features and cardiac features.

Scheie syndrome (MPS IS) is mildest variant of MPS with onset beyond 5 years of age. These cases have normal stature and intelligence with minimum facial and skeletal features, usually characterized by: (a) joint stiffness, (b) severe corneal clouding, and (c) aortic valve disease.

Hunter syndrome (MPS II) is only X-linked recessive MPS, with two clinical variants—a severe form analogous to Hurler syndrome, and a mild form analogous to Scheie syndrome, except: (a) absence of corneal clouding, and (b) slower progression of somatic and neurological deterioration. Communicating hydrocephalus is common in severe form. Enzyme replacement therapy (IV Idursulfase every week) is available.

Sanfilippo syndrome (MPS III) includes four biochemical diverse but clinically similar types of MPS (A–D), each with different enzyme deficiency. These cases usually present at 2–6 years of age with slowly progressive neurological impairment but only mild somatic disease (coarse hair, hirsutism, mild hepatosplenomegaly and skeletal features). Short stature and corneal clouding is rare. Severe neurological deterioration develops by 6–10 years, with death in adolescence.

Morquio syndrome (MPS IV) is characterized by *normal intelligence but severe skeletal deformities*, i.e. (a) short trunk-short stature due to platyspondyly, i.e. flat vertebrae, (b) short neck with unstable odontoid process, susceptible for atlantoaxial subluxation, (c) kyphoscoliosis with dysplastic hips and flat feet, leading to waddling gait. Joint laxity, mild corneal clouding, hepatomegaly, cardiac valvular lesions and abnormal dentition may be present. Most cases survive till 3–4th decade of life.

Treatment involves enzyme replacement therapy (IV Elosulfase) and supportive care with clinical and neuroimaging monitoring for cervical cord compression and immediate neurosurgical intervention.

Maroteaux-Lamy syndrome (MPS VI), in severe form resembles Hurler syndrome, except absence of developmental delay. However, milder variants may be easily confused with Scheie syndrome. Spinal cord compression due to thickened cervical dura matter is common in mild forms. Enzyme replacement therapy (IV Galsulfase) is available.

Sly syndrome (MPS VII) is the rarest MPS with extremely variable presentation, ranging from hydrop fetalis or severe dysostosis multiplex in newborns, to features resembling Hurler syndrome in older children.

11.6.5 PORPHYRIA

Heme, composed of ferrous iron and protoporphyrins, is an essential constituent of hemoglobin, myoglobin and many other enzymes. The porphyrias are inherited disorders of *heme biosynthesis* due to various enzyme defects **(Fig. 11.11)**, leading to abnormal tissue accumulation and urinary/fecal excretion of porphyrins or their precursors. Cutaneous photosensitivity and neurological involvement are predominant manifestations of porphyrin toxicity, apart from visceral features in some cases.

Porphyrias are classified according to the order of defective enzyme in heme biosynthesis **(Table 11.18)** or the site of expression, i.e. a*cute hepatic porphyrias* (ADP, AIP, HCP, VP) or *erythrocytic porphyrias* (CEP, PCT, HEP, EPP). Of these, most common are acute intermittent porphyria, porphyria cutaneous tarda and erythrocytic porphyria, discussed here in greater details.

Acute intermittent porphyria (AIP), is the commonest genetic porphyria, which usually presents beyond puberty.

Clinically, it present with acute episodes of: (a) severe abdominal pain with/without vomiting, mimicking surgical abdomen, (b) neuropathy with proximal muscle weakness and cranial nerve involvements, and (c) cardiovascular signs, e.g. tachycardia with hypertension,

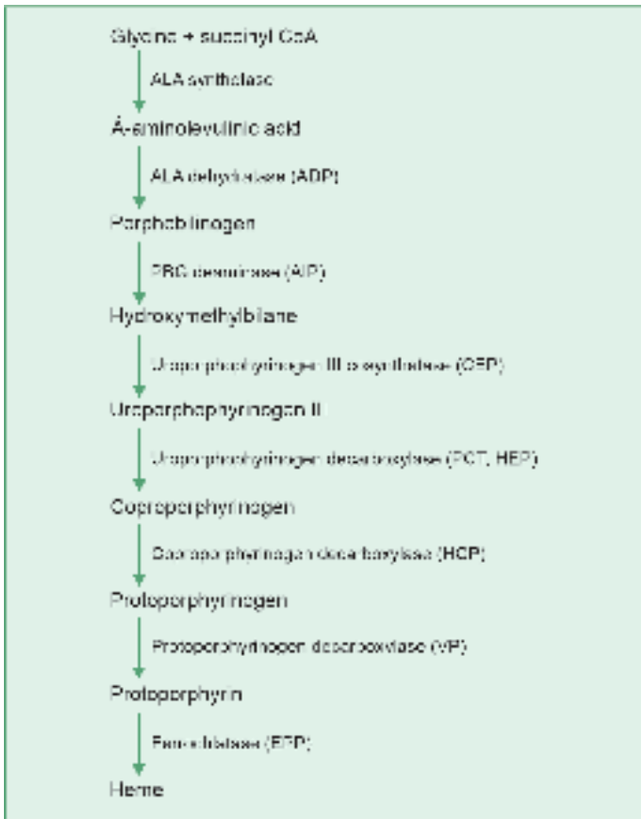

Fig. 11.11: Important steps in heme synthesis and enzymatic origin of various porphyrias.

which may persist even after the episode. Attacks are precipitated by fasting, infections, surgery, drugs/chemical ingestion or hormonal factors, e.g. menses in females. Skin manifestations are absent.

Diagnosis rests on decreased porphobilinogen deaminase activity in erythrocytes, though elevated levels of porphobilinogen in urine on *Watson-Schwartz* screening test or chromatographic studies are highly suggestive.

Treatment is largely supportive during the attack, which may be prevented by adequate caloric intake, avoidance of precipitant drugs and prompt management of infections. IV hematin (4 mg/kg/BD) may curtail severe attacks.

Porphyria cutanea tarda (PCT), the commonest porphyria, which may be inherited (autosomal dominant) or acquired. Acquired PCT is mainly seen in adults after exposure to factors, e.g. alcohol, estrogens or drugs.

Clinically, cutaneous photosensitivity with formation of vesicles over exposed parts of body is pathognomonic of PCT, which may heal with crusting, scarring and residual pigmentation. Neurological or visceral manifestation are absent.

Diagnosis rests on elevated excretion of urinary and fecal porphyrins, specially *isocoproporphyrin* levels in stools. Daily porphyrin excretion in stools exceeds that in urine.

TABLE 11.18: Classification of porphyria

Type	*MOI*	*Skin*	*Neural*	*Visceral*
ALA deficiency porphyria (ADP)	AR	–	+	–
Acute intermittent porphyria (AIP)	AR	–	+	AP
Congenital erythrocytic porphyria (CEP)	AR	+	–	HA
Porphyria cutanea tarda (PCT)	AD	+	–	–
Hepatoerythrocytic porphyria (HEP)	AR	+	–	HA
Hereditary coproporphyria (HCP)	AD	+	+	AP
Varigate porphyria (VP)	AD	+	+	AP
Erythrocytic protoporphyria (EPP)	AD	+	–	–

AP: Abdominal pain, **HA:** Hemolytic anemia, **MOI:** Modes of inheritance

Treatment is symptomatic, though avoidance of sunlight and precipitating factors in acquired disease is necessary.

Erythrocytic protoporphyria (EPP), an autosomal dominant *ferrochelatase deficiency*, typically manifests in childhood, with extreme cutaneous photosensitivity.

Clinically, EPP present with stingy or burning sensations within 1–2 hours of sun exposure followed by erythema and edema. Vesicles are less common but repeated attacks lead to hyperkeratosis of exposed skin and onycholysis. Chronic hepatic disease and gallstones are common. Neuro-visceral involvement is absent.

Diagnosis rests on elevated free protoporphyrin levels in erythrocytes, plasma and stools, with normal urinary porphyrins.

Treatment includes avoidance of sun-exposure and use of topical sunscreen agents to prevent skin burning. Oral administration of β-carotene increases photo-tolerance to some extent.

CHAPTER

12

Newborn

Anitha Haribalakrishna, Jyotsna Shrivastava, Alpa Bhosale, Mukesh Agrawal

Birth is a water-shed event in human life, necessitating various physiological changes to adapt from intrauterine to extrauterine life. Success of this adaptation depends on many biological factors, e.g. genetic composition, gestational age, etc. as well as environmental factors, e.g. maternal health, quality of antenatal and perinatal care and postnatal environment.

12.1 GENERAL TERMINOLOGY

Live birth is defined as *presence of some signs of life after expulsion of baby*, e.g. heart beats, cord pulsations, breaths or definite movements of voluntary muscles, irrespective of their duration or placental/cord separation.

Fetal death is defined as absence of such signs in expelled/extracted products of conception and may be divided into—(a) *Early fetal deaths* or *abortions* (<20 weeks or <500 gm or <25 cm); (b) *Intermediate fetal deaths* (20–28 weeks; 500–999 gm or 25–35 cm), and (c) *late fetal deaths* (>28 weeks, >1000 gm or >35 cm). Intermediate and late fetal deaths are also termed *Stillbirths.*

Intrauterine period spans from the day of conception to the day of delivery (40 weeks or 280 days ±2 weeks). Accordingly, a newborn may be classified as *full term* (37–41 weeks), *preterm* (<37 weeks) or *post-term* (42 weeks). Babies born between 34–37 weeks are also termed as *Late preterms*, while those born before 28 week of gestation are considered as *extreme preterms*.

Intrauterine period includes two important phases in human life—e*mbryonic period* till first 8 weeks, predominantly characterized by organogenesis; and subsequent *fetal period* till birth, characterized by anatomical increase in body size and physiological maturation of various functions.

Neonatal period extends from birth to first 28 days of life and includes two important phases—*early neonatal period* from birth to 7th day and *late neonatal period* from 8th to 28th day.

Low birth weight: Since precise gestational assessment may be difficult in community practice, birth weight (BW) is often used as an indicator of neonatal maturity and health. A term newborn weighs ~3000 ±500 gm. Babies with BW of <2500 gm (up to 2499 gm) are termed *low birth weight* (LBW), while those weighing >3.5 kg are considered as *large for date*. Babies with BW of <1500 gm are also termed as *very low birth weight (VLBW)* and those <1000 gm as *extreme low birth weight (ELBW).*

Perinatal period: Late intrauterine period (>28 weeks or >1000 gm) and early intrauterine period (till 7th day) is considered as a continuum and together, termed '*perinatal period*'.

However, with increasing survival of extreme preterms in recent years, this critical period has been expanded to include a new category, i.e. *extended perinatal period*, from 22 week of gestation (or >500 gm) to 7 days of postnatal life.

12.2 PERINATAL HEALTH INDICATORS

Fetal and neonatal health may be considered as a reliable indicator of health standards in a community and usually measured in terms of following indicators:

Stillbirth rate (SBR) refers to *total number of stillbirths >28 weeks or 1000 gm/total live births 1000*. It is primarily an indicator of the quality of antenatal and obstetrical care in the community. Current SBR in India is estimated as ~ 3/1000 as per sample registration survey (SRS 2022), though seems to be much higher due to frequent non-reporting of stillbirths in rural areas. Congenital malformations and fetal distress are predominant causes of stillbirths.

Perinatal mortality rate (PNMR) is defined as *total number of late fetal deaths(LFD) >28 week + early neonatal death (END) till 7th day, expressed as a rate per 1000 live births per year*.

However as precise assessment of gestation is difficult, a more practical definition has replaced gestation with corresponding birth weight, i.e. 1000 gm, for international comparisons, as follows:

$$\text{PMR} = \frac{\text{LFDs + ENDs >1000 gm x1000}}{\text{Total live births >1000 gm}}$$

TABLE 12.1: Causes of perinatal mortality

- ***Antenatal:***
  - Maternal malnutrition
  - Maternal infections and illnesses
  - Local pelvic
  - Uterine diseases
  - Obstetric complications, e.g. eclampsia, APH
  - Fetal malformations
- ***Intranatal:***
  - Complicated
  - Obstructed labor
  - Birth asphyxia/injury
- ***Postnatal:***
  - Prematurity
  - Low birth weight
  - Neonatal infections
  - Congenital malformations
- ***Others***

APH: Antepartum hemorrhage

All still/live births < 28 weeks, 1000 gm or 35 cm length are excluded from numerator as well as denominator, due to unlikelihood of their survival.

Current status: Current PMR in India is 18/1000 live births (SRS 2022), being higher in rural areas than in urban areas. Despite declining trend in recent years, current PMR is still higher than that in developed countries.

Causes: About 60–70% of perinatal deaths relate to complications of LBW, followed by birth asphyxia and neonatal sepsis in the descending order **(Table 12.1)**. Congenital malformations are emerging as important cause of PMR, after control of other factors.

Prevention: PMR may be considered as single best indicator of fetal and neonatal health in a community. Important measures to reduce PMR include:

- *Pre-conceptional:*
  - Nutritional and health care of adolescents and reproductive-age females.
  - Appropriate birth spacing
- *Antenatal:*
  - Adequate antenatal care including TT immunization, nutritional counseling/ supplementation and iron/ folic acid supplements.
  - Early detection and treatment of maternal/ obstetrical complications
  - Identification of high-risk mothers and referral for institutional delivery
- *Peri-partum:*
  - Safe and clean delivery practices
  - Adequate fetal monitoring/neonatal resuscitation
- *Post-natal:*
  - Essential newborn care including breastfeeding
  - Identification of high-risk newborns with appropriate treatment/timely referral

Neonatal mortality rate (NMR) denotes *total number of neonatal deaths <28 days of life, expressed as a rate per 1000 live births per year,* calculated as follows:

$$\text{NMR} = \frac{\text{Total neonatal deaths >1000 gm} \times 1000}{\text{Total live births >1000 gm}}$$

NMR is further divided as ***Early neonatal mortality rate*** (ENMR), i.e. early neonatal deaths < 7 days/1000 live births) and ***Late neonatal mortality rate*** (LNMR), i.e. late neonatal deaths between 8th and 28th day/1000 live births.

Considering improved survival of extreme preterms/ low birth weights in recent years, a new term ***Extended neonatal mortality rate*** **(ExNMR)** is also in use to include all newborns >500 gm instead of 1000 gm for calculations.

Current NMR in India is 20/1000 live births including an ENMR of 15/1000 and LNMR of 5/1000 (SRS 2022). Throughout the world, NMR is higher in male newborns, perhaps due to biological fragility of male sex.

Low birth weight and related complications, birth asphyxia/injury, sepsis and congenital malformations are four major killers in newborn and important measures to reduce NMR are same as those for PNMR.

Low birth weight rate: Pre-conceptional and antenatal maternal health and nutrition are major determinants of birth weight, which is also influenced by frequency of intrauterine infections.

As all these factors are adversely prevalent in India, low birth weight rate is considered as important indicator of maternal and neonatal health. Current low birth weight rate in India is 18% (NFHS-5, 2021).

Maternal mortality rate (MMR) is an indicator of risk to the women's death due to puerperal causes, computed as total number of female deaths due to puerperal causes*/ total number of live births × 1000.

*Puerperal deaths include all female deaths due to obstetrical complications of pregnancy, childbirth/abortion or within 42 days of delivery/abortion (incidental/accidental deaths due to unrelated causes excluded).

Current MMR in India is 99/1000 live births (SRS 2022), highest in Uttar Pradesh and lowest in Gujarat.

Common causes of MMR in order of frequency include—(a) severe bleeding, (b) infection, (c) unsafe abortions, (d) eclampsia, and (e) obstructed labor. MMR is also related to many social factors, e.g. women's age, parity, birth interval, nutrition, and quality of antenatal care.

12.3 PRENATAL PEDIATRICS

Recent years have witnessed many advances in fetal diagnosis and therapeutics to ensure optimal fetal health and prevent neonatal complications. However, the most

important determinants of fetal health are maternal health, quality of antenatal care and timely identification of high-risk pregnancies to anticipate neonatal problems.

12.3.1 ESSENTIAL ANTENATAL CARE

Neonatal care begins since conception and antenatal care is an important element to ensure maternal, fetal and consequently, neonatal well-being.

Objectives: Antenatal care (ANC) aims to: (a) protect, promote and maintain maternal health, (b) identify high-risk mothers and plan appropriately, (c) teach her the elements of neonatal care, e.g. breastfeeding, and (d) sensitize her for family planning.

Schedule of care: Ideally, each mother should attend ANC clinic, once a month in first 7 months, twice a month in next two months and weekly thereafter. However, *minimum 4 visits are essential, during 3rd, 6th, 8th and 9th month.*

Components of ANC includes:

During first visits

- Registration
- Complete health and obstetrical history
- Detailed physical and obstetrical examination
- Investigations: Hb, urine, ABO/Rh type, VDRL, HIV (if consented) and USG (if possible).

During subsequent visits

- Physical revaluation: sp. for weight, BP and edema
- Obstetrical evaluation for fetal well-being
- Breast examination and counseling
- Investigations:
  - Hb, urine, others as necessary
  - USG in clinically abnormal cases
- Nutritional support
  - Dietary counseling/supplementation*
  - Iron and folic acid supplementation**
- Tetanus immunization***
- Counseling, regarding:
  - Basic child care and breastfeeding
  - Family planning
- Referral of high-risk mothers

*Additional 400 calories

**60 mg iron + 500 mg folic acid from 4th months onward

***Two doses of Td one month apart, last dose at least one month before delivery. Only one dose is necessary, if two doses were received within last 3 years during previous pregnancy.

Current status: NFHS-5 (2019–21) reveals that only 58.1% pregnant women in India receive recommended four antenatal care visits, while only 44.1% receive iron and folic acid supplements for minimum recommendations of 100 days during pregnancy. However, 92% mothers are protected for tetanus.

TABLE 12.2: High-risk pregnancies

Maternal (pre-conceptional) factors

- Age (<16 or >40 years)
- Parity (primi/grand multipara)
- Social factors, e.g. unwed mothers
- Malnutrition (weight <40 kg, height <140 cm)
- Anemia
- Chronic medical disease*
- Rh-negative blood group
- Bad obstetric history

Obstetric (antenatal) factors

- Multiple pregnancies
- Acute medical/surgical illnesses (or abd. trauma)
- *Infections:* TORCH infections, STDs
- Pregnancy induced hypertension, pre-eclampsia
- *Vaginal bleeding:* Placenta previa, APH
- Poly/Oligohydramnios
- *Fetal:* Abnormal maturity/lie, cong. malformations

*Diabetes, hypertension, cardiopulmonary or renal disease.
TORCH: Toxoplasmosis, rubella, cytomegalovirus, herpes simplex.

12.3.2 HIGH-RISK PREGNANCY

'At risk' approach is the most practical and cost-effective tool for antenatal care in resource-poor countries, which means *'Identification of high-risk mothers* **(Table 12.2)** *during antenatal period and arrange more skilled care for them, while continuing to provide appropriate care for other low-risk mothers'*.

High-risk pregnancies are often at-risk to terminate into abortions, stillbirths, prematurity, IUGR and congenital malformations. Common indicators of high-risk pregnancies may be recognizable even before the conception and these case should be managed only at centers where adequate facilities for fetal monitoring, neonatal resuscitation and critical care of sick newborn are available.

12.3.3 FETAL MONITORING

Maternal health is the most important determinant of fetal well-being, affecting its health in many ways **(Table 12.3)**. The term *'fetal monitoring'* refers to clinical, radiological, physiological and biochemical evaluation of fetus *in utero*, though last two steps are necessary only in selected cases. Important components of fetal monitoring are as follows:

I. Assessment of gestational duration by:

- *Last menstrual period* (LMP): Expected date of delivery (EDD) may be calculated by advancing LMP date with 9 months and 7 days.
- *Uterine fundal height* (UFH) is a reliable indicator of gestational length, except in last trimester. UFH is ~20 cm at 20 weeks and 28 cm at 28 weeks Disproportionately more UFH indicates multiple pregnancy, polyhydramnios, and fibroids.
- *Fetal events*, e.g. appearance of heart sounds (16–20 weeks) and *quickening* (18–20 weeks) are not very reliable indicators of gestational length.

TABLE 12.3: Effect of common maternal disorders and drug exposure on fetus and newborn

Malnutrition	IUGR	***Antidiabetic agents***	
Anemia	IUGR, early physiological anemia	Sulfonylurea	Hypoglycemia, ID (insulin safe)
Infections	IUGR, malformations (*see* Chapter 12.14.3)	***Antihypertensives***	
Systemic diseases		β blockers	IUGR, heart block, hypoglycemia
Hypertension	IUGR, birth asphyxia	Capto-/Enalopril	Oligohydramnios
Diabetes	Macrosomia, polycythemia, hypoglycemia	Thiazide diuretics	Thrombocytopenia
Iodine deficiency	Hypothyroidism, goiter, ID	***Antimalarials***	
Thyrotoxicosis	Hypothyroidism, Graves' disease	Quinine	Deafness, thrombocytopenia

		Vitamin D excess	Supravalvular aortic stenosis, others

IUGR: Intrauterine growth retardation; **ID:** Intellectual disability; **NTDs:** Neural tube defects; **TOF:** Tracheoesophageal fistula; **ITP:** Immune thrombocytopenia; **APH:** Antepartum hemorrhage

[1]***Fetal alcohol syndrome:*** Facial dysmorphism, IUGR, developmental delay, learning/behavioral problems

[2]***Fetal hydantoin syndrome:*** IUGR, facial dysmorphism, hypoplastic nails, mild MR

- *USG assessment* is most accurate method for dating gestation in normal fetus. Different fetal parameters are used in different stages of gestation—crown-heel length (up to 12 weeks), bi-parietal diameter (up to 28 weeks) and femoral length beyond this age.

II. Assessment of fetal growth by:

- *Maternal weight gain:* Steady maternal weight gain indicates satisfactory fetal growth. Average healthy Indian woman gains ~ 9–10 kg in pregnancy.
- *Serial abdominal girth* increase of ~1 cm/week from 20th week onwards, indicates normal fetal growth.
- *Serial increase in UFH* is a reliable indicator of adequate fetal growth, when compared with gestation-parto-graphs (fetal growth charts).
- *USG assessment* is a non-invasive and accurate tool to identify intrauterine growth retardation (IUGR) apart from other obstetrical abnormalities, e.g. multiple pregnancies, congenital anomalies, abnormal placental morphology, presence of poly/oligohydramnios, etc. A Bi-parietal diameter <8.5–9.0 cm at full term indicates IUGR. However, *Fetal head/thorax* or *head/abdomen ratio* are more reliable, as somatic growth is more affected in IUGR.

III. Assessment of physiological maturity of fetus is indicated in expected preterm deliveries. It requires amniocentesis with following tests in amniotic fluid (AF):

- Lung surfactant maturity, e.g. L:S ratio (>2)
- Amniotic fluid optical density (> 0.15)
- Renal maturity (AF creatinine > 2 mg/dl)
- Skin maturity by AF cytology (> 20% orange staining cells).

IV. Detection of congenital anomalies is based on:

- Routine screening, e.g. USG or serology.
- Genetic studies, e.g. karyotyping in select cases.
- Amniotic fluid biochemistry:
  - *Raised α-fetoprotein* levels (14–16 weeks) in neural tube defects, exomphalos, gut atresia.
  - *Raised optical density difference* >0.1 in Rh-hemolytic disease with severe hemolysis.
  - *Raised pregnanediol* levels in congenital adrenal hyperplasia
  - *Low human chorionic gonadotropin* levels indicate threatened abortion; *elevated levels* in Down syndrome and molar pregnancy.
  - Specific enzyme assays in suspected IEMs.

α-fetoproteins (AFP) is a glycoprotein, produced by yolk sac and fetal liver from 2nd months onwards. Production peaks at ~14th week, followed by gradual decline with advancing gestation. After birth, AFP production ceases within a few days except in newborns with liver disease. Fetal AFP can cross the placenta (detectable in maternal serum) as well as also appears into amniotic fluid due to shedding of fetal skin.

Maternal *or* amniotic fluid AFP levels are useful biochemical markers of fetal well-being. Normally, maternal serum AFP is ~25 ng/ml at 16th week (optimal time for screening) and rises by ~15% per week till 30th weeks, followed by gradual decline. AFP levels are elevated in neural tube defects, liver defects, some congenital malformations and multiple pregnancies, while reduced in Down syndrome.

V. Assessment for fetal distress: Although clinical monitoring of fetal heart sounds and movements is the simplest tool to assess fetal well-being, following evaluation may be necessary in selected cases to decide the need for immediate intervention:

a. *Indicators of placental dysfunction* (maternal sample)
   - S. placental lactogen (<4 µg/ml after 30 weeks)
   - Plasma/urine estriol (>30% drop from earlier values)

b. *Tests for uteroplacental unit:*
   - *Non-stress monitoring (NST),* i.e. simultaneous recording of Fetal heart rate (FHR), uterine contractions and fetal movements. Acceleration of FHR by >15 bpm *or* for >15 seconds after fetal movement, at least twice in 20 minutes, indicates adequate utero-placental function.
   - *Oxytocin challenge test* to assess effect of oxytocin stimulated uterine contractions on FHR. Persistent slowing of FHR after uterine contraction (*late deceleration*) indicates placental insufficiency.

c. *Direct indicators of fetal distress:*
   - Fetal heart monitoring (absent FHS)
   - Fetal activity record (less/absent movements)
   - Fetal biophysical profile (USG based)
   - Fetal scalp blood sampling for blood gas analysis

Fetal biophysical profile is the most accurate non-invasive test for fetal well-being, using five USG-based fetal parameters—(i) posture, (ii) breathing movements, (iii) gross body movements, (iv) reactive heart rate and (v) volume of amniotic fluid. Each parameters is scored as 2 normal or 0 as abnormal. A combined score of 6 or less indicates *chronic fetal asphyxia.*

Fetal scalp blood sampling for blood gas analysis under endoscopic guidance, is most reliable but invasive test. A scalp pH of <7.1 indicates severe hypoxia and need for immediate delivery.

12.3.4 FETAL THERAPY

Fetal therapeutics is still in fetal stage, though rapid advances in antenatal diagnosis have opened new vistas to prevent or manage fetal disease *in utero*. These interventions may be divided into three categories: (a) preventive interventions in high-risk pregnancy, (b) medical interventions in prenatally-diagnosed cases, and (c) surgical interventions in congenital malformations.

TABLE 12.4: Prenatal interventions (Fetal therapy)

Disorders	*Prenatal intervention*
a. Rec. fetal loss/LBW	Low-dose aspirin
b. Neurological	
– IVH/PVH	Phenobarbitone
– Neural tube defects	Folic acid supplements
c. Respiratory	
– Hyaline membrane disease	Dexamethasone
– Fetal hypoxia	Oxygen, positioning
– Meconium aspiration	Amnioinfusion
d. Hematological	
– Rh-HDN	Umb. exchange transfusion
– Fetal ITP	IVIG, IU platelet infusion
– Thalassemia	Fetal stem-cell transplant
e. Intrauterine infections	
– HIV	LSCS, ART to mother
– Tuberculosis	Anti-tubercular therapy
– Syphilis	Penicillin
– Toxoplasmosis	Spiramycin/pyrimethamine
– CMV	Ganciclovir (via umb. vein)
f. Endocrinal/metabolic	
– CAH	Dexamethasone
– IEMs	Megavitamin therapy
g. Obstetric complications	
– Meconium staining	Amnio-infusion
– Premature labor	Tocolytics, Mg sulfate
– Poly/oligohydramnios	Amnioreduction/infusion
h. Surgical interventions	
– Hydrocephalus	Fetal ventricular tap
– Obstructive uropathy	Fetal urinary shunts
– Chylothorax/hydrops	Thoraco/abdominocentesis
– Multiple pregnancy	Fetal reduction

IVH/PVH: Intraventricular/periventricular hemorrhage, **HDN:** Hemolytic disease of newborn, **ITP:** Immune thrombocytopenic purpura, **ART:** Anti-retroviral therapy, **CAH:** Congenital adrenal hyperplasia, **IEM:** Inborn errors of metabolism, **LBW:** Low birth weight.

Table 12.4 enlists some disorders for which fetal therapy is possible or will be possible shortly, along with modes of intervention. However, some specific strategies are as follows:

Steroids in prematurity: Administration of IM Dexamethasone (Four doses of 6 mg at 12 hourly interval) or IM betamethasone (Two doses of 12 mg at 12 hourly interval), at least 24 hours before delivery is an established intervention in mothers, likely to deliver <34 weeks of gestation. This simple measure reduces the risk of hyaline membrane disease (HMD) and intraventricular hemorrhage (IVH) in preterms by ~30–50%. However, it is contraindicated in presence of chorioamnionitis.

Phenobarbitone in Rh-isoimmunization: Administration of PO phenobarbitone (60 mg OD) for 2 weeks before anticipated time of delivery reduces the severity of neonatal hyperbilirubinemia and need for exchange transfusion. Phenobarbitone therapy has also been claimed to reduce risk of IVH/PVH in preterms, though not supported by evidence.

Folic acid supplements in neural tube defects: In mothers with history of previous birth with neural tube neural tube defects, PO folic acid 0.4 mg (4 mg OD for secondary prevention) once a day from two month before the expected conception to the end of first trimester, reduces the risk of recurrence > 50%.

Anti-retroviral therapy in HIV +ve mothers: Risk of perinatal HIV transmission from mother to the baby is known to reduce from 30–40% in untreated cases to <5% with appropriate antiretroviral therapy to mother, irrespective to her own health.

Intrauterine blood transfusion in Rh-HDN, via cordocentesis, may be life-saving in severe anemia with fetal hematocrit <20%. Repeated simple or exchange transfusions are often necessary till 32 weeks of gestation, followed by elective preterm delivery. In non-immune hydrops, IV albumin infusion may be used to prevent further fluid exudation.

Steroid therapy in congenital adrenal hyperplasia (CAH), with PO dexamethasone (1 mg OD) is indicated throughout pregnancy from 10th week onwards in prenatally detected CAH or history of previous CAH delivery, to prevent virilization of fetus.

Magnesium sulphate in mother undergoing preterm labor given as 4 gm/kg IV loading dose over 30 minutes followed by 1 gm/hour for 24 hours is known to reduce the risk of cerebral palsy and developmental delay.

Megavitamin therapy in inborn errors of metabolism may be useful to prevent mental retardation in prenatally detected cases of methyl-malonic acidemia (IV vitamin B_{12} 5 mg OD) or multiple carboxylase deficiency (PO biotin 10 mg OD), when given in last trimester.

Steroid therapy in maternal immune thrombocytopenia (ITP), during last 2 weeks may prevent fetal isoimmunization. However, prenatally detected isoimmune thrombocytopenia needs platelet infusions and IVIG therapy via cordocentesis to prevent severe fetal hemorrhage.

12.3.5 MULTIPLE PREGNANCY

Multiple pregnancy is an important obstetrical risk factor for fetal loss or neonatal morbidity/mortality, with an incidence of ~1:80 livebirths (for twins) and ~ 1:1000 (for triplets), in India. However, true incidence of twin *conceptions* is much higher (2–3% on USG at 12 weeks), as many of them end in fetal loss or disappearance of one fetus (*Vanishing twin syndrome*). Incidence of multiple pregnancies seems to be rising in recent years, due to increasing interventions for infertility, e.g. ovarian stimulant drugs or *in vitro* fertilization.

Types: Multiple pregnancies may be:

- *Polyovular* (Dizygotic), with release and fertilization of two (or more) different ova at the same time, each with its own chorion and amnion (*dichorionic, diamniotic*). Dizygotic twins are of different sex and blood group in 50% cases.
- *Mono-ovular* (Monozygotic), with fertilization of a single ova but splitting of blastocyst in early phase to develop separately as two fetus. 75% of monozygotic twins share common chorion (*monochorionic*), though almost all of them have separate amnion (*diamniotic*). Monozygotic twins are essentially of same sex, blood group and grossly similar, if not identical, features.

Splitting of blastocyst in late stages may lead to *conjoined or Siamese twins* (~1:50,000 live births), which are usually females and joined to each other at thoraco/abdominal region (thoraco/omphalopagus; commonest), head (craniopagus, rarest) or other sites (incomplete duplication).

Risk factors: While risk factors for mono-ovular multiple pregnancies are unclear, poly-ovular pregnancies are more common in: (a) elderly or multiparous mothers, (b) family history of multiple pregnancy, (c) conceptions after infertility interventions, and (d) women with high gonadotropin levels.

Complications: Apart from frequent abortions or stillbirths, multiple pregnancies are associated with ~3–4 times higher risk of neonatal mortality/morbidity due to various complications **(Table 12.5)**, most important being twin-to-twin transfusion.

Twin-to-twin transfusion (*Fetal transfusion syndrome*) mainly occurs in monochorionic twins, due to common placenta. Artery from one fetus (donor) may acutely or chronically deliver blood into vein of other fetus, leading to *severe anemia, hypovolemia and low birth weight in the donor* and *plethora, polycythemia, hypervolemia and hydrops in the recipient*. Generally, a difference of >5% in Hb and 20% in weight between two fetuses indicates twin-to-twin transfusion. Death of the donor fetus generates plenty of fibrin thrombi, which may be passed-on to surviving fetus with consequent DIC.

Management of multiple pregnancies involves early prenatal diagnosis and timely referral to equipped centers. *Selective fetal reduction* with transabdominal injection of potassium chloride may be required in numerous multiple gestations (3 or more).

Postnatally, all twins should be closely monitored till 24–48 hours for late problems, e.g. hypoglycemia, respiratory distress, anemia, polycythemia, etc. Twin-to-twin transfusion may require immediate blood transfusion to the donor and partial exchange in the recipient.

Prognosis: Although perinatal mortality is ~4-times higher in twins, survival among live born twins is relates to birth weight and gestation (comparable with singletons). Usually, first-born twin is smaller and at-risk for hypoglycemia while second twin has higher risk of birth asphyxia and respiratory distress syndrome. Concordant illnesses, e.g. hyaline membrane disease or infections are common in twins and the weight difference tends to disappear by 4–6 month of age.

TABLE 12.5: Complications of multiple pregnancies

- **Due to uterine overcrowding**
  - Low birth weight
  - Prematurity
  - Positional deformities, e.g. CDH
- **Due to shared blood supply**
  - Twin to twin transfusion
  - Intrauterine hypoxia
  - Vascular anomalies
- **Obstetrical problems**
  - Polyhydramnios
  - Abnormal placenta/antepartum hemorrhage
  - Premature rupture of membranes
  - Abnormal lie (obstructed labor)
- **Postnatal complications**
  - Birth asphyxia
  - Severe anemia in donor twin
  - Polycythemia in recipient twin
  - Hypoglycemia
  - Respiratory distress syndrome

CDH: Congenital dislocation of hip

12.4 DELIVERY ROOM CARE AND NEONATAL RESUSCITATION

Safe delivery is a critical component of *maternal and child health care*, to ensure smooth and uneventful childbirth as well as maternal well-being. Depending on the anticipated risk of complications, a delivery may be planned at peripheral health centers or referral centers.

Delivery room care may be divided into two components: (a) *basic or essential delivery room care* to all newborns, and (b) *neonatal resuscitation*, an emergency that may arise in any, specially high-risk newborns.

12.4.1 ESSENTIAL DELIVERY ROOM CARE

Basic delivery room care begins even before the birth. Important components of essential delivery room care are as follows:

Step I. **Pre-delivery review of antenatal health records:** Although the need for neonatal resuscitation may arise unexpectedly, it is possible to identify many high-risk pregnancies **(Table 12.2)** by review of antenatal records and refer them to adequately equipped centers.

Step II. **Pre-delivery preparations in labor room** to receive the baby and resuscitate, if needed. These include:

- All normal deliveries should be attended by a *trained medical or health attendant*. However, an expert pediatrician should always be stand-by, in case of unexpected emergencies.

- Labor room temperature should be ~25–28°C, to avoid sudden heat loss at birth. A commercial or indigenous-made warmer should be switched-on at least 15 minutes before the expected delivery.
- A pre-warmed baby receptacle (tray), lined with clean linen should be available to receive the baby after delivery, along with enough supply of extra linens.
- Availability of essential resuscitation equipment and drugs **(Table 12.10)** should be ensured, *and* in working condition.
- Universal safety precautions for infection control are necessary to protect not only the baby but also the health-staff. ***6 Cs*** *to ensure minimal asepsis during the delivery include—**C**lean hands with quality hand washing and use of gloves, **C**lean surface to receive the baby, **C**lean perineum, **C**lean blade to cut the cord, **C**lean clamp/ tie to tie the cord, and **C**lean, dry cord with no local application.*

Step III. **Intra-partum interventions** include:

- *Clamping of the umbilical cord*. Normally, the cord should be cut after 30–60 seconds of delivery by a sterile blade, leaving at least 2–3 cm of umbilical stump and tied properly to avoid slipped-ligature and bleeding.

  Delayed cord clamping is recommended in all stable term and preterm babies, who cried immediately after birth to improve hemoglobin status and iron stores. It is specially recommended in IUGR and anemic babies.

  Early cord clamping is recommended in asphyxiated newborns in need for immediate resuscitation, Rhesus isoimmunization and in first-born twin to minimize twin-to-twin transfusion.
- Collection of cord blood sample for grouping/cross matching and screening investigations for intrauterine infections or metabolic disorders, as per local protocol.
- Early skin-to-skin contact and *breast-crawl* to promote early breastfeeding and reduce the risk of hypothermia.
- Inform the mother about baby's gender and well-being.

Step IV. **Receiving the newborn:** Prevention of sudden hypothermia at birth is the most important component of immediate newborn care. As soon as the cord is cut, baby should be received in the pre-warmed tray, transferred under the warmer and wiped gently to clean and dry. No extra efforts should be made to remove the vernix, which protects against hypothermia. Wet linen, after wiping the baby should be discarded and changed.

Step V. **Ensuring the airway patency**, by:

- *Cleaning of oral cavity* for mucus, blood, meconium, etc. manually, by clean gauze piece;
- *Oropharyngeal suction* is not recommended in newborns who start breathing on their own after birth, while in others a low-pressure suction with an *Delee's* oral mucus extractor **(Fig. 31.9)** may be used to clean the airways. Vigorous suction must be strictly avoided to prevent trauma and reflex bradycardia/apnea.
- *Positioning* the baby in supine position with a rolled towel under the shoulders to prevent hyperextension/flexion of neck **(Fig. 12.2)**.

Step VI. **Stimulating the breathing**: While most newborns cry immediately after birth or as soon as the air-passage is cleaned, *gentle physical stimulation* by flicking on soles/rubbing the body may be necessary in others to stimulate first cry. Inverting the baby or *vigorous back-slapping should never be attempted.*

Step VII. **Quick clinical assessment** for resuscitation needs, A*pgar score*, lethal congenital anomalies, birth injuries, gestational age and other complications. Apgar scoring should also be repeated after 5 minutes to predict future neuro-developmental course.

Orifice counting and patency check—congenital anomalies tend to concentrate around natural orifices, e.g. nose, oral cavity, anus, urethral meatus and ears. Since many of them are serious or associated with internal malformations, it is advisable to quickly check these orifices for external abnormality, though there is no need to check the patency routinely with catheter. Esophageal patency must be checked before first feed in high-risk newborns with polyhydramnios, single umbilical artery, other congenital anomalies or frothing.

Stomach wash is recommended only in babies with-(a) cesarean delivery, (b) severe asphyxia, (c) meconium staining.

Step VIII. ***Cleaning of the baby*** must be limited to drying with a clean sterile cloth and gentle removal of blood and meconium. Vernix protects the skin and helps to maintain body temperature and hence, should not be removed.

Step IX. Weighing, tagging (identification) and gender assignment.

Step X. **Initiation of breastfeeding:** In all normal newborns, breastfeeds should be started as early as possible, usually within ½ hour of delivery and in the labor room itself. Though milk output at this time may be negligible, early feeding ensures successful lactation and emotional mother-baby bonding.

Step XI. **Examination of umbilical cord and placenta:** Essential delivery room care is not complete without examination of umbilical cord and placenta **(Table 12.6)**. Single umbilical artery (normally two), is associated with congenital malformations in 10–20% cases.

12.4.2 NEONATAL RESUSCITATION

While most newborns do not require any resuscitation beyond the maintenance of temperature, suctioning of airways and mild stimulation, adverse perinatal events, e.g. birth asphyxia may preclude smooth neonatal cardiopulmonary transition, unless assisted.

TABLE 12.6: Placental exam and its significance

Normal

Placental weight : 400–500 gm
Umblical cord length : 30–50 cm

Abnormal placenta

- *Large size:* IU infections, polyhydramnios, Rh-HDN
- *Small size:* IUGR, maternal malnutrition
- *Type:* Monozygous *vs* Dizygous (in twins)
- *Dull/milky:* IU sepsis
- *Grayish/yellow:* Meconium deliveries, Rh-HDN
- *Nodular:* Oligohydramnios
- *Multiple infarcts:* IU hypoxia, post-maturity
- *Retroplacental hemorrhage:* Severe anemia
- *Histological examination* for tubercles, malaria

IUGR: Intrauterine growth retardation, **Rh-HDN:** Rh-hemolytic disease of newborn

TABLE 12.7: Resuscitation alert (high-risk delivery)

- *High-risk pregnancy* ***(Table 12.2)***

+

- Pre-term/post-term delivery
- Malpresentation, e.g. breech, transverse, etc.
- Obstructed/prolonged labor
- Signs of fetal distress:
  - Meconium stained liquor amnii
  - Altered fetal heart sounds/movements
  - Abnormal tests for fetal well-being, e.g. NST
- Premature rupture of membranes
- Cord prolapse
- Cord around the neck
- Interventional delivery: LSCS, forceps, etc.
- Low Apgar score at 1 minutes (<4)

NST: Non-stress test

Primary goal of neonatal resuscitation is to *establish adequate respiration and cardiac output in asphyxiated newborns at birth*, to prevent early neonatal morbidity/mortality as well as late sequelae of hypoxic-ischemic damage.

Pathophysiology: Asphyxiated babies, whether *in utero* or *post-birth*, respond to the oxygen deprivation in a fairly constant sequence, i.e. development of primary apnea followed by terminal apnea.

Primary apnea is the immediate and transient response to oxygen deprivation, usually preceded by a short period of rapid breathing, followed by *sudden cessation of breathing*, falling heart rate (usually *>100/ min*) but with *maintained blood pressure*. These cases respond well to gentle tactile stimulation with re-initiation of breathing.

Terminal apnea is the response to continued asphyxia, after a brief period of recovery from primary apnea, characterized by *gradual cessation of breathing* after few gasps with significant drop in *heart rate (<100/min)*, *blood pressure* and *unresponsiveness* to stimuli. These patients do not respond to tactile stimulation and need more intensive resuscitation.

In cases of fetal hypoxia, one or both phases may pass *in utero* and the baby may be born in primary or terminal apnea, which is difficult to distinguish and it is safer to assume that s/he is terminal apnea and needs full resuscitation.

Other important considerations in resuscitation of newborns are:

- High airway resistance and pulmonary vascular resistance, due to poor lung expansion in first few breaths,
- Consequent hypoxia and acidosis leading to poor pulmonary perfusion and myocardial dysfunction, and
- Redistribution of blood flow from non-vital to vital organs (diving-in reflex) leading to multi-organ dysfunction .

Resuscitation alert: Although the need for resuscitation may arise unexpectedly, it is often possible to identify high-risk cases on the basis of proper history, review of previous maternal records and monitoring of the obstetrical course **(Table 12.7)**.

Pre-delivery preparations: All high risk deliveries must be attended by an adequately-trained pediatrician, preferably with an assistant. As soon as the need for neonatal resuscitation is felt, a pre-arranged plan of action should be activated to ensure presence of the trained staff and availability/ functioning of resuscitation equipment/drugs, etc. **(Table 12.8)**.

TABLE 12.8: Resuscitation equipments and drugs

- Pre-warmed resuscitation tray
- Pre-warmed warmer/resuscitation trolley
- Suction equipments
  - Low-pressure suction machine
  - Delee' mucus extractor
  - Suction catheter 10,12,14 Fr.
- Oxygen source with humidification and flow gauze
- Bag and mask ventilation
  - Resuscitation (AMBU) bag (250–500 ml)
  - Neonatal face masks
- Intubation equipments
  - Laryngoscope with straight blades (size 0, 1)
  - Endotracheal tubes (size 2.5, 3, 3.5, 4) with adopter/stylet
  - Nasogastric tube
- Medications
  - Umbilical catheters 3.5–5 Fr
  - Syringes and needles
  - Pre-filled Adrenaline (1:10000)
  - IV fluids: Normal saline
  - Naloxone hydrochloride
- Others
  - Timer
  - Linen/ gauze
  - Gloves
- Working electrical points
- Adequate manpower

TABLE 12.9: TABC of neonatal resuscitation

Temperature control
- Warmth under radiant warmer
- Drying the baby
- Removal of wet linens

Airway patency by
- Proper positioning
- Oropharyngeal suction
- Endotracheal suction

Breathing by
- Tactile stimulation
- Positive pressure breathing (PPV)
- Endotracheal intubation

Circulation by
- Chest compressions
- Medications

Principles: Basic principles of neonatal resuscitation include measures to restore and maintain four cardinal body functions—temperature, airway, breathing and circulation, often referred as **TABC** *of resuscitation* **(Table 12.9)**.

Protocol: Current neonatal resuscitation program (NRP), based on American Academy of Pediatrics *recommendations 2020,* propose a step-wise algorithm, as follows **(Fig. 12.1)**:

Step I. Initial assessment, as soon as the baby is delivered, aims to identify babies who need resuscitation, based on three simple parameters: (*a) gestation, (b) tone,* i.e. *posture and movements, and (c) breathing or crying.* No further resuscitation is required if the baby is full term, breathing/crying and moving with flexed posture, except basic delivery room care (Ch 12.4.1).

Babies who are preterm, flaccid or not breathing/crying, need immediate resuscitation with following steps. In them, cord should be clamped and cut as soon as possible, without waiting for minimum 30 seconds (Early cord clamping).

Step II. Initial steps in resuscitation aim to prevent hypothermia, clear the airways and stimulate breathing, by following interventions termed *"initial steps"*, which should be completed within 30 seconds.

a. ***Warm:*** Place the baby under a radiant warmer.
b. ***Dry*** with pre-warmed linens and remove wet linens.
c. ***Stimulate*** by gently rubbing the trunk, back and extremities to stimulate breathing/crying. Do not shake or rub vigorously.
d. ***Position*** the baby in supine position with neck slightly extended (sniffling position) to bring posterior pharynx, larynx and trachea in line and facilitate breathing. To maintain this position, a rolled towel may be placed under the shoulders **(Fig. 12.2)**.
e. ***Clear airway*** by wiping of the nose/mouth, though a gentle suction with a disposable mucus extractor or a 12–14 Fr. catheter may be required to clear the airway in some newborns. Head may be turned to one side to clear secretions in babies with copious secretions. Essentials of a good suction are as follows:
   – Mouth should be suctioned before the nose (M before N);
   – Suction pressure should never exceed 100 mm Hg (130 cm H_2O);
   – Suction catheter should not be inserted too deep, to avoid vagal stimulation and

Intrapartum suction or postnatal tracheal suction in non-vigorous babies with meconium stained amniotic fluid is no longer recommended.

Step III. Re-evaluation: After *initial steps*, baby must be re-assessed at 30 seconds. Approximately 60 seconds (*"the Golden Minute"*) are allotted for completing the initial steps, re-evaluation and beginning the breathing support, if required.

Current guidelines recommend use of two parameters-heart rate (HR) and respiration at 30 seconds, to decide further resuscitation measures, as well as observation for color or monitor for target SpO_2 **(Fig. 12.1)**.

Auscultate the heart or palpate for cord pulsations to assess the HR, which should be counted for 6 seconds multiplied by 10 to arrive at HR/min. Simultaneously, color should be observed over mucus membranes, e.g. tongue to detect central cyanosis (acrocyanosis has no significance in resuscitation).

No further intervention is required in babies with HR >100 and breathing normally, except to ensure warmth, clear airways and monitoring. Other cases need further resuscitation as follows:

– Babies with labored breathing and/or persistent central cyanosis must be provided supplemental oxygen at the rate of 5 L/min with a face mask, along with SpO_2 monitoring.
– Babies with: (a) apnea or gasping respiration, (b) HR < 100 or (c) persistent cyanosis on 100% oxygen must be started on positive pressure ventilation without delay (within the golden minute).

Step IV. Positive pressure ventilation (PPV) should be initiated without delay for indications as above, using a self-inflating resuscitation bag (ambulatory breathing unit or AMBU bag) with face mask **(Fig. 12.3)**. Resuscitation bag usually delivers 21% oxygen at room air without oxygen connection, 40–50% at an oxygen flow rate of 4–5 L/min with no reservoir, and 90–100%, if used with a reservoir. *PPV is contraindicated in cases with diaphragmatic hernia*, but may be used in those with potential meconium aspiration.

Some important considerations for bag and mask ventilation in NRP are as follows:

- *Appropriate position* of the head with slight extension to ensure clear airways.
- *Appropriate size of resuscitation bag (250–500 ml)*

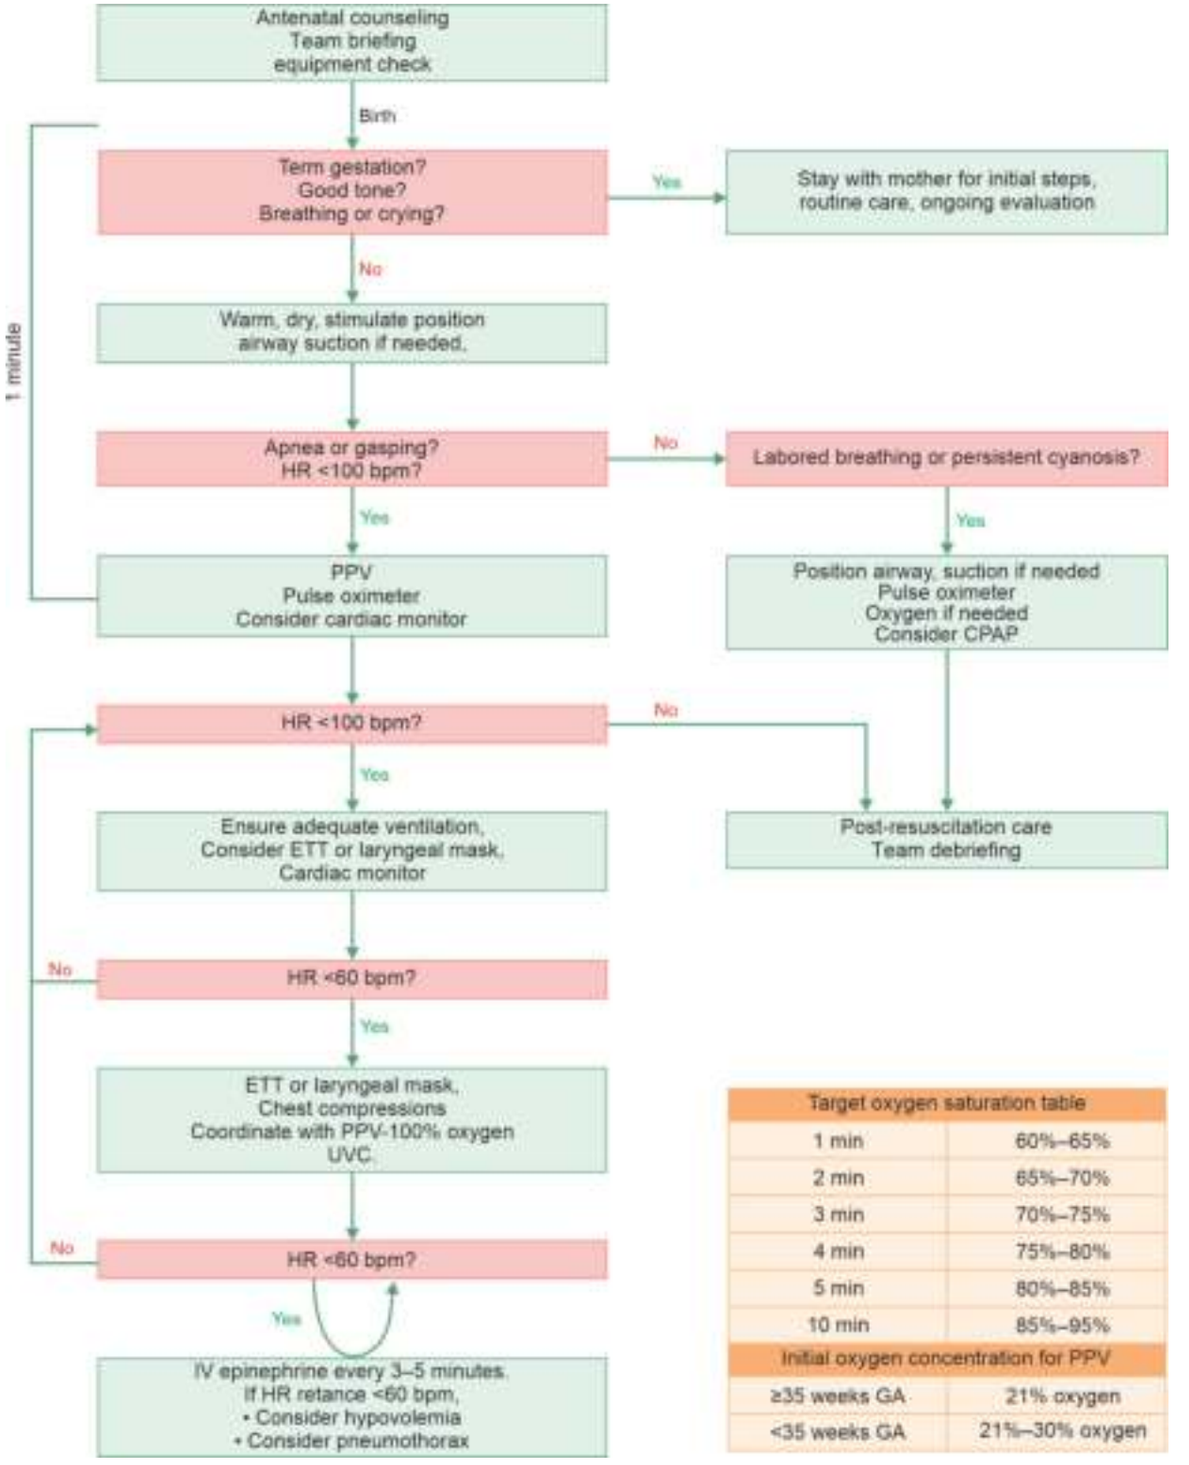

Fig. 12.1: Neonatal Resuscitation Algorithm.
Adopted from: American Heart Association 2020 guidelines.

- *Appropriately fitting face mask to* cover the nose and mouth but not the eyes.
- *Appropriate* FiO_2 with room air in babies >35 weeks and 21–30% for preterms <35 weeks, though should be adjusted later according to SpO_2 monitoring for target values, to the maximum of 100% in case of no improvement in 90 seconds.
- *Appropriate ventilation pressure,* applied by fingers and not the hands. First few breaths require higher bagging pressure (30–40 cm H_2O) to expand collapsed lungs,

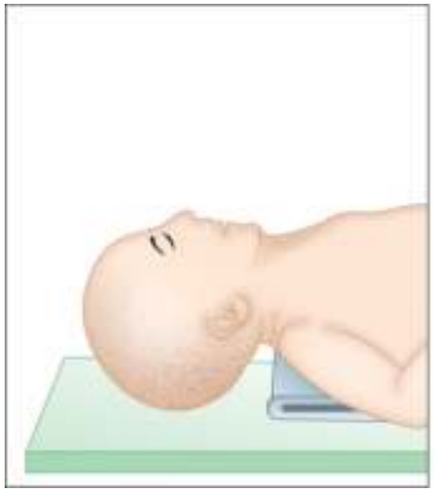

Fig. 12.2: **Proper sniffling positioning for resuscitation.**

Fig. 12.3. **Correct application of face mask (covering mouth, nose and chin but not eyes).**

but subsequent pressure should not exceed 20–25 cm H_2O, to prevent barotrauma.

- *Appropriate ventilation rate* of 40–60/min, following a *squeeze, one, two three, squeeze…* sequence.
- *Successful bag and mask ventilation* is indicated by: (a) good chest rise, (b) symmetric air entry, (c) disappearance of cyanosis, and (d) increase in heart rate. In absence of these indicators with poor chest wall movement and absence of breath sound on auscultation, following reasons and *Corrective steps* should be considered: (a) inadequate seal (reapply mask), (b) blocked airways (reposition the head, clear secretions by suction, and ventilate with mouth slightly open), (c) inadequate pressure (increase pressure slightly).
- PPV may also cause gastric distension due to swallowed air, which can be prevented by insertion of an orogastric tube in stomach, if PPV is required for >2 minutes.

After 30 seconds of effective PPV, baby should be evaluated again for HR to make following decisions:

- Babies with HR >100/min should be continued on PPV with monitoring. As the spontaneous breaths start, rate must be reduced accordingly and PPV can be stopped when baby has good respiratory efforts with HR persistently > 100/min.
- Babies with HR <100 but > 60, who do not improve despite increasing FiO_2 must be considered for endotracheal intubation.

Step V: Endotracheal (ET) intubation is indicated only in small proportion of cases, with: (a) poor response to PPV (HR < 100 and not increasing) after 30 seconds, (b) suspected diaphragmatic hernia, and (c) extreme preterm infants, who are also going to need surfactant therapy. Essentials of good ET intubation include:

- Appropriate size of laryngoscope blade, i.e. straight-blade of size 0 (preterms) or 1 (term).
- Appropriate size of ET tube, i.e. 2.5 for <1 kg; 3 for 1–2 kg; 3.5 for 2–3 kg and 4 for >3 kg.
- Appropriate depth of ET tube, calculated as distance from tip of the nose to tragus + 1 cm.
- Appropriate skill to perform, with each attempt not exceeding >20 seconds. Intermittent bag/mask ventilation for 30 seconds must be given before the next attempt, to prevent hypoxia.
- Correct placement of the ETT must be confirmed by bilaterally equal air entry and chest movement.

A laryngeal mask may be considered as an alternative to ETl intubation in newborns >34 weeks, if it is not feasible or unsuccessful.

Persistent of HR <60 despite effective ET intubation needs to begin with chest compressions and consider medications.

Step VI. Chest compressions aim to improve mechanical pumping of the blood to vital organs, indicated if HR *remains <60/min despite 30 seconds of PPV*. Chest compressions should be stopped once HR exceeds 60/min.

Chest compressions help to mechanically pump blood to vital organs and restore some perfusion and should always be accompanied with PPV.

Chest compressions involve compressing the lower-third of sternum by *two-finger technique* or *by thumb technique* **(Fig. 12.4)**, interspersed with PPV, at a ratio of 3:1 (90 compressions:30 breaths). Essential features of good chest compressions are:

- *Compression rate:* ~ 90/min (with PPV 30/min).
- *Depth:* ~ 1/3rd of chest's antero-posterior diameter.
- Relaxation time more than compression time.

Fig. 12.4: External cardiac massage in newborns: (A) Two-finger technique; (B) Two-thumb technique.

Potential complications include rib fractures, pneumothorax and liver injury. Chest compressions should be discontinued once the HR exceeds 60/min, continuing with PPV at the rate of 40–60/min.

Persistence of HR < 60 despite 60 seconds of chest compressions ad effective PPV, indicates need for medications.

Step VII. Medications have limited role in resuscitation, except epinephrine and volume expanders in some cases. Umbilical vein cannulation is preferred for quick IV access to deliver these medications, as follows:

- *IV Adrenaline* (1:10000) 0.1–0.3 ml/kg, is indicated if HR remains <60/min after 60 seconds of effective PPV and chest compressions and may be repeated every 3–5 minutes. It may also be given intratracheally after diluting in 1–2 ml of normal saline, if IV access is not available.
- *IV normal saline or Ringer lactate* 10 ml/kg, as volume expander in newborns with hypovolemic shock (feeble peripheral pulses despite adequate HR and ventilation).

There is no role of atropine, naloxone and steroids etc during neonatal resuscitation.

Step VIII. Consolidation phase, after initial recovery, involves shifting the newborn to intensive care unit, gradual weaning from respiratory support and correction of fluid, electrolyte and acid–base imbalance, apart from other supportive measures, e.g. antibiotics. *Blood transfusion* (O-negative, irrespective of baby's group), *10 ml/kg*, is indicated in babies with significant peripartum blood loss. *IV dopamine*, 5–10 mg/kg/min is used in shock, if blood pressure cannot be sustained with volume expanders.

When to stop resuscitation? It is a highly ethical and controversial issue though general consensus suggests futility of continued efforts in absence of heart rate for 20 minutes despite all appropriate steps in resuscitation were performed. Vigorous resuscitation is also not favored in: (a) extreme preterms <22 weeks or 500 gm, or (b) presence of lethal anomalies, e.g. anencephaly. However, decision must be individualized on contextual factors.

TABLE 12.10: Apgar scoring system

	Score		
Parameters	***0***	***1***	***2***
1. Appearance	Blue/pale	P. cyanosis	Pink
2. Heart rate	Absent	<100	>100
3. Respiration	Absent	Slow	Crying
4. Tone	Flaccid	Partial*	Flexed
5. Reflex response	Nil	Grimace	Cry

*Upper limbs flexed, lower limbs extended

Apgar score: Apgar scoring system, devised by an anaesthetist nurse Ms.Virginia Apgar, is the most popular evaluation tool to assess cardiopulmonary status at birth. Acronym APGAR stands for five evaluation parameters-***A***ppearance (color), ***P***ulse (HR), ***G***rimace (reflex response to nasal catheter), ***A***ctivity (tone) and ***R***espiration (RR).

Methodology: Apgar scoring involves assessment of these five parameters at 1 minute and 5 minute of age, on a scale of 0–2 with maximum score of 10 **(Table 12.10)**. However, if 5-minute score is <7, then additional scoring is done every 5 minutes till 20 minutes.

Utility: Apgar scoring assists to:

- Identify the need for immediate resuscitation, based on *1-minute score*.
- Predict the late neurological outcome in asphyxiated baby, based on *5-minute score*.

Limitations: the value of 1-minute Apgar score as a resuscitation guide is limited due to following reasons:

- First score is recorded at 1 minute, though resuscitative efforts should not be delayed that long.
- It is unreliable in preterms, congenital neuromuscular disorders or maternal sedation.
- Parameters, e.g. HR, tone, color and reflex activity are themselves dependent on respiration and hence, hardly provide additional information.
- Acrocyanosis (peripheral cyanosis) is common in normal newborns and hence, full score of 10 is unlikely, even in healthy crying baby.

However, 5-minutes score is an excellent predictor of late neurological outcome in asphyxiated newborns.

12.5 EXAMINATION OF A NEWBORN

Neonatal examination is difficult to complete in one sitting. A newborn has to examined repeatedly for complete evaluation, though following examinations are essential in each case: (a) preliminary examination

at birth, (b) comprehensive examination on first day in wards, (c) daily or more frequent follow-up examinations till discharge, and (d) final examination on discharge.

I. Delivery Room Examination

Delivery room examination aims to identify: (a) immediate need for resuscitation, (b) major congenital anomalies, and (c) high-risk neonate in need of advanced neonatal care and includes:

- Review of maternal and obstetrical records
- Assessment for Apgar scoring and vital signs to decide the need for resuscitation.
- Search for congenital anomalies, including orifice count and patency check if required.
- Quick physical evaluation for gestational age, birth weight and genitals for gender assignment, and
- Examination of placenta and umbilical cord for anomalies.

These aspects have been discussed in previous Ch 12.4.1.

II. First Day Examination in Nursery/Postnatal Ward

First day examination in nursery aims to evaluate the newborn *in toto*, to: (a) ensure general well-being, (b) precise assessment of gestation age, (c) identify missed congenital malformations or *warning signals* for sick newborn.

Essential prerequisites of good neonatal examination in nursery include:

- Baby should be examined at least ½ hour after feeding, when alert, comfortable and not crying.
- Nursery temperature should be comfortably warm (28–30°), and fans must be switched-off before unwrapping the baby.
- Examiner's hands should be washed properly for at least 2 minutes with an antiseptic soap and running water, dried and warmed by rubbing.
- A flexible approach is necessary in examination sequence. Traumatic examinations, e.g. patency checks or deep palpation should be deferred till inspection is complete.

A general protocol of neonatal examination in nursery includes:

I. Re-review of maternal/birth records for high-risk factors, e.g. infections, systemic illnesses, obstetric complications and drug therapy, which may affect the postnatal course of baby.

II. Anthropometry: For example, weight and length should be recorded on first day, preferably by electronic balance and infantometer respectively, while head circumference should be recorded after 24 hours, after disappearance of cranial molding.

At birth, a full term newborn weighs ~3 kg, measures ~50 cm and has a head circumference of ~33 cm. However, she/he loses up to 10% of birth weight (15% in preterms) during 1st week but regains it by 10th day (14th day in preterms). Subsequently, a newborn gain ~20–30 gm/day.

Low birth weight (<2.5 kg) or large for date (>3.5 kg) indicate specific problems in postnatal period (Ch 12.11). Birth length may be less in preterms, IUGR, chromosomal disorders and skeletal dysplasias.

III. Examination of vital signs, e.g. temperature, heart rate, respiratory rate, peripheral capillary filling and, blood pressure in selected cases.

- ***Temperature*** should be recorded by axillary digital thermometer. Normal neonatal temperature fluctuates between 36.5 and 37.4°C, with hypothermia as an important warning sign of sick newborn. WHO recommends that neonatal temperature should be recorded once a day in apparently healthy term babies, thrice a day in healthy LBW, 6-hourly in healthy VLBW < 2 kg and every 2 hourly in sick newborns. Use of mercury based rectal thermometers is no longer recommended.
- ***Heart rate*** *(HR)* in newborns fluctuates between 100 and 160/minute. Persistent tachycardia (>180) indicates CCF or arrhythmias, while bradycardia (<100) may be due to—(a) apneic episodes, (b) hypoxic-ischemic injury, and (c) maternal sedation.
- ***Respiratory rate*** (RR) in newborns is often irregular and varies from 30 to 60/minute. Common respiratory abnormalities include apnea, periodic breathing or respiratory distress.
- ***Peripheral capillary filling*** is a reliable indicator of hemodynamic status in newborns, assessed by blanching the heel and recording the time taken to recover its color. *Delayed filling of >3 second is a bad prognostic sign.*
- ***Blood pressure*** (BP) measurements are difficult and not essential in all newborns. BP may be assessed by *flush method* (Ch 17.12), though precise measurement requires Doppler studies. Normal neonatal BP is ~70–80 mm/50–60 mm Hg. While *hypotension* indicates circulatory shock, *hypertension* in newborn is usually due to: (a) renal anomalies, (b) renal artery stenosis, (c) severe coarctation of aorta, and (d) congenital adrenal hyperplasia.

IV. General physical examination needs to be more comprehensive than at-birth evaluation, conducted in a cephalocaudal direction (head-to-toe) to assess gestation age as well as identify minor/major problems, as follows:

- ***General appearance:*** A term newborn tends to assume *in utero* flexed posture and sleeps for >20 hours/day. Appearance includes: (a) posture/movements, (b) general activity, and (c) cry.

Abnormal posture: Limpness or asymmetric movements indicate—(a) hypoxic-ischemic damage, (b) CNS malformations, (c) neuromuscular disorders, (d) birth injuries or (e) pressure deformities in breech deliveries or oligohydramnios.

Abnormal activity: Persistently sluggish activity is a warning signal of sick newborn, usually due to hypoxia, sepsis, hypothermia and hypoglycemia. On the other hand, tremulousness or *jitteriness,* may indicate hypoglycemia, hypocalcemia or hypoxia.

Abnormal cry: Feeble/low-pitch cry indicates sick newborn, while high-pitch cry is common in kernicterus or hypoxic brain damage. Hoarse cry indicates birth trauma with vocal cord paralysis.

- ***Skin*** should be examined for its texture, color, vernix caseosa, lanugo, minor problems and major warning signals.

Vernix caseosa is a cheesy-white substance that covers the fetus till 34–38 weeks of gestation and the amount of vernix decreases with advancing gestation.

Lanugo are soft-fuzzy immature hair over body in preterms, which are gradually replaced by mature vellus hair with advancing gestation.

Skin in term newborn is shiny, pink, with vernix present only at creases and lanugo present only at upper back and dorsum of limbs.

Skin in preterms is thin and delicate, bright-red color, with plenty of vernix and lanugo over entire body. Pedal edema is also common.

Skin in post-terms is lusterless that peels or cracks at creases, and may be yellowish due to intrauterine passage of meconium.

Common benign skin abnormalities in newborns are discussed in Ch 12.7.

Important ***warning signals*** on skin include: (a) severe pallor/plethora, (b) persistent/central cyanosis, (c) deep icterus, (d) *cutis marmoratus*, i.e. pale-mottled skin suggestive of sepsis or hypothermia, (e) bleeding spots, e.g. petechiae or ecchymosis, due to birth injury or bleeding disorders, (f) *sclerema*, i.e. diffuse hardening of skin over cheeks, buttocks, extremities and bony prominences seen in hypothermia, sepsis and hypoglycemia, (g) generalized edema, e.g. hydrops fetalis, and (h) severe infections.

- ***Head*** must be examined for—(a) shape, (b) circumference, (c) soft-tissue abnormalities, and (d) fontanels and sutures.

Shape may be transiently deformed at birth, due to *molding*—overriding of cranial bones by vaginal pressure, which gradually disappears in a few days. *Excessive molding* indicates obstructed/prolonged vaginal delivery.

Head circumference of a normal newborn is ~33–35 cm, which should be recorded only after 24 hours of birth, after molding disappears. *Small size* indicates microcephaly or craniosynostosis, while *macrocephaly* may be familial or due to CNS malformations, e.g. congenital hydrocephalus, hydroencephaly, etc.

Soft-tissue abnormalities of scalp are usually benign, e.g. caput succedaneum or cephalohematoma (Ch 12.10.2). *Craniotabes*, i.e. ping-pong feel due to compressible skull-vault, is physiological in newborns. Large caput, cephalohematoma or lacerations over scalp may indicate significant birth injury.

Anterior fontanel at birth is open, soft, flat and pulsatile with diagonal size of <3 cm, while *posterior fontanel* is closed or admits only a tip of finger. Cranial sutures are open but in close approximation. *Large fontanels* or wide-sutures at birth indicate: (a) prematurity, (b) hydrocephalus, (c) hypothyroidism, (d) osteogenesis imperfecta, etc. *Small fontanels suggest* microcephaly/craniosynostosis. A *third fontanel* between anterior and posterior fontanel, is not a true fontanel but a defect in parietal bones, occasionally present in normal newborns or Down syndrome.

- ***Face*** should be examined for dysmorphic features and asymmetry during cry.

Facial dysmorphism is an important indicator of chromosomal or genetic disorders and generally includes—low hair-line, low-set ears, pre-auricular tags, slanting eyes, epicanthic folds, hyper/hypo-telorism, depressed nasal bridge, micro/retrognathia, cleft lip, etc.

Facial asymmetry on crying may be due to congenital hypoplasia of depressor angularis oris muscle or birth injuries (facial palsy, mandibular injury).

- ***Eye*** examination is difficult in newborns due to *physiological photophobia,* though most babies may open eyes on gentle rocking. A quiet and alert newborn may fix the vision on examiner's face and follow it for few degrees of sideway movements. Pupillary reflex is present from 28th week of gestation.

Common eye abnormalities include: (a) *benign problems*, e.g. conjunctival hemorrhage, nasolacrimal duct obstruction, transient discharge, etc.; (b) *malformations* suggestive of intrauterine infections or chromosomal disorders, e.g. microphthalmia, micro/macrocornea, coloboma, cataracts, or cat-eye-reflex, etc.; and (c) *conjunctivitis*.

- ***Ears*** should be examined for—(a) shape, recoil and deformities, (b) otoscopic exam in select cases and (c) hearing by startle response to sudden sound. Term newborns have well-formed cartilaginous pinna with good elastic recoil, relatively short and straight external auditory canal, easily visible dull-grey tympanic membrane and good startle response.

Transient ear discharge is common during first few days due to retained amniotic fluid. In preterms, ear cartilage is under-developed with slow recoil. Important ear abnormalities include malformed/low-set ears (chromosomal disorders), pre-auricular pits/tags (associated renal anomalies) and persistent discharge (otitis media), etc.

- ***Nose*** should be examined for dysmorphism and patency (by lubricated soft-rubber catheter, if required). Most newborns are obligate nose-breathers.

  Common abnormalities include depressed nasal bridge (hereditary, chromosomal), and *stuffiness* (choanal atresia/stenosis, infection, postural, etc.)
- ***Oral cavity*** must be inspected for cleft lip/palate or benign problems, e.g. natal tooth.
- ***Neck*** is relatively short in newborns but with full movements. Neck injuries are common in breech/transverse lie and may lead to torticollis or sternocleidomastoid tumor (Ch 12.10.2).

  Important neck abnormalities include *webbing* (Turner syndrome), *mid-line mass*, e.g. goiter, cystic hygroma, thyroglossal cysts, and *lateralized lesions*, e.g. branchial cysts/sinuses.
- ***Chest*** must be examined for shape, size, breast nodules, rib-cage and respiratory movements. Neonatal chest is barrel-shaped with prominent xiphisternum. Chest circumference is lesser than head circumference at birth. Breast nodule is ~10 mm in fullterms, with well-defined areola.

  Apart from benign problems, e.g. supernumerary nipples and mastitis neonatorum, also look for wide-spaced nipples (Turner syndrome), tender rib-cage (birth injury) and increased intercostal movements suggestive of respiratory distress.
- ***Spine*** in newborns is relatively straight and more flexible, which should be examined for neural tube defects or its stigmata (midline dimple/tuft of hair, etc.). Sacrococcygeal teratoma presents as a mid-line sacral tumor over spine at birth.
- ***Limbs*** abnormalities may be due to fetal posture, birth injury or congenital malformations. Sole creases are present up to anterior 2/3rd or more of sole in fullterms.

  Common limb problems include—(a) *congenital defects*, e.g. poly/syndactyly, hip dislocation, clubfoot, amniotic bands, etc., (b) *traumatic lesions,* e.g. fractures *or* brachial plexus injuries. Abnormal dermatoglyphics, e.g. simian crease, may indicate chromosomal defects.

  All newborns, specially with breech delivery or oligohydramnios, must be screened for congenital dislocation of hip by Ortolani/Barlow test (Ch 23.2.2).
- ***External genitals*** must be examined to assess gestation and exclude ambiguous genitalia.

  A fullterm male newborn has stretched penile length of 3–4 cm, less-retractile prepuce (physiological phimosis), pigmented scrotum with extensive rugae, and well-descended testes. Penile erection is common.

  Important male genital problems are—micropenis (<2.5 cm at birth); epi/hypospadias; hyperpigmented scrotum in congenital adrenal hyperplasia; undescended testes, hydrocele and inguinal hernia. Testicular volume is unusually small in Noonan syndrome and Klinefelter syndrome and unusually large in Fragile-X syndrome.

  Term female newborns have well-developed labia majora that cover > 2/3rd of minora. A non-purulent discharge is common during 2–7th day due to transplacentally transferred maternal hormones. Some babies develop transient vaginal bleeding on 5–7th day, due to estrogen-withdrawal.

  Common and usually benign female genital abnormalities include labial adhesions, imperforate hymen, hymenal tags and clitoral hypertrophy, though last may be a sign of adrenogenital syndrome. Urine is passed with 24 hours by >95% newborns, *else* should alert about possibility of obstructive uropathy, e.g. posterior urethral valves in males or dehydration.
- ***Anus*** examination is essential in cases who have not passed meconium for 48 hours and includes visual inspection. Also look for fistulous outlets.

V. Umbilical examination is an essential part of neonatal assessment, being the commonest portal of entry for infections.

Normal umbilical cord is ~30–50 cm in length and contains two arteries, one vein, remnants of omphalomesenteric (vitalline) duct, rudimentary allantois and a gelatinous substance (*Wharton's jelly*), all covered by amniotic sheath. Post-delivery, the umbilical stump dries-up and shrivels within 24 hours to turn yellowish black and fall-off by 7–8th day. Umbilical arteries constrict at birth or within 4–6 hours, while vein may be cannulated till 5–7th day. Later, umbilical arteries and vein form *lateral umbilical ligaments* and *ligamentum teres*, respectively.

Common umbilical anomalies at birth include:

- *Single umbilical artery* is present in 5–10/1000 singleton and 35–70/1000 of twin births and signifies presence of other congenital anomalies in ~ 1/3rd cases.
- *Delayed separation of cord* stump beyond >10th day indicates umbilical sepsis or defects of phagocytic function; while *early separation* is usually traumatic (avulsion injury).
- *Umbilical bleeding* may be due to—(a) slipped ligature, (b) trauma, (c) sepsis, or (d) systemic bleeding disorders.
- *Umbilical discharge* is usually due to—(a) sepsis (purulent); but rarely may indicate, (b) patent omphalointestinal duct (fecal discharge), or (c) patent urachus (urinary discharge).
- *Omphalocele*, i.e. herniation of abdominal contents through umbilical ring, covered only by peritoneum without overlying skin (d/d umbilical hernia) may be an isolated defect *or* seen in Trisomy 13 or Beckwith's syndrome. As the herniated sac may contain vital structures, e.g. intestines or liver, it should be immediately covered with sterile saline gauze to prevent drying, till surgery is arranged.
- *Umbilical sepsis, see* Ch12.15.1.

VI. Abdominal examination includes inspection for abnormal appearance or distension (record girth, if distended) as well as palpation for liver, spleen, kidney or unusual mass. At birth, liver may be palpable up to 2 cm, as also the splenic tip and lower poles of kidneys.

Common abnormalities in appearance include: (a) *scaphoid* abdomen in congenital diaphragmatic hernia, (b) *distended* abdomen in necrotizing enterocolitis, intestinal, obstruction or paralytic ileus, and (c) *parietal wall defects*, e.g. omphalocele, ectopia vesicae, gastroschisis, or *prune-belly syndrome*

Hepatosplenomegaly at birth usually indicates intrauterine infection. Ascites in newborns indicates: (i) hydrops fetalis, (ii) lymphatic malformations, or (iii) severe renal disease.

VII. Respiratory examination aims to assess the presence, severity and etiology of respiratory distress (Ch 12.13). Auscultatory findings are unreliable in newborns and should be supported by X-ray, if necessary.

Excessive oral frothing *or* gurgling sounds on chest auscultation, are warning signs for *tracheo-esophageal fistula* and *diaphragmatic hernia,* respectively.

VIII. Cardiovascular examination aims to assess: (a) location of heart sounds, as well as (b) presence of murmurs.

Presence of better audible heart sounds in right hemithorax indicate dextrocardia, situs inversus or dextroversion (due to right lung aplasia or left pneumothorax). In newborns, splitting of S_2 is easily audible with loud P_2 due to high pulmonary vascular resistance.

Presence of a murmur in newborn not necessarily indicates congenital heart disease, since transient functional murmurs are present in 15–20%. Conversely, the absence of murmurs does not exclude a heart disease, as many lesions manifest later when pulmonary vascular resistance drops after lung expansion.

IX. Neurological examination on first day includes assessment of—(a) general behavior, e.g. alertness, activity and cry, (b) active/passive tone, (c) symmetry of limb movements, and (d) primitive neonatal reflexes. Newborn should be neurological examined only when quiet but alert—*Prechtl stage III* **(Table 12.11)**, usually after 1 hour of feeds.

- *Abnormal behavior*, e.g. staring spells, vacant look or shrill cry may indicate seizure activity in newborns, while sluggish activity is a warning sign for septicemia, hypothermia, hypoglycemia and asphyxia. *Jitteriness* indicates hypoglycemia or hypoxic brain injury.
- *Tone* may be assessed indirectly by posture (flexed/extended) or directly by various methods for active tone (arm recoil) /passive tone (Popliteal angle, scarf sign, Heel-to-ear maneuvers) (Ch 12.10.1). *Hypotonia* at birth is a sign of prematurity, neuromuscular disorders, birth asphyxia or critical illnesses, while *Hypertonia* indicates kernicterus, tetanus neonatorum or cerebral damage.
- *Asymmetric limb movements* may be due to *true weakness*, e.g. brachial plexus injury, neural tube defects, etc. *or pseudo-paralysis* in local painful conditions, e.g. fractures, septic arthritis, congenital syphilis, etc.
- *Primitive neonatal reflexes* (NNR) are excellent indicators of neurological disease (*see* below). *Absent or sluggish NNRs* usually indicate prematurity, critically sick newborn or sedation.
- *Deep tendon reflexes* may be exaggerated in newborns due to immature myelination and *ankle clonus* is common. Asymmetry of these reflexes is more informative, suggestive of neuromuscular disorders.
- *Plantar response* is normally extensor in newborns, with a little clinical significance.

Primitive neonatal reflexes, which appear and disappear in fairly consistent sequence during specific periods of development **(Table 12.12, Fig. 12.5)** are excellent indicators of neonatal health, neurological status and development. Note that:

- While most NNRs start developing in late gestation, they mature gradually to reach the optimal level only in full terms. Hence, the strength of reflex response is as important as its presence.
- Absent/sluggish NNRs, apart from illness, may also be due to physiological factors, e.g. feeding or sleep.
- Disappearance of a NNR is necessary before reaching the corresponding milestone, e.g. tonic neck reflex disappears before crawling.
- Persistence of NNRs, beyond the expected age is an important indicator of cerebral palsy.

TABLE 12.11: Prechtl stages of neonatal behavior

Stage	*Behavior*
I	Quiet non-REM sleep, regular breathing
II	REM sleep, irregular breathing
III	*Quiet awake:* Eyes open, minor movements
IV	Active, alert, moderate movements
V	Crying

REM: Rapid eye movement

TABLE 12.12: Common primitive neonatal reflexes

NNR	*Appears*	*Disappears*
Moro's*	28–32 weeks	3–4 months
Sucking/rooting	32–36 weeks	4–6 months
Palmar grasp	28–32 weeks	3–4 months
Plantar grasp	32–36 weeks	8–10 months
Stepping	32–36 weeks	3–4 months
Crossed extension	32–36 weeks	4–6 months
Landau	32–36 weeks	24 months
Tonic neck reflex	1–2 months	4–6 months
Parachute	6–8 months	Persists

*Moro's is the first reflex to appear and disappear

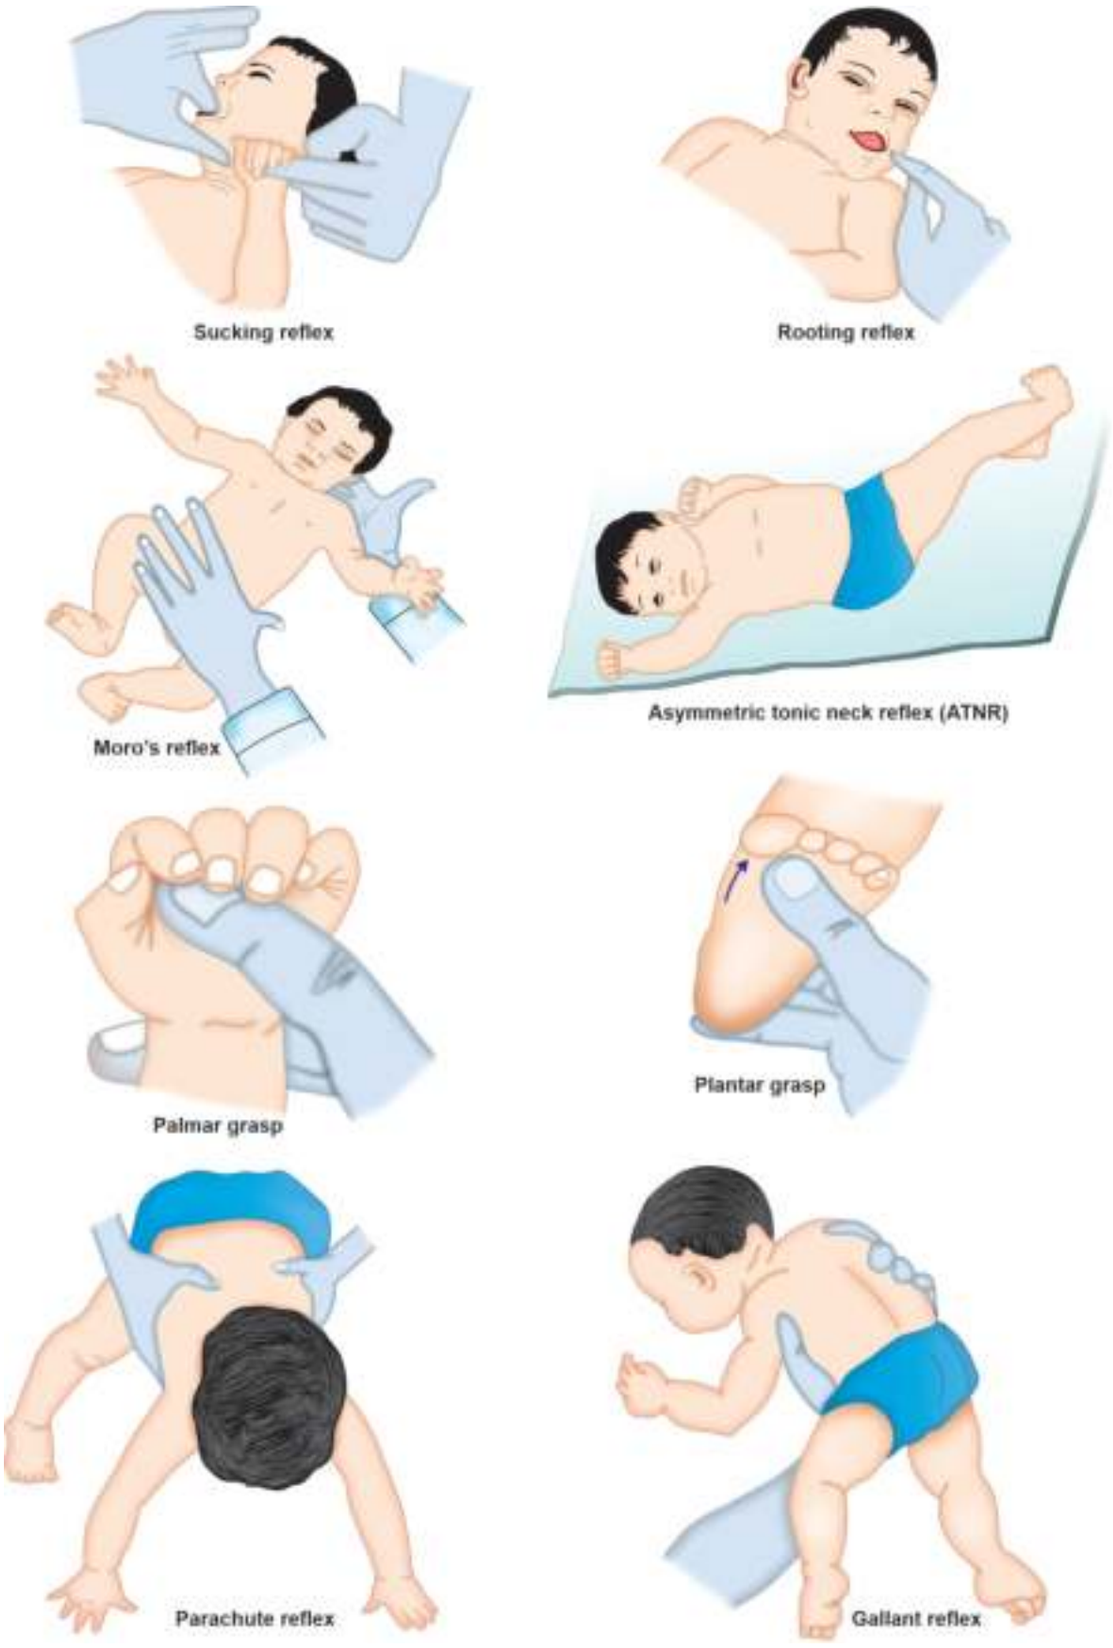

Fig. 12.5: **Common primitive neonatal reflexes.**

Common primitive NNRs are as follows:

Sucking reflex is elicited by touching the baby's lips with a clean finger, leading to sucking movements that should be assessed for strength and rhythm. It is present but weak at 28th week but strong enough by 32 weeks.

Rooting reflex is elicited by stimulating the baby's lips or corner of mouth by examiner's finger, leading to movement of lips/tongue and turning of the head towards the same side, as in search of breast. Sucking and rooting reflexes together are also called *cardinal point reflexes.*

Moro's reflex is elicited by pulling the supine baby halfway to sitting position and suddenly letting his head fall back a short way, supported by examiner's hand. The response consists of sudden abduction and extension of arms with opening of fists (Phase I), followed by adduction and flexion in arms-embracing position (Phase II). Asymmetric Moro's reflex indicates brachial plexus injury or fracture of clavicle.

Startle reflex, elicited by sudden noise (clapping of hands) is similar to Moro's reflex, except flexion rather than extension of arms and absence of second component. Sluggish startle response indicates hearing impairment.

Palmar grasp reflex is elicited by stroking the baby's palm with examiner's index finger, leading to flexion of fingers to grasp it, which is reinforced on attempts to remove the finger. In fullterms, grasp may be strong enough to support the baby's weight. Grasp reflex has to disappear, before the baby learns to release the objects. Persistent grasp is a reliable indicator of cerebral palsy.

Plantar grasp reflex is elicited by stroking the anterior 1/3rd of sole, leading to flexion of toes. Plantar grasp disappears before baby learns to walk.

Stepping reflex (*limb-placement reflex*) is elicited by rubbing the shin of tibia on the side of table that leads to lifting of leg over table's edge.

Walking reflex is elicited by holding the baby upright and pressing the sole of one foot on couch, leading to flexion of opposite leg, as in walking.

Asymmetrical tonic neck reflex (ATNR) is elicited by turning the baby's head to one side, leading to extension of ipsilateral arm and flexion of contralateral knee (*Fencer's position*). ATNR has to disappear before the baby learns to turn from supine to prone position.

Symmetric tonic neck reflex is characterized by extension of arms and flexion of knees when the head is flexed and vice versa. This reflex has to disappear before the baby starts crawling.

Crossed-extension reflex is elicited by gently stroking the sole of a leg *held in extension*, leading to rapid flexion, adduction and then extension of opposite leg. Although this reflex appears at 32 weeks, adduction component is absent in preterms.

Parachute reflex is a protective reflex that appears before walking starts, elicited by holding the baby in ventral suspension and suddenly dropping to some distance, leading to extension of arms, hands and fingers. It is absent or asymmetric in cerebral palsy.

Landau reflex is elicited by holding the baby in ventral suspension, leading to extension of head, spine and legs. Flexion of head in this position leads to flexion of limbs.

III. Subsequent Examinations Till Discharge

Neonatal examination is never complete in one sitting. During hospital stay, all babies need to be re-examined at least twice a day for any warning sign (*see* **Table 12.14)**. However, baby must not be handled too frequently to avoid infections. Routine evaluation on ward rounds include:

- ***History*** regarding—(a) acceptance of feeds, (b) passage of meconium/urine, and (c) other significant events. Failure to pass urine till 24 hours and meconium till 48 hours indicates need of detailed evaluation.
- ***General examination*** specially for—(a) behavior, activity and cry, (b) vital parameters, (c) weight record, (d) icterus, (e) umbilical sepsis, (e) superficial infections, e.g. thrush, conjunctivitis, pyoderma, rash, etc., and (g) warning/danger signs.
- ***Systemic examination*** specially for—(a) abdominal distension, (b) new murmurs, and (c) NNRs.
- ***Maternal examination*** for—(a) general health and diet, (b) local breast/nipple problems, and (c) counseling regarding breastfeeding, temperature control and good baby care practices.

IV. Examination at Discharge

A normal newborn may be discharged after 48 hours, though preterms/small for date and sick newborns need to stay longer. Examination at the time of discharge aims to ensure eventless course at home and includes:

- Thorough clinical examination to exclude danger signals and hitherto missed congenital anomalies.
- Proper maternal counseling about feeding, thermocare, immunization, follow-up, birth registration, and further family planning.

12.6 CARE OF NORMAL NEWBORN

Care of a normal newborn in delivery room has already been discussed earlier. This chapter deals with care in postnatal wards/home.

- **'Rooming in',** i.e. keeping the baby with mother is best option for normal newborns to facilitate—(a) emotional infant–mother bonding, (b) successful lactation, (c) maternal involvement in baby care and (d) prevention of nosocomial infections.
- **Thermoregulation:** Hypothermia is a leading cause of morbidity in normal newborns, which may be prevented by—(a) proper room temperature

(~ 28–30°C), (b) avoidance of direct wind movements, e.g. fans, (c) proper cloths* and wrapping of baby in clean sheets and caps, (d) delayed bath till next day, and (e) oil application without vigorous massage to provide protective insulation against insensible heat loss and stimulation to baby (*touch therapy*).

*Two layers (inner vest and outer frock, to trap the warmth) of soft, loose, easy to wear cotton clothes are advised with additional layers of soft woolen including cap and socks in winter season. Synthetic clothes and diapers must be avoided. A square piece of cotton may be used as diaper.

Kangaroo care is an excellent method to prevent hypothermia, specially in preterms/low birth weights, which involves placement of baby inside mother's clothing with close skin-to skin contact (*see* **Fig. 12.12)**. It also stimulates lactation and emotional bonding between mother and baby.

- **Feeding:** Breastfeeding should be initiated as early as possible, preferably in the labor room itself. Successful lactation requires—(a) early initiation, (b) constant motivation, (c) conductive atmosphere, e.g. privacy, (d) demand feeding, (e) no pre-lacteal feeds, (e) proper technique, (g) management of breast/nipple problems, and (h) adequate maternal nutrition (extra 400–500 calories).
- **Care of the skin:** At birth, baby is covered with vernix caseosa and amniotic fluid, which should be gently wiped-off in delivery room, though vigorously scrubbing should be avoided. The need for first-day bath is controversial and should be avoided during winter season. Subsequently, baby may be bathed or sponged next day with lukewarm water and unmedicated soap. Medicated, e.g. chlorhexidine soap are not advisable, which may be irritant to tender skin and prevent colonization with normal flora. *Dip-baths* should be avoided till cord has fallen.

  Pre-bath gentle oil massage with a non-irritating oil, e.g. olive or coconut oil, is claimed to comfort the baby, improve muscle tone, and strengthen maternal bonding (***touch therapy***). However, due care is necessary to prevent trauma and hypothermia. Practice of instilling a few drops of oil in nose and ears, prevalent in some communities, may lead to aspiration and should be strongly discouraged.
- **Care of umbilical stump:** Umbilical sepsis is the commonest source of infection in normal newborns. It should be kept dry, clean and unsoiled from urine/stool. No topical antibiotic or antiseptic application is required. Cord stump usually falls off on 7–10th day, unless infected. Cord should be regularly examined for signs of umbilical sepsis, e.g. foul smelling pus discharge and peri-umbilical induration.
- **Care of eyes:** Sticky eyes are common in newborns and not necessarily indicate infection. Excessive watering or stickyness may be due to nasolacrimal duct blockage, which opens up spontaneously after 3–6 months. Eyes say be cleaned at birth and then periodically with a sterile cotton-swab soaked in normal saline.
- **Medications** are rarely needed, except:
  - *Single dose of vitamin K* (0.5–1.0 mg, PO/IM) to all normal newborns at birth. Low birth weight or sick newborns should receive it by IM route only.
  - *BCG, OPV and HBV* vaccine is indicated to all newborns before discharge.
  - *IV tetanus immunoglobulin* 250–750 IU, only if mother had not received TT in antenatal period and delivered by untrained *dai*/cord cut by unsterile blade.
- **Clinical monitoring** for—(a) weight changes, (b) warning signals (*see* **Table 12.17)** and (c) adequacy/problems related to breastfeeding. Cases with warning signals need transfer to intensive care.
- **Maternal/family counseling** regarding essential aspects of child care, e.g. prevention of hypothermia, breastfeeding, maintenance of hygiene, etc. should be reinforced on daily rounds and on discharge.

When to discharge: A normal newborn may be discharged after 24 hours, if—(a) accepting feeds properly, (b) has passed urine and stools, (c) has no warning signs as in **Table 12.17**; (d) has received at-birth immunizations, and (e) mother has been counselled about routine newborn care and recognition of warning signs. Follow-up is indicated at 6 weeks.

Follow-up care: *Indian Academy of Pediatrics (IAP)* recommends periodic growth assessment of newborns and infants at—(a) birth, (b) during each immunization visits at 6,10,14 weeks and 6, 9 and 15 months, (c) every 6 months from 18 months to 8 years of age and then, (d) annually during 9–18 years.

During each of these visits, baby should be assessed for—(a) growth, (b) immunization status, (c) common health problems, (d) specific health concerns reported by parents. In addition, mother should also be counseled about infant feeding practices, immunization needs, importance of growth monitoring and watch for red-flags signs.

12.7 MINOR PROBLEMS IN NEWBORNS

Although essentially benign and frequently self-limiting, following problems are common cause of parental concern. No treatment is indicated in these cases, except assurance. However, some of them must be differentiated from more serious pathologies, discussed in later chapters.

a. Common skin problems include:

Milia, i.e. tiny, white dots over nose and face due to blocked and distended sebaceous gland, are common on 2–3rd days and disappear spontaneously **(Fig. 12.6)**.

TABLE 12.13: Common rashes in newborn

Benign and transient
- Milia
- Erythema toxicum
- Pustular melanosis

Pathological
- Staphylococcal pustules,
- Intrauterine infections, e.g. HSV, syphilis
- Cutaneous thrush (candidiasis)
- Staphylococcal scalded skin syndrome
- Toxic epidermal necrolysis

Erythema toxicum, i.e. tiny, discrete, erythematous papules/vesicles over face, trunk and extremities, usually appear on 1–3rd day and persist for as long as one week, before spontaneous resolution **(Fig. 12.6)**. On scrapping, these lesions are filled with eosinophils.

Pustular melanosis *are* benign vesiculobullous eruptions over chin, neck, back and limbs, present at birth, lasting for 2–3 days **(Fig. 12.6)**. On scrapping, these lesions are filled with neutrophils. (***d/d*** Impetigo or Herpes simplex). Some common causes of neonatal rash are given in **Table 12.13**.

Mongolian spots, i.e. slate-blue, well-demarcated spots on trunk, back or buttocks, are present in >50% newborns and usually disappear by 6–24 months **(Fig. 12.6)**. These spots have no relation with Down syndrome. (*d/d Congenital melanocytic nevi*, seen in <1% newborns).

Stork-bites (Salmon patch), i.e. small, diffuse, pinkish-grey macules (capillary hemangioma), are seen in ~40% newborns, specially over eyelids, forehead and nape of the neck (*see* **Fig. 25.3)**. These lesions are usually bilateral, symmetrical and more prominent during cry. Most of them fade spontaneously in 1–2 months. (*d/d Port wine stains*, present at birth as flat, circumscribed, unilateral macules in head/neck region, which enlarge and darken with age).

Acrocyanosis over finger tips and perioral region is very common during first few days of life, which becomes more prominent during cry and improves rapidly after protective clothing. (*d/d* central or persistent cyanosis in cardiorespiratory disorders).

Harlequin color change, i.e. a transient vertical delineation of body into red and pale halves, is a striking but harmless sign of vasomotor instability in first few day of life. (*d/d cutis marmorata*-bilateral diffuse mottling with lacy appearance, suggestive of sepsis or hypothermia).

Physiological jaundice appears in ~70–80% of normal newborns on 2–3rd day of life, and persists till 7–10th day in terms and 10–14th day preterms (*d/d see* Ch 12.14.1).

Edema: Transient pedal edema is common in preterms, while its persistence indicates possibility of Turner syndrome or lymphatic malformations, e.g. Milroy disease. (*d/d* generalised edema is seen in hydrops *fetalis,*

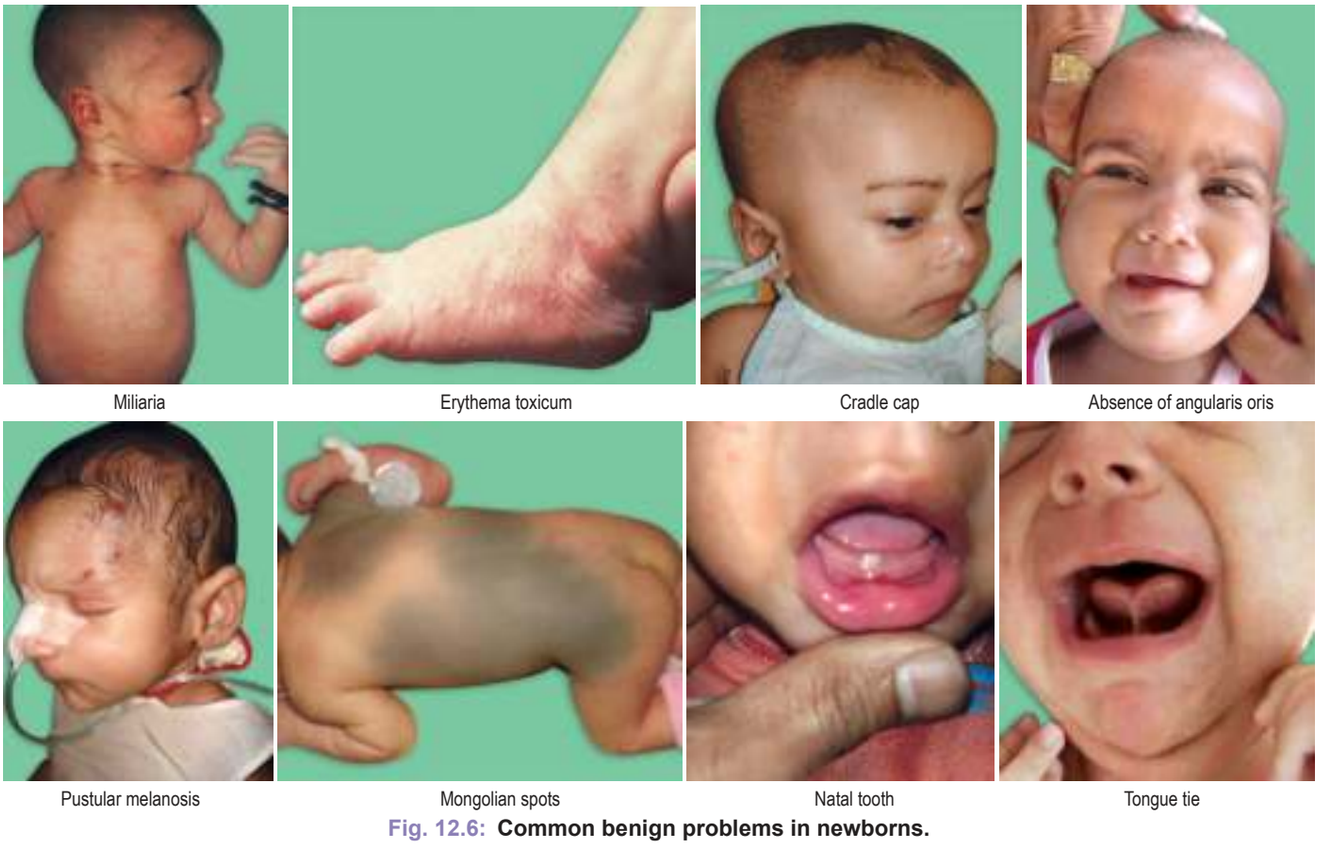

Fig. 12.6: Common benign problems in newborns.

of immune (Rh-incompatibility) or non-immune (renal agenesis, severe anemia) origin.

Subcutaneous fat necrosis, i.e. patchy induration over buttocks, cheeks and limbs that resolves spontaneously. (*d/d* diffuse *sclerema* in sepsis, hypothermia).

b. Common problems of oral cavity include:

Epstein pearls are tiny, white masses over hard palate near midline, due to temporary accumulation of epithelial cells (retention cysts) that disappear spontaneously within a few weeks. Similar lesions may be present on gums (epithelial pearls) and prepuce (prepucial pearls).

Sucking pads/sucking callus are temporary callosities over lips and cheeks respectively, due to accumulation of extra fat and stratified epithelium, which disappear after some time.

Natal tooth are not uncommon in normal newborns, usually seen at the site of lower incisors, representing a supernumerary or prematurely erupted deciduous tooth **(Fig. 12.6)**. Extraction is not indicated unless loose or hurts during breastfeeding. (*d/d* Ellis-van Creveld syndrome).

Tongue-tie due to short ventral frenulum is common, but rarely leads to feeding or speech problems **(Fig. 12.6)**. A thick and tight frenulum with notches over the tongue, may be snipped at 3 months.

c. Common ocular problems include:

Physiological photophobia is common in normal newborns during first few weeks of life.

Subconjunctival hemorrhage, usually near the outer canthus is common in vertex delivered newborns, which resolve spontaneously in 1–2 weeks.

Unilateral mucoid eye discharge is seen in ~5% of newborns, due to incomplete canalization of naso-lacrimal duct. Frequent massage over nasal sides and cleaning of eyelids with lukewarm water is enough in most cases, before spontaneous resolution by 3–6 months. Topical antibiotics are indicated only if discharge is mucopurulent. Persistent cases (>6 months) may need punctal probing or dacryocystorhinostomy.

d. Common genital problems include:

Physiological phimosis is present in ~80% newborns, which rarely interfere with micturation and resolves spontaneously by 2–3 years. *Prepuce should not be etracted forcibly*.

Transitory hydrocele due to persistent *processus vaginalis* is common in male newborns, presenting as unilateral scrotal enlargement with small fluid-sac and usually resolves spontaneously by 3–4 months.

Vaginal discharge: A whitish, mucoid vaginal discharge is common in female babies during first few days of life, due to the transplacentally transferred maternal estrogen on vaginal mucosa. No treatment is required. (*d/d* purulent discharge in infections).

Vaginal bleeding: 20–25% female babies develop vaginal bleed on 3–7th day due to withdrawal of maternal estrogens. It clears spontaneously in 2–3 days, with no specific treatment except local cleaning. (*d/d* hemorrhagic disease of newborn or other bleeding disorders).

e. Mastitis neonatorum is a misnomer, since it is not an infection but merely indicates breast hypertrophy on 3rd–4th day, due to effects of transplacental maternal hormones and disappears in a few days. A creamy liquid may also ooze-out from nipples. No treatment is necessary. Engorged breast should not be squeezed, which may cause inflammation.

f. Common GIT problems include:

Vomiting: Transient vomiting soon after birth may be due to swallowed maternal blood/amniotic fluid, which may be easily controlled by gastric lavage.

Possetting, i.e. effortless regurgitation of some curdy milk is common in newborns and indicates developmental immaturity of cardiac sphincter in early infancy. It is more common in vigorous babies, during rapid limb movements and soon after feeding.

Aerophagia, i.e. swallowing of air during feeding and overfeeding are two commonest causes of possetting, specially in bottle-fed babies. Adequate burping after each feed is all that is required in these cases. Vomiting associated with bile, blood, abdominal distension or poor weight gain in newborn is pathological and need detailed evaluation.

Diarrhea: Appearance and frequency of stools in normal newborns vary according to the postnatal age and type of feeding, apart from individual variations.

- ***Meconium,*** *the Initial stools* during first 48–72 hours are typically black, thick, viscid and odorless, passed 5–6 times a day. The color and consistency changes gradually to transitional stools.
- ***Transitional stools,*** from 3–7th day are relatively watery, greenish, explosive and contain mucus or solid soapy flakes. Stools may be passed ~8–10 times/day, gradually culminating into breast-milk or top-milk stools.
- ***Breast-milk stools:*** A breastfed baby passes dark yellow or greenish semi-watery stools, usually 5–6 times a day but frequency may vary from once a week to 10–15 times a day. Although worrisome for parents, this pattern is physiological and must not be construed as diarrhea.
- ***Top-fed babies*** tend to be relatively constipated and pass thicker and lighter stools.
- ***Hyperactive gastro-colic reflex*** is a common cause of increased stool frequency in newborns and early infancy, characterized by passage of stools soon after feeding. Problem improves spontaneously by 3–6 months.

Pathological diarrhea is more common in top-fed or sick newborns, indicated by sudden increase in frequency and fluidity of stools and needs need careful evaluation.

Constipation: Nearly 95% of newborns pass first stools within 24 hours of birth, and failure to do so by 48 hours indicates possibility of intestinal obstruction or ano-rectal malformations. Newborns with higher intestinal atresia, e.g. duodenal atresia, may pass 1–2 stools initially, before developing absolute constipation and abdominal distension.

Constipation is a common cause of parental concern, though normal variations are common in stool frequency. Top-fed children tend to be more constipated due to high-solute load and relative dehydration. Mild constipation may be overlooked, though significant discomfort may be relieved by glycerine rectal suppository after excluding pathological causes.

Constipation from 2nd week of life, with/without intermittent attacks of diarrhea suggests a possibility of Hirschsprung disease or hypothyroidism.

Hiccups: Most normal newborns develop hiccups, specially after feeds, due to distension of stomach with diaphragmatic irritation.

g. Dehydration fever: Some healthy newborns may develop transient fever on 2–3rd day of life, specially during summer season due to immature heat-loss mechanisms. Fever rarely exceeds 38.5°C and baby remains active and keen to feed. No treatment is required except adequate feeding and reducing the environmental temperature.

h. Sneezing or noisy breathing is common in newborns, frequently confused with *common cold*. As newborns are obligate nose-breathers, severe nose block may interfere with feeding, which can be managed with nasal instillation of 1–2 drops normal saline, 10–15 minutes before feeds. Nasal decongestants are contraindicated.

i. Excessive cry: During first 4–6 weeks, babies usually sleep throughout the day and cry at night probably due to *in utero* pattern. (*in utero* babies sleep while pregnant mother is working in daytime due to rocking effect).

While duration, intensity and pattern of cry may vary in different newborns, common causes may be—(a) hunger, (b) discomfort, e.g. wet, soiled, too hot, too cold, (c) insect-bites, (d) aerophagia or abdominal colic (e) blocked nose, and even (g) loneliness.

Babies often cry before passing urine due to unpleasant sensation of full bladder. However, crying during (rather than before) micturation may indicate dysuria with possibility of urinary tract infection.

Some unusual neonatal cries include *shrill high-pitched* cry in kernicterus or cerebral hypoxia; *weak, low-pitched* cry in hypotonia disorders; *intermittent* cry in abdominal colic, *sudden cry* due to insect-bite, etc.

Evening colic is well-recognized entity of unknown etiology, characterized by unexplained sudden crying spells during evenings with flexion of thighs and flushing of face. Each spell lasts for a few minutes to a few hours and continues for many days with consistent regularity and timing before spontaneous disappearance by 2–3 months (Ch.4.1).

12.8 HIGH-RISK NEWBORN

High-risk newborn is defined as "*a newborn with abnormal maternal, antenatal, peripartum or neonatal indicators, suggestive of higher than the normal risk of morbidity and mortality, who should be under close observation by experienced pediatrician and nurses*".

About 10% of all live births fall in this category, which need to be either delivered in a hospital set-up or immediately transferred to intensive care unit.

Indicators: A high-risk newborn may be identified at birth due to: (a) high-risk pregnancy, (b) high-risk delivery or (c) postnatal characteristics, e.g. abnormal gestation, birth weight, congenital malformation, etc. Other newborns are added to this category, when exhibit any *warning signals* in later neonatal period **(Table 12.14)**.

Care of a high-risk newborn depends on the time when the risk is identified and the expected severity of complications. While specific measures are discussed in later chapters, important management strategies include:

- Early identification of high-risk pregnancy during antenatal visits, referral to a suitable neonatal care center and if possible, intrauterine interventions.
- Comprehensive review of case-records before delivery for resuscitation alert and adequate resuscitation facility/expertise at the time of delivery.
- Assessment of delivered newborn for high-risk status or warning signals and timely transfer to appropriate neonatal care center.

TABLE 12.14: High-risk neonate

- **History of high-risk pregnancy (Table 12.2)**
- **History of high-risk delivery (Table 12.7)**
- **High-risk neonatal factors at birth**
  - Prematurity/postmaturity
  - Small for date/large for date
  - Major congenital malformations
- **Presence of warning (Danger) signals**
  - Sluggish activity or cry
  - Inability/refusal to accept feeds
  - Hypo/hyperthermia
  - Respiratory distress
  - Vacant stare, seizures or jitteriness
  - Not passed urine within 24 hours
  - Not passed meconium within 48 hours
  - Appearance of icterus <24 hours
  - Persistent vomiting, choking or frothing
  - Abnormal bleeding

Levels of neonatal care: According to the facilities and expertise, neonatal care centers are classified into three levels (*tiers*):

Level I care is the minimal care level, that should be available to all normal term newborns with birth weight *>2000 gm.* It may be provided at home or peripheral health center with minimum facilities and includes:

- *Basic antenatal care*, including identification of high-risk pregnancies.
- *Delivery*, by traditional birth attendant, using safe delivery practices. *Basic delivery kit*, supplied to these workers under MCH programs include—a sterile blade, clean thread, cotton gauze and an antiseptic soap.
- *Essential neonatal care* including—(a) proper temperature maintenance, (b) promotion of breastfeeding, and (c) maintenance of adequate asepsis and infection control measures.
- *Timely referral* to higher center.

In National Heath Mission (India Newborn action plan), each birthing facility must have as *Newborn care corner (NBCC)* for level I care, to identify and refer at risk or sick babies to higher centers.

Level II care is required in 15–20% newborns with: (a) birth weight 1500–2000 gm, (b) gestation 32–36 weeks, (c) referrals from level I care, and (d) neonatal problems, e.g. mild/moderate birth asphyxia, Rh incompatibility, common malformations, respiratory distress and maternal diabetes.

It requires pediatrician's supervision and continuous nursing care but not the extensive investigations and intensive care. It should be available at all district hospitals, major and teaching hospitals and nursing homes, dealing with more than 1000–1500 deliveries annually. Important components of level II care include:

- Delivery attended by a trained pediatrician, with adequate resuscitation facility,
- Neonatal care by trained nursing staff, under a pediatrician's supervision
- Facility to provide warmer care, phototherapy, IV infusions/drugs, etc.

In National Heath Mission (India Newborn action plan), each first referral units, e.g. community health centers, must have *Newborn stabilization units (NBSU)* at block level and *Special newborn care unit (SNCU)* at district levels.

Level III care is needed in ~ 5% newborns, mainly with—(a) birth weight < 1500 gm, (b) gestation <32 weeks, (c) referrals from level II care, and (d) serious neonatal complications, e.g. severe birth asphyxia, major congenital malformations, severe respiratory distress, etc. NICUs should be available at select regional centers or in hospitals with >3000 deliveries per year, with following facilities:

- Round the clock availability of pediatrician/neonatologist and trained nursing staff.
- Round the clock availability of allied facilities, e.g. pediatric surgeons, blood bank and pathological/radiological investigations.
- Advance diagnostic, monitoring and therapeutic facilities, e.g. blood gas monitoring, drug delivery systems (infusion pumps) and procedures, e.g. exchange transfusion, peritoneal dialysis and total parenteral nutrition.

In National Heath Mission (India Newborn action plan), each district hospital or major centers must have *Special Newborn Care units (SNCUs) or Neonatal intensive care units (NICUs),* in addition to NBCC and NBSU.

Humanized neonatal care: In the current neonatal intensive care environment, a preterm or sick baby is subjected to many non-intentional noxious stimuli, which are believed to have adverse effects on his/her physiological stability and maturity. Humanized intensive care is not an alternative to high-tech care but is complimentary, to provide holistic care with a human touch, in a baby-friendly womb-like ambience in NICU.

Important components of this concept include:

- Minimum noise levels in NICU (leads to startle, apnea, HR/BP fluctuations)
- Minimum light exposure without compromising visual monitoring (excessive light exposure alters circadian rhythm and REM sleep).
- Prone/side-nursing positioning
- Minimum handling
- Breast or expressed breastfeeding
- Allowing the mothers in nursery.
- Gentle tactile stimulation/cuddling (*touch therapy*)
- Stimulation of special senses, e.g. auditory (soft music), visual (bright colored objects or maternal faces), olfactory (placement of cotton swabs soaked with mother milk in incubators).

Mother-neonatal intensive care unit (M-NICU) is novel concept in humanized neonatal care, where mother is permitted to stay next to the baby in NICU and is encouraged to participate in his/her care after some training, including Kangaroo mother care.

12.9 TRANSPORT OF A SICK NEWBORN

Transport of a sick newborn may be necessary for transfer to higher center (inter-facility transfer) or within the same center for investigation purposes (intra-facility transfer). Intra-facility transfer must be avoided, as far as possible. During the transfer, baby has to cope not only with primary illness but also with adverse environmental factors, e.g. cold, jerks, noise, etc., which can further compromise the survival.

It is always preferable to anticipate complications and transfer the high-risk baby *in utero*, though it is not

always possible due to logistic or medical reasons. In such cases, following principles should be observed to ensure safety of the baby.

- **Pre-transport preparations:**
  - Evaluate the genuineness of indication.
  - Communicate with parents about the reason for transport and get their consent.
  - Ensure availability of the vacancy at referral center and willingness to accept the transfer.
  - Arrange a well-equipped mode of transport, e.g. ambulance, well in advance.
  - Arrange a trained health-care provider to accompany the baby, who is well-versed with resuscitation procedures. Mother may also be encouraged to travel with baby.
  - Provide a detailed referral note, stating the reason for referral, pre-transport condition and treatment given along with necessary investigation reports.
  - Ensure availability and working condition of resuscitation equipments, including oxygen cylinder, etc. during trasnport
- **Stabilization of the baby:**
  - Resuscitate if required,
  - Ensure clear airway and breathing support during transport,
  - Correct hypothermia and ensure proper temperature support,
  - Secure good vascular access,
  - Give medications as required, till the baby reaches its destination.
- **During transport:**
  - Inform the referral center about expected time of arrival
  - Use the shortest and fastest route for transfer
  - Ensure proper ambient temperature in the vehicle
  - Do not open the windows or doors of the vehicle to avoid wind drafts
  - Continuously monitor the vital signs.
- **Hand-over the baby:**
  - Re-evaluate the baby before hand-over to referral team
  - Hand-over the baby, referral note and all left-over medicines, etc. to proper person
  - Inform them about any emergencies/changes during the travel time.
  - Counsel anxious parents and introduce them to the new team
  - Take the acknowledgement of transfer from new team including their assessment on arrival for records.

12.10 BIRTH INJURIES

Birth injuries are defined as *avoidable and unavoidable mechanical or hypoxic-ischemic injury, incurred by an infant during labor and delivery*. This definition excludes all injuries before the onset of labor during procedures, e.g. amniocentesis, *or* after delivery, i.e. during resuscitation.

TABLE 12.15: Risk factors for birth asphyxia/injuries

- **Maternal factors**
  - Cephalopelvic disproportion
  - Maternal sedation
- **Obstetric factors**
  - Prolonged or precipitate labor
  - Abnormal presentations
  - Uterine dystocia
  - Unattended/unskilled delivery
  - Meconium aspiration
- **Fetal factors**
  - Macrosomia
  - Prematurity/postmaturity
  - Congenital malformations

As the definition suggests, birth injuries may be classified into two categories—(a) birth asphyxia or hypoxic-ischemic injury, and (b) mechanical injuries.

Some important risk factors for hypoxic or mechanical birth injuries are given in **Table 12.15**. Apart from immediate problems, birth injuries are one of the most important causes of physical/mental handicap in later life.

12.10.1 BIRTH ASPHYXIA

Birth asphyxia (perinatal asphyxia) denotes *clinicopathological consequences of perinatal hypoxic-ischemic injury, due to late fetal, obstetrical or immediate postnatal causes*.

Diagnostic criteria for birth asphyxia depend on the purpose of diagnosis. While simplistic definition by National neonatology forum (NNF), i.e. *gasping, inadequate or no breathing at 1 minute* is appropriate to assess the immediate needs of resuscitation, many of these newborns recover completely after adequate resuscitation, without residual neurological deficits.

For the purpose of long-term outcome, American Academy of Pediatrics suggests following essential diagnostic criteria for perinatal asphyxia:

- Persistence of Apgar score 3 at 5 minutes,
- Fetal acidosis, i.e. cord blood pH <7.0,
- Signs of hypoxic-ischemic encephalopathy, e.g. seizures, coma, hypotonia, etc.
- Signs of multi-organ dysfunction.

Pathophysiology of birth asphyxia is multifactorial and complex—the common denominator *being lack of oxygen supply to various fetal tissues* during intrauterine, peripartum or immediate postnatal period. Intrauterine hypoxia is perhaps more important than the intrapartum asphyxia in causation of hypoxic-ischemic injury.

Immediate response to hypoxia in fetus or newborns is similar to that seen in older children, i.e. bradycardia and hypertension (*diving-seal reflex*), followed by a series of compensatory or protective events *as follows*:

a. *Re-distribution of blood flow* from less vital to vital organs, e.g. brain, heart and adrenals. Intra-cerebrally

TABLE 12.16: Multi-organ dysfunction in birth asphyxia

• CNS	HIE, IVH/PVH, cerebral edema
• CVS	Myocardial ischemia, hypotension
• Lungs	Pulmonary hypertension, hemorrhage, RDS
• Renal	Acute tubular/cortical necrosis
• GIT	Hemorrhage, stress ulcerations
• Blood	Disseminated intravascular coagulation (DIC)
• Metabolic	SIADH, hypoglycemia, hypocalcaemia
• Others	Adrenal hemorrhage

HIE: Hypoxic-ischemic encephalopathy, **IVH/PVH:** Intra/peri ventricular hemorrhage, **SIADH:** Syndrome of inappropriate ADH secretion, **RDS:** Respiratory distress syndrome

too, blood flow is re-distributed towards brainstem from cerebral cortex.

b. *Compensatory autonomic response* which is primarily sympathetic in term babies (↑HR, BP) and parasympathetic (↓ HR, BP) in preterms.

c. *Compensatory metabolic responses*, i.e. switch-over from aerobic to anaerobic metabolism.

However, prolonged hypoxia and consequent acidosis leads to many adverse pathophysiological changes, responsible for multi-organ dysfunction **(Table 12.16)**.

Diagnosis of birth asphyxia may be evident even before the delivery with signs of fetal hypoxia, e.g. bradycardia, altered fetal movements, meconium stained liquor, etc.

Postnatally, these cases are either apneic or have inadequate spontaneous breathing with persistently low Apgar score (3), cyanosis or pallor (*Asphyxia livida or Asphyxia pallida*), bradycardia and poor peripheral perfusion or hypotension.

Neurological damage in asphyxiated newborns varies according to the gestation age, generally presenting as *Hypoxic-ischemic encephalopathy (HIE)* in term neonates, and *Intraventricular-periventricular hemorrhage (IVH/PVH)* in preterms, as follows:

Hypoxic-ischemic encephalopathy (HIE): The term HIE refers to various "neuro-pathological changes and their clinical consequences in asphyxiated newborns, especially in *term or near-term babies".*

Pathogenesis of HIE is complex but main contributory factors include:

- *Increased neuronal cell permeability* due to hypoxia and acidosis.
- *Immature autoregulation of cerebral blood flow*, i.e. parallel changes with systemic blood pressure, leading to cortical hemorrhage in hypertensive states or ischemia/infarcts in hypotensive states.
- *Secondary necrosis* in hemorrhagic/ischemic areas, leading to neuronal loss and gliosis.
- Late development of focal/multicystic leukomalacia, porenchephalic cysts, cortical atrophy and *status marmoratus* (gliosis with hypermyelination) amongst survivors, with long-term sequelae.

TABLE 12.17: Severity grading for HIE

	Stage		
	I	***II***	***III***
Sensorium	Alert	Lethargic	Stupor/coma
Tone	N/↑	Hypotonia	Flaccid
Reflexes	↑	↑	Absent
Seizures	Absent	++	Decerebration
Moro's reflex	Strong	Weak	Absent
Pupils	Dilated	Constricted	Non-reacting
EEG	Normal	Abnormal	Burst suppression
Duration	<24 hours	2–14 days	>14 days
Outcome	Good	Variable	Death/sequelae

*or Isoelectric

Neuropathological changes in HIE also vary with gestational age, usually limited to watershed area (border-zones between areas supplied by different cerebral vessels) in fullterms, e.g. deeper cortical tissues in parasagittal region. Preterms have more diffuse pathology, also involving sub-cortical region specially in periventricular area and often associated with IVH.

Clinical manifestations of HIE may be apparent at birth or develop gradually, depending on the timing and severity of hypoxic insult. Common indicators of HIE include:

- Unresponsiveness to stimulation with sluggish reflexes,
- Hypotonia that may persist or change to hypertonia in a few hours, and
- Seizures, which may be multifocal, recurrent and/or refractory.

Severity of HIE may be graded according to *Sarnat and Sarnat classification* **(Table 12.17)** for prediction of outcome.

Diagnosis of HIE is mainly clinical in a full-term newborn with history of birth asphyxia, supported by:

- *Neuroimaging studies*, e.g. USG, CT/MRI. MRI is the preferred investigation and early neuroimaging findings include—(a) cortical infarcts, (b) cerebral edema, (c) intraventricular hemorrhage; while later studies may reveal, and (d) cortical atrophy and (e) focal/multicystic leukomalacia and/or porencephalic cysts.
- *EEG* has a prognostic significance with presence of isoelectric or burst-suppression patterns suggestive of moderate to severe HIE.
- *Lumbar puncture* is used to exclude meningitis and subarachnoid/intraventricular hemorrhage. Brain-specific creatinine kinase level (CK-BB) in CSF is a useful indicator of the severity of neuronal injury.

Management of HIE is supportive and involves:

- *Cardiopulmonary support* to ensure adequate ventilation (O_2, assisted ventilation) and perfusion (vasopressors,

volume expanders). A systemic mean arterial blood pressure of 45–50 mm Hg in term babies (35–40 mm in babies weighing 1–2 kg and 30–35 mm in those < 1 kg) is advisable.

- *Fluid restriction* to reduce cerebral edema and manage SIADH, preferably with 60 ml/kg/day of DW 10%.
- *Anticonvulsants* to prevent seizures and further neurological damage. Phenobarbitone is the preferred anticonvulsant in HIE and high-dose prophylactic phenobarbital may decrease neurodevelopmental impairment in these cases. Second-line anticonvulsants, e.g. Phenytoin or Levetiracetam should be added in refractory cases and stopped once the baby is seizure-free for > 72 hours. Phenobarbitone must be continued till discharge or even later, till the baby is neurologically normal. EEG may be used to decide the need to continue Phenobarbitone is doubtful cases.
- *Monitoring and control of other complications*, e.g. hypothermia, hypoglycemia, hypocalcemia, dyselectrolytemia and coagulation abnormalities.
- *Therapeutic hypothermia* to maintain the core temperature at 33.5°C during first 48–72 hours of birth, has been reported to reduce the mortality or neurodevelopmental morbidity in HIE, due to decrease in release of neurotoxic mediators, e.g. glutamate, free radicals, nitric oxide, lactate, etc. Complications include thrombocytopenia, bradycardia, subcutaneous fat necrosis and overcooling with cold-injury syndrome.

While emerging as a preferred intervention for HIE in developed countries, efficacy and safety of induced hypothermia has not been established in Indian settings and NNF recommends that it should be used only in a tertiary care setting under supervision by a trained team and only in selected group of newborns.

Efficacy of newer therapeutic modalities, e.g. free radical scavengers/removers, e.g. allopurinol or vitamin E; cerebral flow stabilizing agents, e.g. phenobarbital or calcium channel blockers, etc. is still in experimental stage.

Outcome depends on the severity of HIE, gestational age and co-existing complications. While most cases with Grade I HIE recover fully, grade II and III disease has progressively higher mortality (~ 5% and ~75%) and late neurological sequelae (~20% and ~100%).

Important neurological *sequelae* are—(a) cognitive deficits or mental retardation, (b) motor deficits, e.g. *cerebral palsy*, (c) epilepsy, (d) visual or hearing loss, and (e) hydrocephalus.

Apart from clinical staging, other *poor prognostic indicators* include—(a) HIE in a preterm baby, (b) low Apgar score or absence of spontaneous respiration at 20 minutes, (c) persistence of abnormal neurological signs at 2 weeks of age, and (d) abnormal EEG or CT scan.

12

Intra/periventricular hemorrhage (IVH/PVH) is primarily a neurological complication of birth asphyxia in *preterms*, with incidence being inversely related to gestational age and birth weight, i.e. 60–70% in babies <1000 gm, 10–20% between 1000–1500 gm and rare in newborns >1500 gm or 34 weeks.

Pathogenesis: IVH is rarely present at birth and usually develops during first 3 days of life. Subependymal germinal matrix, i.e. lining of the ventricular walls, is susceptible for rupture and bleeding *in preterms* due to—(a) higher vascularity, (b) poor tissue support to vasculature, and (c) immature autoregulation of cerebral blood flow—a protective mechanism that prevents sudden changes in cerebral perfusion pressure on systemic pressure changes in sick babies. Bleeding in germinal matrix may extend into ventricles (IVH) to cause obstructive hydrocephalus, and/or outwards into cerebral parenchyma (PVH). PVH or periventricular infarcts due to ischemic/reperfusion injury may later progress to develop as *periventricular leukomalacia* (PVL).

Clinical manifestations depend on the severity of IVH/PVH and ~25% cases are asymptomatic. Others may present on 2–3rd day, with:

- Early signs, e.g. sluggish/absent Moro reflex, sluggish activity and hypotonia. Progressive pallor or sudden drop in hematocrit is an early indicator of IVH/PVH.
- Recurrent apneic spells, acidosis and shock.
- Feeble or high-pitched shrill cry, seizures, bulging anterior fontanel and progressive coma in severe cases. While mild cases recover in a few days, others may progressively deteriorate or have a waxing and waning course, due to re-bleeds.

Diagnosis may be confirmed and classified **(Table 12.18)** on USG, which is routinely indicated in all high-risk preterms <1500 gm on 3rd day and 2nd week of life. USG also helps to assess the course of disease, i.e. progression, arrest or regression of hydrocephalus and development of PVL or porencephalic cysts.

CT/MRI is indicated only in—(a) suspected cases with intra-parenchymal bleed/infarcts, and (b) term infants with more chances of subdural/subarachnoid hemorrhage.

Management includes: (a) supportive measures, e.g. control of seizures, shock and anemia, (b) reduction of intraventricular pressure by repeated lumbar punctures or ventriculostomy, and (c) evacuation of subdural hematoma, if present.

TABLE 12.18: USG criteria for severity of IVH (Volpe's Classification)

Grade	*USG finding*
I	Bleeding limited to periventricular area (germinal matrix)
II	IVH filling 10–50% of ventricle
III	IVH filling >50% of ventricle or ventricular dilatation
IV*	IVH with periventricular hemorrhagic infarct

*not a part of Volpe classification

Prognosis depends on the severity and location of bleed. Apart from early death, *complications* include-(a) post-hemorrhagic hydrocephalus, and (b) residual sequelae due to PVL/porencephalic cysts, e.g. motor deficit, e.g. *cerebral palsy*, mental retardation, seizures, etc. Posthemorrhagic hydrocephalus, though develops in 10–15% babies with IVH, often gets arrested after a few days/weeks and most cases do not require shunting.

12.10.2 MECHANICAL BIRTH INJURIES

Incidence of mechanical birth injuries in India is estimated to be ~ 2–7/1000 live births, accounting for ~ 2–3% of neonatal deaths **(Table 12.19)**. Some important mechanical birth injuries are as follows:

Caput succedaneum is a diffuse, edematous and often ecchymotic *swelling of the soft tissue* covering the presenting part, e.g. scalp or face, which may extend across midline and sutures. It disappears spontaneously within a few days of life and no treatment is necessary.

Cephalohematoma is a *sub-periosteal hemorrhage*, essentially limited by sutural lines and presenting as unilateral (or rarely bilateral) soft and fluctuant scalp swelling. Swelling usually appears after a few hours of birth due to slower bleed in confined space, enlarges for few days and reabsorbs spontaneously in 3–6 weeks.

Incidence: It is seen in 1–2% of deliveries, more common in obstructed labor, forcep deliveries or vacuum extractions.

TABLE 12.19: Common mechanical birth injuries

- **Cranial injuries**
  Caput succedaneum
  Cephalohematoma
  Skull fractures (linear/depressed)
  Intracranial hemorrhage
- **Cervical injuries**
  Cervical spinal injuries
  Sternocleidomastoid tumor
- **Peripheral nerve injuries**
  Brachial plexus injury
  Erb-Duchenne paralysis
  Klumpke's paralysis
  Phrenic nerve injury
  Facial palsy
- **Limb injuries**
  Fractures (clavicle, humerus, femur)
  Dislocation of upper femoral epiphysis
- **Visceral injuries**
  Liver (subcapsular hematoma)
  Splenic rupture/hematoma
  Adrenal hemorrhage
- **Superficial Soft-tissue injuries**
  Skin abrasions, laceration, ecchymosis
  Genitals: Scrotal hematoma, hematocele
  Eye: Subconjunctival hemorrhage
  Retinal/vitreous hemorrhage

Diagnosis is obvious clinically, but may be confirmed on X-ray skull that reveals subperiosteal bleed and rarely, an underlying linear skull fracture **(Fig. 12.7)**.

D/D includes *caput succedaneum* **(Table 12.20)** and *cranial meningocele* (pulsatile, increases on crying, underlying bony defect on X-ray).

Complications are uncommon but include—(a) anemia, (b) hyperbilirubinemia, (c) infection, if erroneously aspirated.

Management: *Aspiration or surgical drainage is contraindicated*, to avoid the risk of infection. No intervention is needed in small hematomas, though babies with large swellings should be observed and treated for complications, e.g. severe anemia or hyperbilirubinemia.

Brachial plexus injuries are common in large babies, specially when excessive lateral traction is applied to deliver shoulder in vertex deliveries or extended arm in breech deliveries.

Clinically, these injuries may present as upper-plexus (*Erb-Duchenne paralysis*) or lower-plexus (*Klumpke's paralysis*) injury or both.

- **Erb-Duchenne paralysis,** i.e. injury to upper roots of brachial plexus (C_{5-6}) is characterized by:
  - *Abnormal limb position with* adducted and internally rotated arm with pronated forearm (*Policeman stick appearance)*, due to weakness of abductors, external rotators and supinators **(Fig. 12.8A)**.
  - *Asymmetrical Moro's reflex* (d/d fracture, osteomyelitis/ arthritis, dislocation)

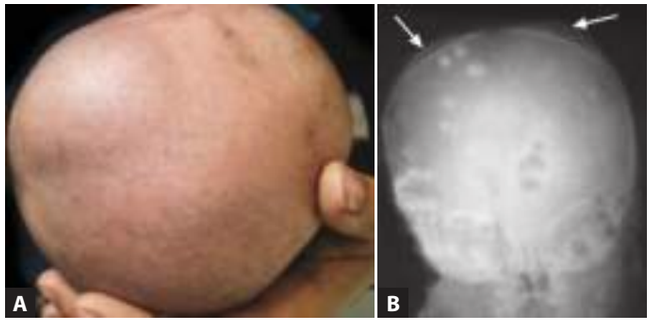

Fig. 12.7: Cephalhematoma: (A) Clinical appearance; (B) X-ray skull.

TABLE 12.20: Caput succedaneum *vs* cephalohematoma

	Caput succedaneum	*Cephalohematoma*
Location	Soft tissue	Sub-periosteal
Extent	Diffuse	Limited by sutures*
Onset	At birth	Few hours after birth
Color	Ecchymotic	Skin colored
Disappears	< 7 days	> 3–6 weeks
X-ray skull	Normal	± Linear fractures
Complications	Very rare	Anemia, jaundice

*unless underlying fracture is present

Figs. 12.8A and B: **Brachial plexus injury: (A) Erb's palsy; (B) Klumpke's palsy.**

  - Normal power in forearm (except pronation) and hands with *preserved grasp reflex*
  - Associated ipsilateral diaphragmatic paralysis due to phrenic nerve palsy ($C_{3–5}$) in some cases.
- **Klumpke's paralysis,** due to lower-plexus injury ($C_{7–8}$ T_1) is relatively rare, presenting with:
  - Weakness of wrist and hand movements with abnormal position (*Accoucher's grip*) **(Fig. 12.8B)**
  - *Absent grasp reflex*.
  - Associated *Horner syndrome* (ptosis and miosis on affected side) due to injured T_1 sympathetic fibres.

Management of brachial plexus injuries involves-(a) intermittent immobilization with splints in neutral position to prevent contractures during first 1–2 weeks, and (b) gentle massage with increasing range of motion exercises after 7–10 days. Recovery is unlikely beyond 6 months, when neuroplasty or nerve grafting must be considered.

Prognosis depends on whether the nerve fibers are merely injured (recovery in 2–3 months) or truly lacerated (permanent functional loss). Upper plexus injury has better prognosis than lower plexus injury. A intact gasp reflex suggests > 80% chances of recovery.

Skull fractures are common during breech or instrumental deliveries and may be linear or depressed. Some fractures may be associated with intracranial bleeding. No treatment is necessary for linear fractures without intracranial hemorrhage, while depressed fractures need neurosurgical assessment.

Clavicular fractures are most common bony injuries in macrosomic babies, delivered with shoulder or breech presentation. These babies present with restricted movement of affected arm (pseudoparalysis) with asymmetric Moro's reflex. No intervention is required except splinting and healing usually occurs in 2–4 weeks.

Intracranial hemorrhage in newborns may be broadly divided into 2 types:

a. **Subdural, epidural or subarachnoid hemorrhage**, are more common in term newborns, usually caused by (a) mechanical head injury in obstructed labor, precipitate deliveries or forceps application, (b) bleeding disorders, e.g. DIC, immune thrombocytopenia, etc. and (c) intracranial vascular malformations.

   These cases usually present with recurrent seizures, progressive head enlargement with bulging fontanels and anemia in late neonatal period. Diagnosis may be confirmed on USG or CT scan. Surgical evacuation of hematoma is indicated only in symptomatic cases.

b. **Intraventricular/periventricular hemorrhage**, is mostly seen in *preterms with birth asphyxia*, discussed earlier in Ch 12.10.1.

Sternocleidomastoid tumor (Torticollis) is actually a *sub-facial or intramuscular hematoma in sternocleidomastoid muscle* due to over-stretching and laceration of muscle fibers during delivery of impacted head in breech/shoulder deliveries. Some cases are also thought to be hereditary or *in utero* muscle infection.

Clinically, these cases present on 10^{th}–14^{th} day with:

- A *well-circumscribed, non-tender small mass* (1–2 cm) over mid-sternocleidomastoid muscle, which gradually enlarges for 2–4 weeks, before regressing completely by 6–8 months **(Fig. 12.9)**.
- *Torticollis* with head tilted on same side and chin elevated and rotated on opposite side. Torticollis usually disappears with mass, but may persist for many years due to residual scarring and leads to secondary deformities, e.g. craniofacial asymmetry, scoliosis and gaze abnormalities.

Fig. 12.9: **Sternocleidomastoid tumor.**

Treatment includes frequent gentle over-stretching of the neck on opposite side (taught to mother) in early months and bed-time splinting in corrected position. Surgical lengthening by division of sternal portion of muscle is indicated only in persistent torticollis beyond 6–8 months.

12.11 GESTATION AND BIRTH WEIGHT DISORDERS

Low birth weight (LBW) refers to the babies weighing with < 2500 gm at birth, while those <1500 gm and <1000 gm at birth are termed very low birth weight (VLBW) and extremely low birth weight (ELBW).

Based on the intrauterine growth and position on the intrauterine growth charts **(Fig. 12.10)**, all babies at birth may be classified, irrespective of the gestation, as:

- *Appropriate for date (AFD)*, i.e. birth weight within the normal limits (10^{th}-90^{th} percentile) for gestation
- *Small for dates (SFD)*, i.e. birth weight less than normal (<10^{th} percentile) for gestation
- *Large for date (LFD)*, i.e. birth weight more than normal (>90^{th} percentile) for the gestation.

However in practice, LBW, irrespective of the gestation, has been identified as the most important markers of adverse perinatal and neonatal outcome in India, with reported rate of ~18% as per recent NFHS-5,2021. Since gestational age is main determinant of birth weight, the term LBW encompass both – preterm LBW and term LBW, discussed in following sections.

12.11.1 PREMATURITY (PRETERM-LBW)

Prematurity is defined as a *live birth before the completion of 37th week of gestation* (up to 36 weeks and 6 days). Live births before 28th week are generally referred as *extreme prematurity*.

Causes: Preterm labor may be *spontaneous* due to various maternal and fetal factors or *induced* on medical grounds **(Table 12.21)**. Many spontaneous preterm labors are preventable by timely medical care.

TABLE 12.21: Causes of prematurity

- **Maternal ill health**
  - Chronic systemic diseases
  - Severe anemia
  - Infections of genitourinary tract
- **Uterine abnormality**
  - Incompetent cervix
  - Bi-cornuate uterus
- **Obstetric complications**
  - Twin pregnancy
  - Antepartum hemorrhage, placenta previa
  - Poly-/oligohydramnios
  - Premature rupture of membranes
- **Fetal factors**
  - Fetal hypoxia and distress
  - Hydrops fetalis
  - Serious congenital malformations
- **Idiopathic**

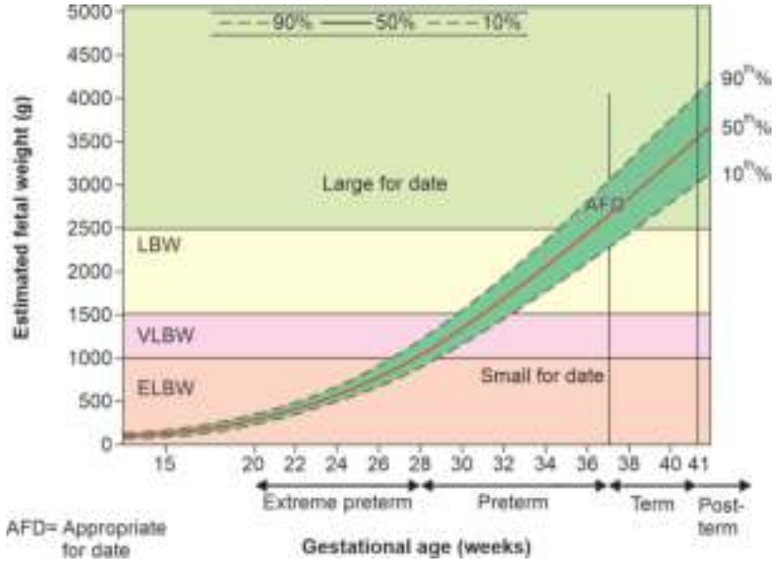

Fig. 12.10: **Fetal Growth Chart: Estimated fetal weight percentiles at different gestational ages (WHO).**

TABLE 12.22: Common clinical and neurological features at different gestational ages

Clinical features	*<28 weeks*	*28–32 weeks*	*32–36 weeks*	*Full-terms*
Physical				
a. Breast nodule	Nil	<5 mm	5–10 mm	>10 mm
b. Ear cartilage	Crumpled/no recoil	Soft/some recoil	Firm/good recoil	Firm/instant recoil
c. Plantar creases	Nil	Faint, anterior sole	Deep, transverse only	criss-cross, all sole
d. Skin				
– Appearance	Thin, gelatinous	Hyperemic	Thick, dry	Thick, peeling ±
– Vernix	All over	All over	Reduced	Flexural only
– Lanugo	None	+++	++	Scanty
e. Male genitals				
– Scrotum	Shiny, red	Rugosities +	Darker, rugosities ++	Dark, rugosities +++
– Testis	B/L undescended	At least 1 in Ing. canal	At least 1 in scrotum	B/L descended*
f. Female genitals				
– Labia majora	Covers <1/3rd minora	Covers >1/3rd minora	Covers >2/3rd minora	Covers whole minora
Neurological				
a. Posture	Frog-like	Only arms flexed	Legs partly flexed	Well flexed
b. Arm recoil	Nil	Incomplete	Complete	Complete and brisk
c. Popliteal angle	180°	180–150°	150–120°	<120°
d. Scarf sign	Complete	Beyond midline	Only till midline	not reaching midline
e. Heel to ear	Reaches up to ear	Reaches up to neck	Reaches up to waist	Doesn't touch waist
f. Square window	90°	60°	30°–45°	None

Clinical attributes of prematurity vary with gestational age **(Table 12.22)**, though some important indicators are as follows:

- **Physical features** in preterms include:
  - ***Skin*** *is shiny, hyperemic,* covered with plenty of *vernix caseosa (a* whitish greasy substance to prevent hypothermia) and *Lanugo* (soft-fuzzy hair on back and limbs). *Pedal edema* is common in extreme preterms.
  - ***Sole creases*** are absent or poorly developed, seen in only some parts of soles.
  - ***Ear cartilage*** is poorly formed and shows slower recoil, when crumpled. Eyes are tightly closed in extreme preterms.
  - ***Breast nodule****,* felt as an induration by rolling-over between fingers, is poorly developed.
  - ***Genitals:*** In *male preterms,* scrotum is shiny and less pigmented with poorly developed scrotal rugosities and undescended or partially descended testis. *In female preterms*, labia majora is widely separated to covers only a part of labia minora. In fullterms, labia minora is almost invisible.
- **Neurological features** in preterms include:
  - ***Posture:*** Preterms have a prominent head lag and stay in a *pithed-frog posture* with extended limbs due to marked hypotonia, as against the fully-flexed fetal posture in fullterm.
  - ***Hypotonia*** is a prominent feature in preterms, as evident by their posture as well as when tested for active tone (poor arm recoil) and passive tone (popliteal angle, Scarf sign or heel to ear maneuver).
    - *Popliteal angle* is measured behind the knee on complete flexion at hip and maximum extension at knee.
    - *Scarf sign* is tested by adducting one upper arm towards opposite shoulder and checking the position of elbow on full adduction.
    - *Heel to ear* maneuver involves an attempt to touch the ear with baby's heel and *see* its maximum possible reach.
  - *Immature joint mobility,* as indicated by *Square window sign*. *Square window* is the angle formed at wrist after complete flexion to touch the forearm with fingers.
  - *Immature neonatal reflexes,* which appear gradually with advancing gestation **(Table 12.12)**.

Assessment of gestation age depends on—(a) date of last menstrual period, (b) antenatal records, e.g. fundal height and USG, and (c) physical and neurological features of newborn. Birth weight is not a reliable criteria for diagnosis of prematurity, as it does not exclude SFD/IUGR babies.

Various scoring systems, based on physical and neurological features, e.g. *Dubowitz criteria* or *Ballard scoring* **(Table 12.23)** are available for precise postnatal assessment of gestation age.

TABLE 12.23A: Modified Ballard scoring system for assessment of gestational age

A. PHYSICAL CRITERIA

Score →	–1	0	1	2	3	4	5
Skin	Sticky, friable transparent	Gelatinous, red, translucent	Smooth, pink, visible veins	Peeling, rash, few veins	Cracking, pale, rare veins	Parchment deep cracks, no vessels	Leathery, cracked, wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	—
Plantar surface	HTL <50 mm (<40 mm; –2)	HTL >50 mm No creases	Faint red marks	Ant. transverse crease	Creases in ant 1/3rd	Creases on entire sole	—
Breast	Imperceptible	Barely perceptible	Flat areola, no bud	Stripped areola, 1–2 mm bud	Raised areola, 3–4 mm bud	Full areola 5–10 mm bud	—
Eye/ear	Eye lids fused Loosely: –1 Tightly: –2	Eye lids open, pinna flat, stays folded	Slight curved pinna, soft, slow recoil	Well-curved pinna, soft but ready coil	Firm pinna instant recoil	Thick cartilage, stiff ear	—
Genitals *(male)*	Scrotum flat and smooth	Scrotum empty, faint rugae	Testes in upper canal rare rugae	Testes descending, few rugae	Testes down, Good rugae	Testes pendulous, deep rugae	—
Genitals *(female)*	Clitoris prominent, labia flat	Prominent clitoris, small L. minora	Prominent clitoris, enlarging minora	Majora and minora equally prominent	Majora large, minora small	Major covers clitoris and minora	—

B. NEUROLOGICAL CRITERIA

Posture	—						—
Square window (wrist)	90°	90°	60°	45°	30°	0°	—
Arm recoil	—	180°	140–180°	110–140°	90–110°	<90°	—
Popliteal angle	180°	160°	140°	120°	100°	90°	<90°
Scart sign							—
Heal to ear							—

HTL: Heel-Toe length
Methodology: Calculate the total score by adding individual scores on each physical (A) and neurological (B) parameters as per **Table 12.26 A** and then assess gestational age (in weeks) by using following **Table 12.23**.

TABLE 12.23B: Gestational maturity as per new Ballard score

Score	–10	–5	0	5	10	15	20	25	30	35	40	45	50
G. Age	20	22	24	26	28	30	32	34	36	38	40	42	44

Physiological handicaps and complications: A premature child has many physiological immaturities or handicaps, rendering him susceptible for many complications in immediate postnatal or later life **(Table 12.24)**. Important handicaps include:

- ***Thermoregulation immaturity*** *(hypothermia)* due to-(a) excessive heat loss via larger surface area and thin skin, and (b) poor heat production due to less brown fat.
- ***Respiratory immaturity*** with *poor*-(a) central control (*apneic spells*), (b) cough-reflex *(aspiration pneumonia)*,

TABLE 12.24: Complications of prematurity and LBW

		Preterms	*FT/SFD*
a.	***Asphyxia (perinatal)***		
	HIE	+	++
	IVH/PVH	+++	+
b.	***Breathing (respiratory)***		
	Hyaline memb. disease	+++	–
	Apneic spells	+++	–
	Meconium aspiration	+	++
	Postnatal aspiration	+++	+/–
	Pulmonary hemorrhage	+	+++
c.	***Cong, malformations***	+	+++
	PDA	+++	–
d.	***Hypothermia***	+++	+
e.	***Metabolic***		
	Hypoglycemia	+	+++
	Hypocalcemia	+++	+
	Kernicterus	+++	+
	Drug toxicities	+++	+
	Late metabolic acidosis	+++	+
f.	***Gastrointestinal***		
	Feeding difficulties	+++	+/–
	Necrotizing enterocolitis	+++	+/–
g.	***Hematological***		
	Anemia	+	++
	Polycythemia	+	++
	Hematologic disease of newborn	+	++
h.	***Infections***		
	Postnatal infections	+++	+
	Intrauterine infections	+	+++
i.	***Outcome***		
	Immediate	Poor	Good
	Long-term growth	Good	Poor
	Other late complications*	++	+

*e.g. Cerebial palsy, mental retardation, retinopathy of prematurity, broncho-pulmonary dysplasia
IVH/PVH: Intraventricular/periventricular hemorrhage,
HIE: Hypoxic-ischemic encephalopathy

(c) ventilatory efforts due to highly compliant chest wall, (d) alveolar expansion due to surfactant deficiency *(hyaline membrane disease)*, (e) alveolar diffusion due to cuboidal epithelium, and (f) perfusion due to trans-PDA shunting.

- ***Circulatory immaturity*** with—(a) delayed closure of ductus arteriosus *(PDA)*, (b) increased vascular permeability, and (c) immature autoregulation of cerebral blood flow *(IVH/PVH)*.
- ***Neurological immaturity*** with—(a) generalized hypotonia/hyporeflexia, (b) immature germinal matrix *(IVH/PVH)*, and (c) impaired blood–brain barrier (*Kernicterus*). However, hypoxia is better tolerated by preterms than term babies.
- ***GIT immaturity*** with *poor*—(a) sucking/swallowing reflexes *(feeding difficulties)*, (b) palato-pharyngeal competence *(recurrent aspiration)*, (c) esophageal sphincter competence *(gastroesophageal reflux)*, (d) gastric volume *(inability to tolerate large feeds)*, (e) digestive enzymes, e.g. lipase, trypsin and lactase, activity *(digestive/absorptive problems)*, and (f) intestinal motility and stasis *(gut infections)*.
- ***Hepatic immaturity*** with *poor*—(a) glucuronyl transferase activity *(hyperbilirubinemia)*, (b) nutrient metabolic activity *(hypoglycemia, hypoproteinemia)*, and (c) drug metabolism *(increased risk of toxicity)*.
- ***Renal immaturity*** with *poor*—(a) glomerular filtration rate *(solute overload, drug toxicity)*, (b) urinary concentration *(dehydration)*, (c) sodium conservation *(hyponatremia)*, and (d) acidification capacity *(late metabolic acidosis)*.
- ***Immunological incompetence*** *(infections)* due to—(a) low IgG levels via maternal transfer, (b) low secretary IGA, phagocytic, complement activity, and (c) impaired cell-mediated immunity.
- ***Hematological immaturities*** with—(a) poor iron stores *(apnea of prematurity)*, (b) deficiency of clotting factors (*bleeding tendencies*).
- ***Nutritional problems*** due to—(a) poor stores *(hypoglycemia, hypocalcemia)*, (b) higher requirements due to higher surface area, tissue turnover, catch-up growth, etc. and (c) poor intake.
- ***Endocrinal immaturity***, e.g. transient hypoparathyroidism *(osteopenia of prematurity)*.

Management of a preterm child begins before birth, including—(a) delaying elective preterm deliveries as long as possible, and (b) referral to well-equipped centers, (c) antenatal steroids, to enhance lung maturity. All preterm deliveries should be attended by trained neonatologist and delayed clamping of cord helps not only to improve iron stores but also to reduce the risk of intraventricular hemorrhage and other morbidities.

While Borderline preterms may be managed as term babies, postnatal management of a preterm baby depends on the gestational age, birth weight and presence of complications. While borderline preterms can be managed as term babies only, most babies weighing < 2000 gm or 34 weeks of gestation need careful consideration for physiological handicaps and potential complications. Important steps include:

a. **Intensive care:** All preterms <1500 gm, <32 weeks or with complications, e.g. infections or congenital malformations, need to be hospitalized in level-III NICU. More mature babies without major problems may be managed in level-II nursery, provided constant monitoring is possible.
b. **Thermoregulation** is the most important determinant for survival during first 24 hours. All preterm babies should be prevented from hypothermia by appropriate

measures, depending on their clinical gestation and clinical status, as follows:

- ***Kangaroo mother care (KMC)*** be initiated immediately after birth in babies in all borderline preterms/LBWs, weighing >1800 gm, provides they are otherwise stable and have no other complications. Proper 2–3 layer clothing including mittens and cap is required during intervening period.
- ***Warmer-care*** is usually required in babies < 1800 gm as well as all sick/unstable LBWs, providing a thermoneutral environment to minimize oxygen and metabolic requirements. Ideal thermoneutral environment varies with gestational age, though ~33–35°C is adequate for most preterms (Ch 12.12). However, most of them, specially those between 1200–1800 gm can also be shifted to KMC after few days of observation and stabilization.
- Temperature control is also necessary during transfer of these babies from delivery room to NICU as well as during investigations and blood sample collections.
- Body temperature must be monitored frequently in all preterms, using an axillary digital thermometer, at least 2–4 hourly on the first day of life.
- Relative humidity must be maintained at 40–60% to prevent drying of airways, thickening of secretions and insensible water loss from the lungs.

c. **Nursing position:** It is preferable to keep these babies in prone position (except immediately after feeding and when sick) to facilitate drainage of oropharyngeal secretions (prevents aspiration), passage of flatus (less abdominal distension) and lesser effort for ventilation. However, many workers advise supine position for ease of clinical supervision.

d. **Nutrition:** Quantity and mode of feeding is an important issue in preterm care due to—(a) higher nutritional requirements, and (b) physiological immaturity in sucking, swallowing, digestion and absorption of feeds.

Nutritional requirements of these babies vary with gestation, weight, nursing environment and associated complications, as follows:

- *Higher fluid requirements* **(Table 12.25)** due to high basal metabolic rate well as excessive losses via kidney (physiological diuresis), GIT (physiological diarrhea), lungs (physiological tachypnea) and skin (large surface area).
- *Higher energy requirements* coupled with inability to accept large volume feeds. Preterm feeds should provide ~130 cal/kg with higher caloric density of ~70 cal/100 ml.
- *Higher protein requirements* due to increased tissue synthesis and immature metabolism of essential amino acids. Consequently, preterm-feeds should provide ~ 2.5–3.0 gm/kg proteins, with whey:casein ratio of 60:40 (as in breast milk), and all essential amino acids in appropriate amounts.
- *Low lactose/starch digestibility*, due to physiological lactase/amylase deficiency. Carbohydrates should not exceed 40–50% of preterm feed, of which at least 50% should be as glucose polymers, e.g. maltodextrin, polycose.
- *Poor fat digestibility/absorption*, due to physiological deficiency of pancreatic lipase and bile salts. Medium chain triglycerides, e.g. coconut oil, which are directly absorbed in portal circulation without micelles formation, are better tolerated in preterms. As essential fatty acid deficiency is common in preterms, 1% of total energy should be provided by linoleic acid.
- *Higher sodium requirements* due to inadequate renal conservation capacity. A preterm feed should provide ~2.5–3.5 mEq/kg/d of sodium (4–8 mEq/kg in VLBWs).
- *Micronutrient supplementation* **(Table 12.26)** is necessary due to poor stores and higher requirements. However, iron supplements should be delayed till ~2–4 weeks, due to potential risk of hemolytic anemia (competitive vitamin E deficiency) and pathogenic diarrhea (iron binds lactoferrin-an inhibitor of *E. coli* growth).

While the precise mode of feeding depends on the acceptability by the baby, following general guidelines may be used for initial feeding decisions in different categories of preterms **(Table 12.27)**:

TABLE 12.25: Fluids requirement (ml/kg) in preterm/LBW

Day of life	*>1500*	*1000–1500*	*<1000*
1st	60	80	100
3rd	90	110	130
5th	120	140	160
7th	150	170	190

Simple thumb rules:
- Fluid needs in 3 weight categories differ by 20 ml.
- Daily requirements in each category increase by 15 ml/day

Add 20 and 40 ml/kg for babies under phototherapy and warmers respectively

TABLE 12.26: Essential nutrient supplements in preterms/LBW

Nutrient	*Daily dose (except vitamin K)*
Vitamin A	1000 IU
Vitamin D	400–800 IU
Vitamin K	0.5–1.0 mg **weekly**
Vitamin C	35 mg
Vitamin E**	5–25 IU
Folic acid	50 mg
Iron***	2–3 mg/kg
Calcium	220 mg
Phosphates	100 mg

*From 2 weeks onwards, except vitamin K (from birth)
**In VLBWs only, till 36 weeks maturity is reached
***After full enteral feeding established, not later than 8 weeks

TABLE 12.27: Modes of feeding in preterms/LBW

	Birth weight (gm)		
	<1200	***1200–1800***	***>1800***
Begin with	IV	Gavage	BF or K&S
Switch to (1–3 days)	Gavage	K&S	BF
Switch to (1–2 weeks)	K&S	BF	BF
At discharge	BF	BF	BF

K&S: Katori and spoon, **BF:** Breastfeeding

Uncomplicated preterms >1800 gm or >32 weeks usually accept breastfeeds and may be fed directly or via bondla/spoon by mothers.

Preterm milk is qualitatively different from term-milk on following counts-Low caloric density (51 vs. 67), high proteins (2.2 vs. 1.1 gm), low lactose (6.0 vs. 7.0 gm), low fat (1.6 vs. 3.5 gm), high sodium (2.6 vs. 0.7 gm) and high Ca/P ratio (20/10 vs. 34/15 mg). (All values/100 ml milk, composition changes with gestation)

Uncomplicated preterms 1200–1800 gm or 28–31 weeks usually require intragastric feeding of expressed breast milk (EBM) for first few days, followed by Bondla/spoon feeding or direct breastfeeds, as soon as acceptable.

It is advisable to begin with 60–80 ml/kg/d of EBM on first day (on lower side in better weight babies and increase by 15 ml/kg every day till ~150 ml/kg/d is reached. Volume of each feed may be calculated by dividing the total daily requirement with number of feeds.

Position of nasogastric tube should be checked before feeding, as also the amount of pre-feed aspirate, which should not exceed >1/3rd of previous feed. Increased pre-feed suggests poor gastric emptying—an early indicator of necrotising enterocolitis, intestinal obstruction or paralytic ileus.

Human milk fortifiers (HMF) are natural or commercial substances, used to improve energy content of EBM without significant volume load. These include *vegetable oils*, e.g. coconut oil or safflower oil (2–3 drops/20 ml feed) and *commercial preparations* (~ 2 cal/gm; 1 gm/10 ml feed). HMF may be used in uncomplicated infants < 1800 gm, after 1st week, to enhance caloric density of EBM.

Complicated or extreme preterms (<1200 gm or < 28 weeks) usually need parenteral nutrition for first 48–72 hours, provided as 60–80 ml/kg of 5% dextrose, higher side in lighter babies. Sodium and potassium must be added in IV fluid after 48 hours. Fluid requirements increase with increasing age as 10–15/ml/kg/day, to a maximum of 150 ml/kg/day after the first week.

While most preterms can be gradually switched on oral feeds, those who need parenteral nutrition for more than one week, must be considered for *total parenteral nutrition* (Ch 27.4.5).

Non-nutritive sucking or trial breastfeeding is advised to all babies on parenteral or nasogastric feeding, to promote lactation and emotional bonding. While the breast milk from own mother is best and gestation-specific for preterms, breast milk from milk-bank or other mothers may be used in cases with maternal death/serious illness. If it is inevitable to use top milk, only a preterm-specific formula milk must be used rather than term-milk formulas or animal-milk, to avoid solute overload and other complications.

e. **Monitoring:** All preterms should be constantly monitored for adequacy of feeding, weight gain and danger signals and IV sites. Non-invasive devices, e.g. apnea alarms and pulse oximeter are frequently used to monitor extreme/complicated preterms.

All babies in hospital must be weighed daily to assess adequacy of nutrition. Preterm babies loose ~15% of birth weight in first week (vs 10% loss in terms) and regain it by 10th-14th day (7–10 days in terms), followed by gaining ~15–20 gm/day, even 20–40 gm/day as they approach near term (catch-up growth). Fenton charts may be used to monitor infant's growth in preterms till they reach 50 weeks of gestational age.

f. **Prevention of nosocomial infections** requires: (a) restricted-entry in nursery, (b) minimal handling, (c) proper hand-washing, (d) ensuring asepsis during diagnostic/therapeutic interventions, and (e) early detection/treatment infections. Prophylactic antibiotics are not necessary in preterms, except those with other risk factors.

g. **Discharge criteria** for preterms include: (a) weight >1800 gm with steady gain, (b) absence of complications or need for parenteral medications, (c) adequate feeding with acceptance of direct breastfeeding or EBM with Bondla/spoon, (d) Complete age-appropriate immunization, (e) Adequate maternal counseling for general baby care, thermo-care, feeding and follow-up.

It is advisable to keep mother and baby in intermediate care or regular postnatal ward for a few days after discharge from NICU, to ensure baby's well-being.

Outcome of prematurity depends on its severity and presence of complications. With therapeutic advances, even babies as young as 22 weeks (>500 gm) are salvageable. However, survival of extreme preterms has also increased the risk of late sequelae in these babies and *Follow-up* of all preterms is necessary at periodic intervals till at least one year, to assess catch-up growth and identify late sequelae.

12.11.2 INTRAUTERINE GROWTH RETARDATION

The term intrauterine growth retardation (IUGR) or small for date (SFD) or Small for gestational age (SGA) is reserved for those LBW babies, who are born *fullterm*

TABLE 12.28: Causes of IUGR (small for date LBW)

- **Maternal factors** *(poor nutrition/chronic hypoxia)*
  - Age <20 or >35 years
  - *Parity:* Primipara or grand-multipara
  - Undernutrition or poor weight gain in pregnancy
  - Anemia
  - Chronic cardiac or pulmonary disease
  - *Abuse:* Drugs, alcohol, smoking
- **Placental factors** *(↓ uteroplacental blood flow)*
  - Structural abnormalities
  - Abruptio placentae
  - Vascular infarcts: Hypertension, pre-eclampsia
  - Multiple gestations (twin-twin transfusion)
- **Fetal factors** *(↓ growth potential)*
  - Chromosomal/genetic disorders, e.g. trisomies
  - Dysmorphic syndromes/congenital anomalies
  - Intrauterine infections
  - *Metabolic:* Insulin/insulin-like growth factor deficiency
- **Idiopathic**

or preterm, with birth weight 2 SD or 10th percentile for their gestation, thus excluding preterm-AGA.

Causes: Fetal growth depends on adequate transplacental supply of nutrients and oxygen from mother as well as on its inherent growth potential. Consequently, IUGR may be caused by:

- Maternal malnutrition or chronic hypoxic states, e.g. anemia, cardiopulmonary diseases, etc.
- Decreased placental blood flow due to placental abnormalities, or
- Decreased fetal growth potential, e.g. intrauterine infections or chromosomal disorders.

Maternal malnutrition, anemia and intrauterine infections are three leading causes of IUGR in India **(Table 12.28)**.

Clinical features: Clinical features of IUGR babies vary according to the timing of intrauterine insult and may be divided into 3 categories:

a. ***Symmetrical IUGR*** *(hypoplastic SFD),* due to fetal insult in first trimester, before organogenesis is complete. All growth parameters, e.g. weight, length and head circumference are proportionately affected in these babies, giving them a *tiny appearance* and *high ponderal index* >2. For ponderal index calculation, *see* footnote of **Table 12.33**.

b. ***Asymmetrical IUGR*** *(malnourished SFD),* due to fetal insult in late gestation. As fetal weight is disproportionately more affected than length or head circumference, these babies have a *marasmic* appearance with low ponderal index <2.

c. ***Mixed SFD,*** with adverse intrauterine factors operative throughout the gestation.

Diagnosis of IUGR may be suspected antenatally on the basis of: (a) discrepancy between gestational age by history and fundal height, and (b) USG findings, e.g. low BPD for gestation (<8.5 cm at 37 weeks), or fetal head-thorax or head-abdomen ratio. Important differences between asymmetric and symmetric IUGR are given in **Table 12.29**.

TABLE 12.29: D/D asymmetrical *vs* symmetrical IUGR

	Symmetrical	***Asymmetrical***
Timing of IU insult	Early	Late
Common cause	IU infections	Mat. malnutrition
Appearance	Tiny	Marasmic
Length and head circumference	Reduced	Near normal
*Ponderal index**	>2	<2
Malformations	Common	Uncommon
Cellular pathology	Hypoplasia	Hypotrophy
Growth potential	Poor	Preserved

***Ponderal Index:** Weight in gm/length in $cm^3 \times 100$

Complications: FT/SFD are physiologically as mature as normal term newborns and complications related to prematurity are uncommon despite low birth weight. However, these babies are more prone for (a) *perinatal asphyxia* due to placental dysfunction, (b) *hypoglycemia* due to poor stores, (c) *congenital malformations* due to intrauterine infections, (d) *hypothermia* due to scanty body fat, (e) *poor growth potential* in long-term.

PT-SFDs have additional risk of complications related to prematurity as enumerated in **Table 12.27**, which also summarizes important difference between complications in fullterm and preterm LBWs.

Management of IUGR is similar to that of preterms, as discussed in previous chapter, with following special considerations:

- *Delivery room care*—as IUGR babies are more prone for intrauterine asphyxia, regular fetal monitoring with emergency LSCS facility and neonatal resuscitation should be available.
- As these babies are prone for hypoglycemia, early breastfeeding should be ensured, with periodic glucose monitoring.
- Congenital malformations and stigmata of intrauterine infections should be carefully looked in FT-SFD cases.
- Polycythemia, if symptomatic, should be managed by partial exchange with plasma.

Outcome: Chances of immediate survival are better in FT-SFD babies than in preterms. However, growth potential is often reduced in them and unlike preterms, SFDs do not show catch-up growth, ultimately ending with short-stature.

12.11.3 LARGE FOR DATE BABIES

Babies, born with birth weight of >90th percentile or 2 SD for their gestation, are termed as *large for date* (LFDs) babies.

TABLE 12.30: Causes of *Large for Date Baby*

- Constitutional
- Maternal diabetes, ovarian tumors
- *Fetal:* Hypothyroidism, congenital adrenal hyperplasia
- *Chromosomal:* Wiedemann-Beckwith syndrome
- *Others:* Hydrops fetalis, cerebral gigantism

Causes: *Constitutional large size* and *infants of diabetes mother* (IDM) are most common causes of LFDs in India, apart from others **(Table 12.30)**. Some unique causes of LFD are as follows:

Wiedemann-Beckwith syndrome is probably a defect in chromosome 11, characterized by large body size (macrosomia), macroglossia, exomphalos, organomegaly, and characteristic groove on ear lobe along with other anomalies. These babies are prone for hypoglycaemia and Wilms' tumor.

Cerebral gigantism (Sotos syndrome) is of unknown etiology, characterized by large body size, large hands/feet, macrognathia, and mental retardation.

Clinically, most LFDs are asymptomatic except their size and features of causative disease, if present. However, even the constitutional LFDs are prone for: (a) obstructed labor, (b) hypoglycemia, and (c) polycythemia.

Management includes close monitoring of hematocrit and blood glucose levels during first 72 hours, and regular feeding. Additional sugar/oil fortified EBM may be given to prevent hypoglycemia, polycythemia. Primary disease should be managed appropriately.

12.11.4 POST-MATURITY

Babies born *after 42 completed weeks of gestation* are termed post-mature, post-term or post-dated babies.

Generally, beyond the term-gestation, placenta cannot sustain adequate fetal growth and develops degenerative changes, leading to fetal hypoxia, distress, growth retardation and sometimes, death.

Etiology: Most cases are *idiopathic* and born to Primiparous mothers. Rare causes include fetal anencephaly (delayed labor induction) or chromosomal defects, e.g. *Seckel's syndrome*.

Clinically signs of post-maturity include:

- Long, thin and wasted appearance with low birth weight, due to fetal dysplasia.
- Lack of vernix caseosa with peeling of skin, long nails and deep sole creases at birth.
- Yellowish staining of skin, nails and umbilical cord, due to *in utero* passage of meconium.
- Complications, e.g. meconium aspiration syndrome, birth asphyxia are common.

Management of these babies includes close monitoring for fetal distress, management of birth asphyxia and meconium aspiration syndrome, and prevention of hypoglycemia by early feeding. Application of oil on skin prevents it from peeling and dryness.

12.12 THERMOREGULATION DISORDERS

Temperature regulation is the one of the most important aspect of neonatal care, even in normal newborns. Fetus, who enjoys an isothermic environment (37°C) *in utero*, is suddenly exposed to low environmental temperature at birth, leading to rapid drop in body temperature (~ 0.3°C/min) by all modes of heat loss: (a) *evaporation* of amniotic fluid, (b) *convection* due to wind movements, (c) *radiation* due to temperature gradient, and (d) *conduction* to substances in contact with skin, e.g. linens.

Normal thermoregulation: Sudden cooling of neonatal skin stimulates *cutaneous thermoreceptors*, which convey the information to heat regulation centers in *pre-optic anterior hypothalamus*. Efferents from these centers are mainly *sympathetic* (adrenergic) in nature and stimulate various mechanisms for heat conservation and production, as follows:

- *Heat conservation* by peripheral vasoconstriction;
- *Heat production* by increased muscular activity, e.g. crying, limb movements, etc. Shivering mechanisms are not mature in newborns.
- *Heat production* by metabolic thermogenesis.

Metabolic thermogenesis is the predominant mode of heat production in newborns, which involves oxidation of metabolic fuels (brown fat) in presence of glucose and oxygen. *Brown fat* is a highly active metabolic substrate due to large number of mitochondria, predominantly present at the nape of neck, interscapular region, axilla, groin, and around kidneys and adrenals. In a FT-AGA baby, brown fat accounts for ~4% of body weight. Since most of it accumulates in last trimester, preterms have much lesser brown fat, and hence, more susceptible for hypothermia.

Thermoneutral environment: Human body can maintain its temperature only within a limited range, beyond which hypothermia or pyrexia results. However, maintenance of temperature even within this range requires constant metabolic activity, either to generate the heat or to increase evaporative heat loss, e.g. sweating.

Thermoneutral environment is *the narrow range of temperature at which baby can maintain its temperature with minimum metabolic activity and oxygen requirements*. It varies according to gestation, birth weight and postnatal age, ranging from ~33–31°C in full terms to ~35–33°C in VLBWs (higher value of the range is for first day of life and lower value is for 4th day onwards).

WHO recommends that neonatal temperature should be recorded in axilla once a day in apparently healthy term babies, thrice a day in healthy LBW (2–2.5 kg), 6-hourly in healthy VLBW <2 kg and every 2 hourly in sick newborns, using digital thermometer (mercury thermometers have been phased out). Low-reading rectal thermometer must be avoided due to risk of injury but may be used in sick, hypothermic babies with due care, gently inserted ~3 cm (2 cm in preterms) after greasing.

Rectal temperature represents body-core temperature, ~0.5–1.0°C higher than surface temperature.

Clinically too, temperature may be roughly assessed by touching the baby by the dorsum of hand on abdomen and hand/feet. Normal both abdomen and limbs should be warm. Warm abdomen and cold limbs indicate *"cold stress"* and cold abdomen and feet indicate *"Hypothermia"*.

Spectrum of temperature in newborns spans from *severe hypothermia* (<32°C) to *moderate hypothermia* (32–35.9°C), *cold stress* (36–36.4°C), *normal temperature* (36.4–37.4°C), *fever or hyperthermia* (37.5–38.5°C) and *hyperpyrexia* (>38.5°C).

12.12.1 HYPOTHERMIA

Hypothermia is more common and serious problem in newborns than fever or hyperthermia, defined as *skin temperature of <35.5°C or core temperature of <36°C*.

Etiology: Newborns are more susceptible to hypothermia than adults, due to—(a) disproportionately higher heat loss from larger surface area and lesser fat insulation, and (b) inadequate shivering thermogenesis. As metabolic thermogenesis is the only effective thermal defense in them, hypothermia is commonly seen in newborns with:

- Lack of brown fat, e.g. preterms and SFDs.
- Substrate deficiency, e.g. birth hypoxia, hypoglycemia.
- Circulatory insufficiency, e.g. infections and shock.
- Impaired central control, e.g. disorders affecting hypothalamus/neurological pathways.

In addition, cold exposure during procedures and transport, etc. further contributes to hypothermia in sick babies.

Pathogenesis: Prolonged hypothermia affects various metabolic activities **(Fig. 12.11)** leading to complications, e.g. (a) hypoglycemia, (b) cellular hypoxia, (c) metabolic acidosis, (d) septicemia due to impaired immune functions, and (e) poor weight gain due to diversion of metabolic substrates for heat production. In addition, impaired blood–brain barrier due to acidosis and other factors in hypothermia increases risk of kernicterus at relatively lower bilirubin levels.

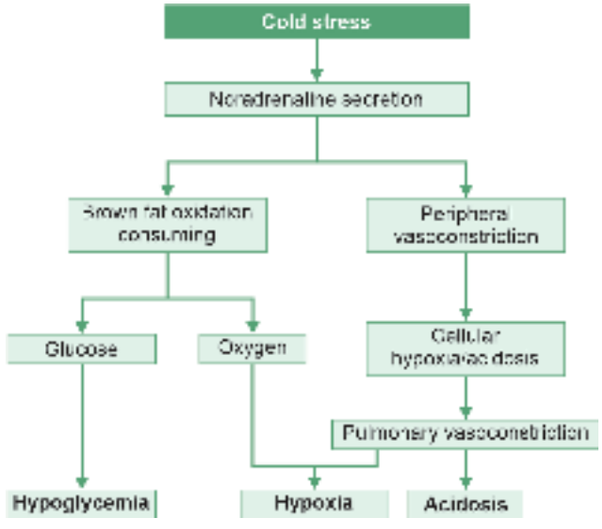

Fig. 12.11: Pathogenesis of hypothermia.

Clinical manifestations of hypothermia depends on its severity, including:

- *Changes in activity*, e.g. restlessness with excessive crying and body movements to generate heat in early cold stress, followed by sluggishness and inactivity.
- *Skin changes*, e.g. cold-clammy skin specially over limbs, followed by generalized mottling or pallor due to vasoconstriction and finally development of *sclerema*-characterized by hardening of skin, best appreciable over cheeks and shin of the tebia due to solidification of saturated fatty acids in subcutaneous tissue.
- *Depressed autonomic functions*, e.g. bradycardia, slow breathing and hypotension.

Diagnosis rests on digital/rectal temperature values. Simultaneous recording of axillary and core temperature with a *difference of >2°C indicates shock*.

Prevention of hypothermia is perhaps the most important step in neonatal care and includes:

- ***At birth***, by conducting the delivery in warm labor room (28–30°C), pre-warming of resuscitation area, receiving the baby on pre-warmed towels, wiping the baby well, wrapping in dry-warm linins and early breastfeeding to prevent hypoglycemia.
- ***In PNC wards*** by rooming-in with mother, keeping the room warm and baby covered, delayed bath till 24 hours and minimum handling. *Kangaroo mother care*, i.e. keeping the baby nestled inside the mother's cloths with close skin-to-skin contact is best method to provide warmth and prevent hypothermia in newborns, which also helps in promotion of breastfeeding and emotional bonding (Ch 12.12.2).
- ***In sick babies*** (NICU care) by—warm room, individual heat sources, e.g. incubators or radiant heat warmers, and minimum exposure during diagnostic and therapeutic procedures.
- ***During transport***, with use of transport incubators or thermocol boxes.

WHO, in 1997, recommended a set of inter-linked measures *(warm-chain)* during and soon after the delivery to minimize heat loss in newborns **(Table 12.31)**. Failure to implement any one of them will break the chain to put the baby at risk for hypothermia.

Management of hypothermic newborn includes:

- ***Gradual warming*** of baby in an incubator or warmer. Sudden warming may precipitate apneic spells and temperature gradient between baby's skin temperature

TABLE 12.31: Ten steps of warm chain (WHO 1997)
1. Warm delivery room
2. Immediate drying
3. Skin to skin contact
4. Breastfeeding
5. Bathing and weighing postponed
6. Appropriate clothing/bedding
7. Mother and baby together
8. Warm transportation
9. Warm resuscitation
10. Training and awareness raising

and environmental temperature should never exceed 1.5°C. However, severely hypothermic newborns may be warmed rapidly till skin temperature reaches 34°C, followed by slow warming.

- ***Continuous temperature monitoring*** by skin probes. Servo-control incubators or warmers are preferable, as they automatically adjust heater output according to baby's skin temperature.
- ***Substrate supplementation***, i.e. I/V Dextrose 10% (2 ml/kg bolus) and oxygen, to fulfil increased demand for metabolic thermogenesis. *IV hydrocortisone* (5 mg/kg 8 hourly for 3–5 days) may be used in cases of severe sclerema.
- ***Treatment of complications***, e.g. infections, hypoglycemia, acidosis, hypoxia, bleeding manifestations, etc.

Prognosis: Prolonged and severe hypothermia is associated with high mortality (25–50%). Sclerema and bleeding manifestations indicate poor prognosis.

12.12.2 KANGAROO MOTHER CARE

Kangaroo mother care (KMC) refers to a novel, low–cost intervention in care of the preterm or low birth weight infants, by nursing them in close skin-to-skin contact with mother or other caregiver, to promote temperature control, breastfeeding and emotional bonding, as well as to prevent hypothermia and infections.

First described by Dr Edgar Ray, Columbia, in 1978, the term derives its name from the similarities of marsupial baby care in Kangaroo species. KMC can be started at hospital and continued at home after discharge.

Benefits: Important benefits of KMC include: (a) reduced risk of hypothermia, (b) higher rates of exclusive breastfeeding, (c) better weight gain with early hospital discharge, (d) lesser morbidity in hospital and also post-discharge, (e) better emotional bonding between mother and baby, and (f) involvement of mother and family in neonatal care, reducing the stress associated with facility-care.

Prerequisites for successful KMC include birth weight <2500 gm and (a) baby should be hemodynamically stable*, (b) mother should be willing, with good health and hygiene, (c) support at the hospital as well as at home, (d) regular monitoring as well as post-discharge follow-up.

*KMC can be initiated in otherwise stable babies on IV fluids, tube feeding or oxygen. Most babies >1800 gm/>34 weeks can be directly managed with KMC; while lighter ones may need technology-based care in early days, till stable enough for KMC.

Procedure of KMC involves following steps:

Step I. Pre-KMC preparations including: (a) counseling the mother, spouse and other caregivers, (b) demonstration of actual procedure and answering their queries/apprehensions, (c) provision for appropriate, warm, front-open clothes for mother and baby; and (d) provision for suitable sitting arrangement, (e.g. reclining chairs) and adequate privacy.

Step II. Positioning of the mother–baby pair involves:

- Mother should be sitting or lying comfortably, preferably in semi-reclined posture;
- Baby's head should be placed between the mother's breasts in an upright position.
- Baby's head should be turned to one side in slightly extended position to ensure open airways and adequate eye to eye contact with mother.
- Baby's hips should be flexed and abducted in a "frog" position; the arms should also be flexed.
- Baby's abdomen should be at the level of the mother's epigastrium as maternal breathing stimulates the baby, reducing the risk of apnea.
- Baby's bottom should be supported with a sling/binder.
- Both mother and the baby should be properly covered as one unit **(Fig. 12.12)**.

Each skin-to-skin contact session should not last less than one hour to avoid frequent handling. Duration may be gradually increased up to 24 hours a day, interrupted only for changing diapers. Mother can eat and sleep in

Fig. 12.12: **Kangaroo mother care (KMC).**

KMC position, with proper support, preferably in semi-reclining position. KMC can be initiated in preterms within 24 hours of life (Early KMC) or even in babies on ventilators.

Monitoring: Babies during KMC should be closely monitored, specially in initial sittings, to ensure that: (a) neck is not too flexed/extended, (b) breathing is normal, and (c) feet and hands are warm. Mother should also be educated to watch for these parameters at home.

Feeding: KMC stimulates lactation and mother must be trained to feed the baby in KMC position. She must also be trained to express her milk and feed the baby by spoon, if required. Gavage feeding may continue during KMC, depending on the condition of baby.

When to stop KMC: Mother and baby may be discharged depending on their clinical status with adequate training and motivation to continue KMC at home, till it is comfortable and baby is not wriggling-out to show she/he is uncomfortable. Post-discharge, babies on KMC should be followed up till 37 weeks or 2500 gm weight, when KMC usually becomes unnecessary.

12.12.3 HYPERTHERMIA

Hyperthermia, i.e. core temperature exceeding 37.5°C, is of relatively lesser clinical significance in newborns, than older children.

Transient hyperthermia (overheating) is common in normal newborns due to ineffective mechanisms of heat loss, e.g. sweating, and should not be taken as indicator of underlying disease. *Sweating*—a most important mechanism to control fever in adults, is immature in newborns/infants <3 months.

Warmer care is a common cause of overheating in newborns, differentiated from true fever on the basis of—(a) normal appearance and activity, (b) pink skin (pale in fever), and (c) proportionately warm soles/palms with <2° difference between temperature at abdomen and hands (>3° in fever).

Persistent hyperthermia (fever) in newborns may be due to: (a) high environmental temperature, (b) infections (though hypothermia is more common), (c) dehydration, (d) CNS disorders, and (e) drugs, e.g. atropine derivatives.

Dehydration fever, lasting for 1–2 days, is a common problem in newborn during summer months due to poor fluid intake, specially in breastfed babies. However, baby remains alert and active despite fever. No treatment is needed, except monitoring for more serious causes.

12.13 RESPIRATORY DISORDERS IN NEWBORN

Respiratory functions in newborns are hampered by many *physiological handicaps*, e.g. (a) erratic central drive, (b) poor nasopharyngeal coordination, (c) excessively pliant airways and chest walls, (d) relative immaturity of surfactants, (e) cardiovascular transition at birth, and (f) higher oxygen requirements. Superimposed on these are other common and pathological problems, e.g. immature mechanical or immune defense mechanisms, congenital malformations and perinatal hypoxia.

12.13.1 D/D RESPIRATORY DISTRESS

Respiratory distress (RD) in newborn is a clinical diagnosis, defined as *tachypnea*, i.e. *(RR >60/min), associated with inspiratory intercostal retractions, expiratory grunt and cyanosis*.

Etiology: Intrauterine/postnatal pneumonia, meconium/milk aspiration, hyaline membrane disease (HMD) and congenital malformations are four major causes of RD in newborns, apart from other respiratory/extra-respiratory problems **(Table 12.32)**.

Diagnostic approach in neonatal RD includes:

I. Assessment of severity, based on
- *Signs of RD*, e.g. respiratory rate (RR), presence/severity of cyanosis, chest-wall retractions or grunt and air-entry on auscultation **(Table 12.33**, Downes' score).
- *Signs of hypoxia*, e.g. general activity, level of alertness, nature of cry, acceptance of feeds, etc., and
- *Laboratory indicators*, e.g. blood gas analysis.

TABLE 12.32: Causes of respiratory distress in newborns

Respiratory causes
- *Developmental:* HMD, TTN
- *Anatomical:* TOF, diaphragmatic hernia
- *Aspiration:*
  - Intrauterine (e.g. meconium)
  - Postnatal (e.g. milk)
- *Infections:* Intrauterine or postnatal pneumonia
- *Iatrogenic:* Pneumothorax, BPD
- *Others:* Wilson-Mikity syndrome

Extra-respiratory causes
- *Cardiac:* CHDs, myocarditis
- *Hematological:* Severe anemia, polycythemia
- *Neurological:* Birth asphyxia, diaphragmatic palsy
- *Metabolic:* Acidosis, inborn errors of metabolism

HMD: Hyaline membrane disease, **TTN:** Transient tachypnea of newborn, **TOF:** Tracheo-esophageal fistula, **BPD:** Bronchopulmonary dysplasia

TABLE 12.33: Clinical respiratory distress scoring

	Respiratory distress score		
Sign	***0***	***1***	***2***
RR	<60	60–80	>80/apnea
Cyanosis	Nil	At room air	At 40% O_2
Retractions	Nil	Mild	Moderate/severe
Grunting	Nil	Mild*	Loud
Air entry	Good	↓	Minimal

Interpretation: 0–4: Mild; 4–7: Moderate; >7: Severe
*audible only by stethoscope

TABLE 12.34: Causes of respiratory distress and age of onset

At birth or within 24 hours
- Meconium aspiration syndrome
- Transient tachypnea in newborn
- Hyaline membrane disease
- Birth asphyxia
- Intrauterine pneumonia
- Congenital airway obstruction or lung aplasia
- CNS trauma or malformations

Between 1st–7th day
- Postnatal aspiration
- Neonatal sepsis/pneumonia
- CHDs and CCF
- Iatrogenic—pneumothorax, acidosis

After first week
- Neonatal sepsis/pneumonia
- CHDs and CCF
- *Others:* Bronchopulmonary dysplasia, Wilson-Mikity syndrome

II. Etiological diagnosis depends on:
- *Gestational age:* HMD is an exclusive problem of preterms, while meconium aspiration syndrome (MAS) and transient tachypnea of newborn (TTN) are mostly seen in term babies.
- *Age of the onset* is a useful indicator of probable pathology for RD **(Table 12.34)**.
- *History of antenatal problems*, e.g. maternal diabetes (HMD), intrauterine infections (CHDs), polyhydramnios (tracheoesophageal fistula), oligohydramnios (lung aplasia), etc.
- *History of obstetric complications*, e.g. fetal distress (perinatal pneumonia), premature rupture of membranes (sepsis), meconium-stained delivery (MAS), cesarean delivery (TTN) low Apgar score (birth asphyxia) and neonatal resuscitation (pneumothorax), etc.
- *History of excessive frothing* from mouth on first day (tracheoesophageal fistula), choking/vomiting after feeds (postnatal aspiration).
- *Examination findings*, e.g. murmurs (CHDs), signs of sepsis (pneumonia), scaphoid abdomen (diaphragmatic hernia), etc.

III. Laboratory investigations depend on suspected cause, though following are necessary in all cases:
- X-ray chest
- *Sepsis screen*, e.g. CBC, PS and CRP levels
- Arterial blood gas analysis (ABG), in severe cases
- Tests for surfactant maturity (in preterms)

Other investigations, e.g. echocardiography for CHDs and metabolic screening for inborn errors are indicated in selected cases.

Management of RD depends on etiology, though general principles include:
- *Respiratory support* with humidified O_2 or assisted ventilation, as per clinical severity and ABG reports.
- *Supportive care,* i.e. adequate warmth, nutrition, fluid/electrolyte maintenance and prophylactic antibiotics. Parenteral nutrition is preferable in severe RD, due to risk of aspiration with oral feeds.
- *Continuous monitoring* by clinical assessment, non-invasive pulse oximetry and periodic ABGs.
- *Treatment of other complications*, e.g. hypoglycemia, acidosis, fluid/electrolyte imbalance, infections and anemia. Packed cell transfusion is indicated in babies with hematocrit <40, to improve oxygen-carrying capacity.
- *Treatment of primary cause*.

12.13.2 COMMON RESPIRATORY PROBLEMS

Some important causes of respiratory distress in newborns are as follows:

Hyaline membrane disease (HMD) is a common cause of respiratory morbidity/mortality in preterms, denoting *developmental immaturity of lung surfactant.* Surfactant deficiency leads to end-expiratory alveolar collapse and poor alveolar expansion on inspiration, with consequent decrease in lung compliance, complex ventilation-perfusion abnormalities and progressive respiratory failure.

Incidence of HMD is inversely related to gestational age. HMD may develop in 60–80% of preterms <28 weeks, 15–30% of preterms between 28 and 32 weeks and very rarely after 34 weeks. Incidence in Indian newborns is relatively less, probably due to high incidence of maternal infections that accelerate lung maturity.

Pathogenesis: Lack of the *surfactant*—a complex mixture of phospholipids and proteins that lines the inner surface of alveoli, is the core-pathology in HMD**.** Surfactant is secreted by alveolar type II pneumocytes from ~20th week onwards in increasing quantity, specially in last trimester. Main function of this surfactant is to prevent complete alveolar collapse during expiration and facilitate their expansion on next inspiration.

Surfactant deficiency is mostly developmental, in preterms. Other uncommon causes include—(a) delayed maturity in infants of diabetic mothers, and (b) destruction of type II alveolar cells due to perinatal complications, e.g. birth asphyxia, acidosis, hypothermia, Rh hemolytic disease and shock.

Surfactant deficiency means more negative pressure is required during inspiration to expand the collapsed alveoli of fetal lung. Inability of the highly compliant chest wall in preterms to generate enough negative inspiratory pressure leads to progressive alveolar atelectasis and hypoxia.

Diffuse atelectasis and hypoxia/acidosis-led vasoconstriction elevate pulmonary vascular pressure, leading to pulmonary hypertension > right to left shunt through PDA > ventilation-perfusion mismatch with increased alveolar:arterial oxygen gradient; and ultimately, respiratory failure **(Fig. 12.13)**.

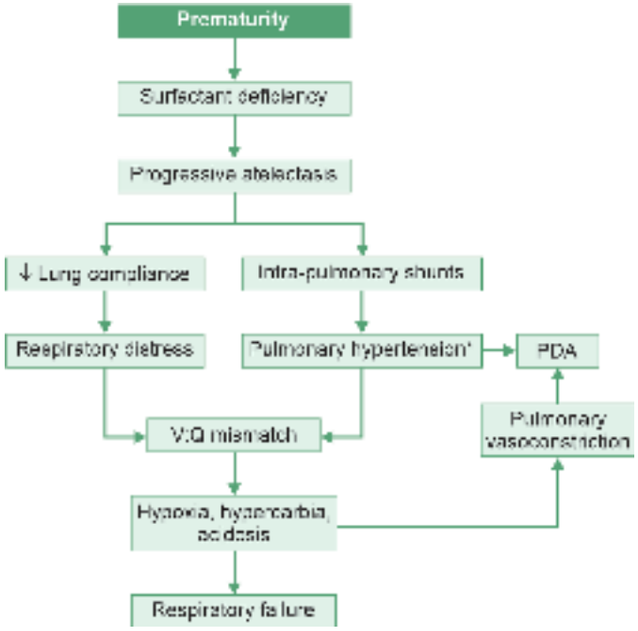

Fig. 12.13: Pathogenesis of HMD.
*Pulmonary hypertension > ↑ Rt ventricular pressure > PDA with Rt>Lt shunt

Autopsy findings in HMD reveal—(a) poorly expanded lungs, which do not float on water, (b) diffuse atelectesis, and (c) characteristic hyaline membrane on inner alveolar surfaces.

Clinical manifestations: HMD presents with progressive RD *since birth*, with—(a) tachypnea, (b) inspiratory chest-wall retractions, (c) expiratory grunt due to partially closed glottis—a protective mechanism to prevent end-expiratory alveolar collapse, and (d) cyanosis. Auscultatory findings are non-specific, with diminished breath sounds and fine inspiratory rales.

Untreated cases rapidly progress to respiratory failure in next 2–3 days, complicated with acidosis, hypotension, hypothermia and hypoglycemia.

Diagnosis of HMD should be considered in any preterm with progressive RD since birth, confirmed by:

- ***Chest X-rays:*** Radiological picture changes during the course of disease with (a) characteristic *fine reticular granularity with air bronchogram, (b) complete white-out appearance in severe disease* due to collapsed lungs, and (c) late *complications*, e.g. hyperinflation or pneumothorax **(Fig. 12.14)**.
- ***Surfactant maturity tests*** by—(i) shake test, (ii) biochemical tests, e.g. Lecithin-sphingomyelin ratio (L:S > 2 indicates adequate maturity).
  Shake test is a simple and bedside qualitative test to detect surfactant activity in amniotic fluid (antenatal prediction) or gastric juice (postnatal diagnosis). Add 0.5 ml of amniotic fluid/gastric aspirate in a mixture of normal saline (0.5 ml) and 95% ethyl alcohol (1.0 ml). Shake the mixture vigorously for 15 seconds and allow to stand it for 15 minutes. Presence of a rim of bubbles over >2/3rd of top liquid circumference indicates adequate surfactant activity. This test is false-positive if blood/meconium is present in test sample.
- ***Blood gas abnormalities*** are characterized by progressive hypoxemia, hypercarbia and metabolic acidosis.

Fig. 12.14: Hyaline membrane disease: White-out appearance with airbronchogram.

Prevention: Avoidance of prematurity is the most important prevention against HMD, though in unavoidable cases, following steps are necessary:

a. ***Postpone elective preterm labor*** as long as possible and assess surfactant maturity by amniotic fluid shake test or L:S ratio, before the induction.

b. ***Antenatal steroids*** to mother, if preterm labor is inevitable before 34 weeks, as total four doses IM dexamethasone 6 mg 12-hourly for our doses at least 24 hours before delivery is highly effective to accelerate surfactant maturity. Efficacy is maximum when baby delivers within 24 hours to 7 days after steroid and same course may repeated once (only) after 7–14 days if baby has not yet delivered and gestation is still < 34 weeks.

c. ***Prophylactic surfactant therapy*** at birth. However, early use of CPAP in delivery room is as effective as prophylactic surfactant therapy to prevent HMD.

Management of HMD aims to: (a) ensure adequate gaseous exchange in the lungs, (b) prevent further alveolar collapse and facilitate their expansion, (c) increase lung surfactant activity, (d) correct hemodynamic/metabolic abnormalities, and (e) manage secondary complications, i.e. infections, pneumothorax, etc.

All suspected HMDs must be managed in NICU with appropriate ventilatory support. Important steps include:

i. ***Initial stabilization*** with: (a) oxygen supplementation, (b) thermoregulation, (c) fluid/electrolyte correction,

(d) blood transfusion (if Hct <40) to improve oxygen carrying capacity, (e) treatment of complications, e.g. hypoglycemia, metabolic acidosis and infections, and (f) continuous monitoring.

ii. ***Ventilatory support*** is essential in most cases, though the mode of ventilation is guided by clinical severity, blood gas reports, and patient's breathing efforts.

Continuous positive airway pressure ventilation (CPAP) at a continuous distending pressure of 5–8 cm H_2O, is the ventilation of choice in HMD, indicated in cases with *PaO_2 <50 mm Hg despite 60% FiO_2 and able to breath spontaneously*. CPAP prevents complete collapse of alveoli at the end of expiration and thus facilitates longer gaseous exchange and easier re-expansion during inspiration. A recent meta-analysis suggests that non-invasive positive pressure ventilation (NIPPV) is superior to biphasic positive airway pressure (BiPAP) or CPAP ventilation to reduce the need of mechanical ventilation.

Assisted mechanical ventilation is indicated in babies with: (a) persistent ABG abnormalities despite 100% oxygen and CPAP or (b) no spontaneous respiration. Positive end-expiratory ventilation (PEEP) is indicated in these cases for the same reason as for CPAP in spontaneously breathing baby.

Mechanical ventilation must aim to keep PaO_2 50–70 mm Hg, $PaCO_2$ 45–65 mm Hg and pH 7.20–7.35, to ensure adequate ventilation without the risk of lung injury or oxygen toxicity. Recommended range of SaO_2 is 91–95%. At the time of weaning from ventilator, it is preferable to shift on nasal CPAP, followed by humidified high-flow oxygen (2–8 L/min) by nasal cannula.

iii. ***Surfactant replacement therapy (SRT)*** has revolutionized the prevention and treatment of HMD. Currently, two types of surfactants are available—biologically derived and recombinant preparations, former being more effective due to presence of surfactant proteins A and B.

SRT is complementary to CPAP and must be started as early rescue therapy within 2 hours of delivery in extreme preterms who require intubation in labour room or or later in babies on CPAP with FiO_2 requirements of > 40%.

Irrespective of the type, 100 mg/kg of surfactant, is instilled endotracheally via a catheter. After each 1–2 ml dose, infant must be given continuous positive pressure ventilation before next aliquot till full dose is administered. Surfactant can be administered by either *intubation-surfactant-extubate (INSURE)* technique or *less invasive surfactant administration (LISA)*.

Effective surfactant therapy is associated with rapid clinical improvement and correction of blood gas abnormalities. Rescue therapy is most effective when started within 24 hours of birth and usually 2–4 doses may be required at 6–12-hour interval. Pulmonary hemorrhage is the most important complications of surfactant therapy, apart from hypotension.

iv. ***Closure of PDA:*** Raised pulmonary pressure due to collapse alveoli and hypoxia-induced pulmonary arteriolar constriction in HMD leads to significant right-to-left shunting though PDA, which accentuates hypoxia. Pharmacological closure of ductus is indicated with 3 doses of either IV Indomethacin (0.2 mg/kg at 0,12 and 24 hours or Ibuprofen as 10 mg/kg (loading), followed by 5 mg/kg after 12 and 24 hours) However, currently IV Paracetamol 15 mg/kg 6-hourly is the preferred choice for closure of hemodynamically significant PDA. Prophylactic intervention is not indicated.

Outcome: Although most untreated cases of HMD are fatal, appropriate surfactant and ventilation therapy has reduced the mortality to ~10% in best centers. However, late complications, e.g. bronchopulmonary dysplasia or retinopathy of prematurity due to oxygen toxicity, are common in survivors.

Meconium aspiration syndrome (MAS): Intrauterine passage of meconium in amniotic fluid is an indicator of fetal distress and meconium-stained amniotic fluid (MSAF) is present in ~10–20% of deliveries. Meconium is a strong mucosal irritant. Babies born to MSAF deliveries are likely to aspirate it during first breath and develop meconium aspiration syndrome (MAS). However, only 5–10% of MSAF deliveries develop MAS, specially in term babies with thick meconium. .

Pathophysiology of MAS involves:

- *Airway obstruction* by aspirated meconium, leading to distal atelectasis (complete obstruction) or emphysema (partial ball-valve mechanism).
- *Chemical pneumonitis* due to constituents of meconium and release of inflammatory mediators (cytokines).
- *Surfactant injury* due to cytotoxic effects of meconium on alveolar type II cells.
- *Pulmonary hypertension* (PPHN) due to pulmonary vasoconstriction, and
- *Secondary infection*.

Clinically, MAS is more common in *term babies (rare in preterms)* and presents with progressive RD after 4–6 hours of birth. Chest may be hyperinflated with variable clinical signs in initial few hours, followed by signs of secondary bacterial pneumonia. MSAF babies often have external signs of meconium staining, e.g. greenish yellow staining of skin, nails and umbilical cord.

Diagnosis rests on history of MSAF delivery and development of respiratory distress after 4–6 hours in a term baby. Chest X-ray in suspected MAS should be delayed for 4–6 hours, to allow the radiological signs to

Fig. 12.15: **Meconium aspiration syndrome: Perihilar coarse opacities**

develop, which include: (a) bilateral perihilar/diffuse coarse opacities, (b) patchy emphysema/atelectasis, (c) pneumothorax (20–40%), and (d) consolidation due to super-infection **(Fig. 12.15)**.

Prevention: As per recent Neonatal resuscitation program (NRP) guidelines, resuscitation for a MSAF newborn must be on same protocols as for others and previously practiced interventions, e.g. endotracheal suction in non-vigorous babies or avoidance of positive pressure ventilation, are no longer recommended.

Management: All babies born to MSAF deliveries should be X-rayed after 6 hours of birth and observed for RD till 24 hours. In established MAS, treatment is largely supportive including: (a) oxygen or ventilatory assistance, (b) antibiotics to prevent/treat secondary infections, (c) chest physiotherapy, and (d) supportive measures including continuous monitoring. Mechanical ventilation is indicated in cases with severe hypoxemia (PaO_2 < 50 mm Hg) and hypercarbia ($PaCO_2$ > 60 mm Hg). *Steroids are contraindicated and may flare-up the bacterial pneumonitis.*

Other options, e.g. Sildenafil or Nitric oxoid therapy may be considered in cases with persistent pulmonary hypertension in newborn (PPHN).

Outcome: While mild cases may improve in 2–3 days, mortality is very high (>20–30%) in severe cases. Pneumothorax is most common complication. Survivors have higher risk of developing asthma in later life.

Perinatal pneumonia is the commonest cause of neonatal respiratory distress in India (>50%), which may be intrauterine or postnatal in origin.

Intrauterine pneumonia is more common in *term or post-term babies* due to higher risk of fetal distress and aspiration of amniotic contents.

Important *risk factors* include: (a) intrauterine infections, (b) premature rupture of membranes, (c) foul-smelling liquor amnii, (d) prolonged/obstructed labor, and (e) repeated vaginal examinations.

Infection is acquired either *in utero* by aspiration of infected amniotic fluid or during the passage through infected birth canal. Vaginal pathogens, e.g. *E. coli*, enterococci, Group B streptococci (rare in India), *Listeria monocytogenes* and Chlamydia are common causes of intrauterine pneumonia. Most cases manifest in first 3 days of life, except Chlamydia infections, which present as interstitial pneumonia in 2nd–3rd week.

Postnatal pneumonia is more common in *preterms or sick newborns* with following *predisposing factors:* (a) postnatal aspiration, (b) history of resuscitation, (c) cardio-respiratory problems, (d) surgical/intensive care (nosocomial infections).

Infection is acquired on post-natal aspiration or hematogenously from other septic sites. Nosocomial organisms, e.g. Klebsiella, Pseudomonas and staphylococci are predominant pathogens in these cases.

Diagnosis of perinatal pneumonia depends on clinic-radiological findings along with cultures from maternal genital tract and neonatal throat swab, gastric aspirate and blood. There is a good correlation between vaginal and neonatal pathogens in intrauterine pneumonia.

Treatment is guided by local antibiotic policy, preferably, an aminoglycoside with ampicillin/cloxacillin/cephalosporin, along with supportive care including ventilator assistance, if required.

Transient tachypnea in newborn (TTN) is a common, *self-limiting* cause of RD in *full-term* babies, born to cesarean or precipitate deliveries. *In utero*, lungs are filled with alveolar fluid, which is squeezed-out during vaginal passage due to external pressure. Lack of such pressure in LSCS or precipitate births, delays clearance of this fluid leading to TTN.

Clinically, these cases present with tachypnea since birth but without other signs of respiratory distress, e.g. intercostals recessions, cyanosis, etc. and baby is typically alert and active. Tachypnea usually subsides after 48–72 hours, with absorption of lung fluids via lymphatics.

Diagnosis rests on exclusion of other causes for RD. Chest X-ray may be normal or shows hyperinflated lungs with perihilar streaking due to dilated lymphatics and prominent interlobar fissure.

Management: TTN is self-limiting and no treatment is necessary except oxygen supplement, till tachypnea resolves.

Postnatal aspiration pneumonia is common in newborns with structural/functional oropharyngeal abnormalities, e.g. preterms, cleft palate, tracheoesophageal fistula and gastroesophageal reflux.

Clinically, these cases present at any postnatal age with history of sudden choking or vomiting, followed by dyspnea and cyanosis. Localized crepts may be present.

Diagnosis: Presence of milk in trachea on endotracheal intubation confirms the diagnosis. Chest X-ray shows parahilar streaking in early stages and diffuse/localized bronchopneumonia after super-infection.

Treatment is largely supportive, with prophylactic antibiotics.

Pneumothorax in newborns may be due to: (a) high pressure bag/mask resuscitation or mechanical ventilation, (b) staphylococcal pneumonia, (c) meconium aspiration, and (d) rupture of a congenital emphysematous bullae (*spontaneous pneumothorax).*

Clinically, pneumothorax should be suspected in any sick/ventilated child with sudden onset/deterioration of RD and blood gas abnormalities. X-ray chest is diagnostic. Transillumination of the chest on affected side using a fiber-optic probe might add to diagnosis.

Treatment includes emergency intercostal drainage in large *or* progressive pneumothorax, along with antibiotics and supportive care.

Pleural effusion in newborns may be due to: (a) chylothorax due to congenital/traumatic pathology of thoracic duct, (b) staphylococcal pneumonia, and (c) hydrops fetalis.

Chylothorax is more common on right side, filled initially with colorless fluid that turns to milky-white appearance, after a few days of feeding. Most cases recover spontaneously, though they should be fed on medium-chain triglycerides to reduce chyle production.

Persistent pulmonary hypertension in newborn (PPHN) or persistent fetal circulation (PFC) is a common hemodynamic complication in sick newborns, characterized by pulmonary vasospasm or hyperplasia leading to pulmonary hypertension and consequent right to left shunting through foramen ovale or PDA.

Clinically, PPHN is commonly seen in critically sick newborns with birth asphyxia, meconium aspiration, sepsis, acidosis, and hypoglycemia; and presents with persistent cyanosis and respiratory distress, despite adequate treatment of primary illness.

Diagnosis is confirmed by presence of a PaO_2 gradient between pre-ductal (right arm) and post-ductal (lower limb) arterial blood samples and/or on echocardiography. Chest skiagram may be normal.

Management includes—(a) correction of primary disease and complications, e.g. acidosis, (b) assisted ventilation, and (c) pulmonary vasodilators, e.g. Sildenafil, tolazoline, prostaglandins and dopamine. Nitric oxide inhalation (20 ppm) for 3–5 days to relax vascular smooth muscles may reduce the need for extra-corporeal membrane oxygenation (ECMO) which may be life-saving.

Diaphragmatic paralysis due to birth injury in large size babies with breech delivery is more common on right side, frequently associated with Erb's palsy. These cases may be asymptomatic or present with RD and paradoxical respiration. Diagnosis rests on paradoxical diaphragmatic movements on fluoroscopy. These cases must be differentiated from eventration, which is usually on left side, without paradoxical movements or Erb's palsy.

Bronchopulmonary dysplasia (BPD) is a chronic pulmonary complication of prolonged assisted ventilation, due to the combined effect of: (a) oxygen toxicity, (b) ventilator barotrauma, and (c) PDA. Incidence of BPD is inversely related to the gestational age. Most cases present with difficulty in weaning from ventilator/oxygen, after control of primary disease. Chest X-ray shows progressive nodular opacities with diffuse hyperinflation.

Severity of BPD is classified at the time of assessment on discharge or at 28 days (28–56 days in preterms <32 weeks), as *mild* (breathing at room air), *moderate* (need <30% oxygen) or *severe* (need >30% oxygen or positive pressure ventilation).

Specific treatment is not established, though diuretics, bronchodilators and a short course of steroids may allow these cases to wean from ventilator/oxygen. Recurrent chest infections and wheeze is common in survivors and ~1/3rd of them die in early infancy.

Neonatal stridor indicates inspiratory obstruction, usually due to: (a) developmental laryngomalacia, (b) luminal obstruction due to mucus, meconium or postintubation edema, (c) congenital anomalies, e.g. laryngotracheal webs, stenosis or cysts, (d) vocal cord palsy, and (e) external airway compression by vascular rings or cervical tumors.

Laryngomalacia is the commonest cause of persistent stridor, due to developmental flaccidity of laryngeal structures. Stridor is more prominent in supine position and typically reduces in prone position. Baby is otherwise comfortable without RD and feeds adequately.

Diagnosis rests on typical effect of posture on intensity of stridor and exclusion of other causes. No treatment is necessary except nursing in prone position and stridor gradually disappears after 4–6 months.

Neonatal apnea: Transient cessation of respiration without cyanosis or bradycardia is common in ~30–40% preterms, termed as *periodic breathing*, with no pathological consequence.

Apnea is defined as *sudden cessation of breathing for >20 seconds or of any duration associated with cyanosis and bradycardia,* which may lead to significant hypoxia and neurological damage.

Etiology: Recurrent apnea indicates gestational immaturity (*apnea of prematurity*) or a serious underlying disease

TABLE 12.35: Causes of recurrent apnea in newborn

- Apnea of prematurity (<32 weeks/1500 gm)
- Hyperthermia/hypothermia
- Neonatal septicemia
- *CNS:* Seizures, hypoxic-ischemic encephalopathy
- *Metabolic:* Hypoglycemia, dehydration
- *Respiratory:* Milk aspiration, RDS
- *Hematological:* Severe anemia
- *Drugs:* Maternal sedation
- *Others:* Painful stimuli, e.g. suction

(Table 12.35). Apnea, though not necessarily recurrent, may also develop due to (a) central causes, e.g. excessive sedation, (b) airway obstruction, e.g. neck-flexion or secretions. Aspiration is common even in term babies due to airway obstruction, e.g. milk aspiration or a reflex reaction to painful stimuli, e.g. suction.

Pathophysiology: Recurrent apnea of prematurity typically develops 2nd to 5th day and indicates immaturity of medullary centers to sustain adequate respiratory drive, due to poor afferent responsiveness *or* neurotransmitters insufficiency. Apnea within 24 hours of birth or after 5th day is more likely to be secondary.

Diagnosis: Recurrent apnea, except in extreme preterms, needs exclusion of serious underlying causes as well as environmental factors, e.g. hyperthermia.

Management: Apart from treatment of identified cause, specific management of apnea includes:

- ***During the attack:*** (i) airway suction, (ii) gentle physical stimulation, (iii) 100% oxygen to correct cerebral hypoxia, and (iv) positive pressure ventilation, if not responding to stimulation.
- ***Prevention of further attacks*** by: (i) avoidance of hyper/hypothermia and reflex apnea, (ii) continuous 40% oxygen supplementation or low pressure CPAP, (iii) drug therapy, and (iv) mechanical ventilation, if necessary.

Drug therapy for recurrent apnea includes IV Caffeine citrate 20 mg/kg loading followed by 5–7.5 mg/kg every 24 hours till 34 weeks of gestation or seven days post-weaning off respiratory support, whichever is later.

Surgical disorders, e.g. tracheoesophageal fistula, diaphragmatic hernia, etc. are important causes of respiratory distress on first day of life, discussed in Ch 14.6 and 14.7.

12.14 NEONATAL JAUNDICE

Jaundice is a common cause of parental concern in newborns, though most cases are benign and transient, due to developmental immaturity in bilirubin metabolism (*physiological jaundice*) rather than a pathological disease. However, it is essential to differentiate physiological from pathological jaundice, as in the later case, bilirubin levels may rise to dangerously high levels and cause neurological damage or *Kernicterus*.

Normal bilirubin metabolism may be divided into following steps:

a. ***Bilirubin production:*** About 3/4th of the bilirubin is derived from the breakdown of hemoglobin in reticuloendothelial system, while rest comes from myoglobin or heme-containing enzymes. One gram of hemoglobin produces 34 mg of bilirubin.

b. ***Transportation to liver:*** After production, bilirubin is transported to liver, mostly bound with albumin and partly as free bilirubin. The albumin-bind bilirubin cannot cross the blood–brain barrier (BBB) and hence, not neurotoxic. However, free unconjugated bilirubin is fat-soluble and readily crosses the BBB with potential risk of kernicterus.

c. ***Hepatic conjugation:*** In liver, bilirubin dissociates from albumin to enter hepatocytes and combines with *Ligandin* (Y-protein) to reach the site of conjugation, i.e. *endoplasmic reticulum*. Here, it conjugates with glucuronic acid in presence of an enzyme *Uridine diphosphate glucoronyl transferase* (UDPGT), to form mono-/di-glucuronides, i.e. *conjugated bilirubin*. Unlike unconjugated bilirubin, conjugated bilirubin is water soluble and cannot cross BBB (non-neurotoxic).

d. ***Excretion of conjugated bilirubin:*** Conjugated bilirubin is excreted in bile to reach the intestines, where part of it is further metabolized for excretion as *stercobilinogen* in stools and *urobilinogen* in urine. Normal gut flora is essential for conversion of conjugated bilirubin into stercobilinogen/urobilinogen.

e. ***Enterohepatic circulation:*** Part of the conjugated bilirubin excreted in gut, reverts back to unconjugated form by enzyme β-*glucuronidase* and re-absorbed again for liver metabolism.

12.14.1 PHYSIOLOGICAL JAUNDICE

Physiological jaundice is a sign of developmental immaturity in bilirubin metabolism, seen in >50% of Term newborns and >80% of preterms.

Cardinal features of physiological jaundice are:

- Onset beyond 24 hours of birth (N: 48–72 hours)
- Maximum intensity on 4th day (5/6th day in preterms)
- Maximum. Serum bilirubin <12 mg/dl (<15 in preterms)
- Disappears by 10th day (14th day in preterms)
- Active newborn without other problems

Etiophysiology: Physiological jaundice indicates various developmental immaturities in newborns, as follows:

- *Increased bilirubin production*, ~3 times higher than in adults, due to higher hemoglobin content and shorter lifespan of fetal RBCs (90 days).
- *Developmental hepatic immaturity* with relative deficiency of *Ligandin* for bilirubin transport within hepatocytes and UDPGT for conjugation.

- *Underdeveloped gut flora*, with inadequate conversion of conjugated bilirubin into excretable pigments-stercobilinogen and urobilinogen. Consequent delay in bilirubin excretion facilitates entero-hepatic circulation.
- *Increased enterohepatic circulation* due to high β-glucoronidase activity in gut, especially when feeding is delayed. Early feeding promotes development of normal flora, which destroys this enzyme and limits enterohepatic circulation.

These physiological handicaps are more pronounced in preterm, LBW and sick newborns, e.g. hypoglycemia, asphyxia, etc., leading to *exaggerated physiological jaundice.*

Diagnosis of physiological jaundice rests on cardinal features (as above) and exclusion of pathological causes.

Management: No specific treatment is needed in physiological jaundice, except—(a) proper feeding, (b) prevention of hypothermia, and (c) clinical monitoring and follow-up after 10–14 days to confirm disappearance of jaundice. However, cases with exaggerated physiological jaundice need to be treated as pathological jaundice.

12.14.2 DIAGNOSTIC APPROACH IN NEONATAL JAUNDICE

Neonatal jaundice may be physiological or pathological due to many causes **(Table 12.36)**. Diagnostic approach in these cases aims to answer following questions:

Step I. Whether it is pathological? Neonatal jaundice is considered as pathological in presence of any of the following features:

- Appears within 24 hours of birth,
- S. bilirubin >12 mg/dl (>15 in preterm)
- Persistence of icterus > 10th day (>14th day in preterm),
- Sick child, e.g. vomiting, lethargy, poor feeding, apnoea, hypothermia, etc.

All suspected cases of pathological jaundice require detailed investigation to identify the cause, constant monitoring and timely therapeutic interventions.

Step II. Whether it is predominantly unconjugated or conjugated? Pathological jaundice may be broadly divided in: (a) *unconjugated or* indirect, or (b) *conjugated* or direct hyperbilirubinemia. Conjugated hyperbilirubinemia is relatively less common and usually manifests beyond 2nd week of life with progressive icterus and typical *clay-color* stools.

Step III. What is the precise cause? Hemolytic disease of newborn (Rh/ABO incompatibility), septicemia and congenital haemolytic anemia are three leading causes of unconjugated jaundice, while conjugated jaundice usually indicates extrahepatic biliary atresia (EHBA) or neonatal hepatitis. However, other causes **(Table 12.40)** should be excluded

Step IV. What is the severity? While serial bilirubin level is the best indicator for severity in neonatal jaundice,

TABLE 12.36: Causes of neonatal jaundice

- **Physiological**
- **Pathological (predominantly unconjugated)**
  - ***Overproduction of bilirubin***
    - *Hemolytic disease of newborn (Rh/ABO)*
    - *Congenital hemolytic anemia:*
      - Membrane defects, e.g. H. spherocytosis
      - Enzyme defects, e.g. G6PD deficiency
      - Hemoglobinopathies, e.g. Thal. major
    - *Acquired hemolysis* due to
      - Polycythemia
      - Cephalohematoma
      - Intrauterine infections, septicemia
      - *Drugs:* Vitamin K, sulfonamides, etc.
  - ***Impaired hepatic metabolism***
    - *Inherited enzyme defects:*
      - *UDPGT deficiency:* Crigler-Najjar syndrome
      - Specific Y/Z protein (Ligandin) deficiency
      - *IEMs:* Galactosemia, Gilbert syndrome
    - *Inhibition of enzyme activity*
      - Breast-milk jaundice
      - Lucey-Driscoll syndrome
      - Drugs, e.g. chloramphenicol, aminoglycosides
    - *Endocrinal disorders:* Hypothyroidism
- **Pathological (predominantly conjugated)**
  - ***Impaired excretion (cholestasis syndromes)***
    - *Neonatal hepatitis*
      - Idiopathic neonatal hepatitis
      - Intrauterine infections
      - *Metabolic:* galactosemia, α_1 antitrypsin deficiency
    - *Biliary tract malformations*
      - Extra-hepatic biliary atresia (EHBA)
      - Intra-hepatic biliary atresia (IHBA)
      - Choledochal cysts
    - *Inspissated bile syndrome*
    - *Inherited:* Dubin-Johnson syndrome
  - ***Increased enterohepatic circulation***
    - *Intestinal stasis:* IHPS, meconium ileus
    - *Poor gut flora:* Delayed feeding, prolonged antibiotics

IHPS: Infantile hypertrophic pyloric stenosis

TABLE 12.37: Clinical assessment of the severity in neonatal jaundice (Cramer criteria)

Icterus visible on..	*Expected bilirubin levels*
Face	<5 (4–8 mg/dl)
Upper trunk	<8 (5–12 mg/dl)
Lower trunk	<10 (8–16 mg/dl)
Arms and legs	<15 (11–18 mg/dl)
Palm and soles	>15 mg/dl

Table 12.37 provides a commonly used "Kramer criteria" for clinical assessment of severity.

A diagnostic algorithm for neonatal jaundice is given in **Fig. 12.16**, though important diagnostic clues are as follows:

Clinical evaluation, with special reference to:

- Age of appearance **(Table 12.38)**

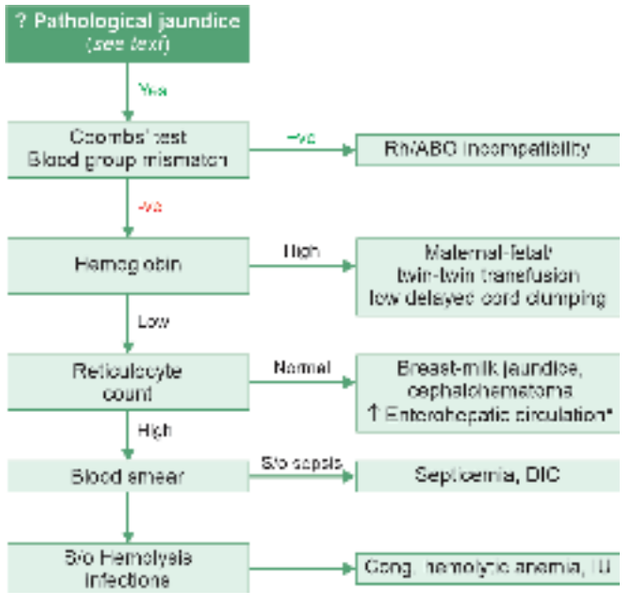

Fig. 12.16: Diagnostic algorithm for N. hyperbilirubinemia.
*For example, paralytic ileus, late feeding, intestinal obstruction

TABLE 12.38: Age of onset in neonatal jaundice

- **Within 24 hours of Birth**
  - Hemolytic disease of newborn (Rh/ABO)
  - Intrauterine infections
  - Cong. hemolytic anemia, e.g. thalassemia major
  - Maternal medications, e.g. Vit K, sulfonamides, etc.
  - Crigler-Najjar syndrome
- **Between 24 and 72 hours**
  - All of the above, plus
  - Physiological jaundice
  - Exaggerated physiological jaundice
  - Neonatal sepsis
- **Between 72 hours and 14th day**
  - All of the above, plus
  - Breast milk jaundice
  - Septicemia
  - Gut stasis/sterilization: IHPS, antibiotic therapy
- **Beyond 14th day of life**
  - Neonatal hepatitis (idiopathic, secondary)
  - Biliary atresia (EHBA/IHBA)

IHPS: Infantile hypertrophic pyeloric stenosis

- Duration of icterus: Persistent icterus > 2 weeks may be due to hypothyroidism, Crigler-Najjar syndrome, neonatal cholestasis disorders, or inspissated bile syndrome.
- Perinatal problems, e.g. preterm, asphyxia, sepsis.
- General appearance and activity level.
- Type of feeding (breast milk jaundice).
- Exposure to drugs causing hyperbilirubinemia

Laboratory evaluation include:

- *Baseline investigations* in all cases
  - Serum bilirubin levels (total and direct)
  - Blood grouping (ABO/Rh type)
  - *Hemolysis screen:* Hct, Hb and P. smear
  - *Sepsis screen:* TLC, band-cell count, CRP
- Investigations in indirect hyperbilirubinemia
  - Serological tests for intrauterine infections
  - Hb electrophoresis, osmotic fragility, G6PD estimation for congenital hemolytic anemia.
  - Metabolic screening for enzyme defects
- Investigations in direct hyperbilirubinemia
  - Hepatobiliary scan
  - Liver biopsy

12.14.3 UNCONJUGATED HYPERBILIRUBINEMIA

Unconjugated hyperbilirubinemia is a major cause of concern in early neonatal period, due to potential risk of neurotoxicity. Hemolytic disease of newborn (HDN) due to Rhesus or ABO blood group incompatibility is the commonest cause of severe unconjugated hyperbilirubinemia. Followed by breast milk jaundice and Crigler-Najjar syndrome, etc. Minor blood group incompatibilities, though probably more common, rarely produce significant hemolysis.

Rhesus hemolytic disease of newborn (Rh-HDN) is characterized by severe hemolysis of fetal RBCs in a Rh +ve fetus/newborn born to Rh-ve mother, due to transplacental transfer of maternal anti-D (anti-Rh) antibodies. In India, ~5% of mothers are Rh-negative. Rh blood group system is characterized by three antigens, i.e. C, D and E. Of these, D is the most important antigen and hence, anti-Rh antibodies are also commonly termed as anti-D antibodies.

Pathogenesis: There are no inborn anti-Rh antibodies in humans and production of anti-D antibodies in mother requires sensitization of her immune system by exposure to Rh +ve antigen. Usually, this sensitization occurs during first trimester by seepage of Rh+ve fetal RBCs to maternal side via immature placenta, which stimulates maternal anti-D IgG production. However, initial sensitization may also occur during previous deliveries, abortions/stillbirths or Rh +ve blood transfusions.

These antibodies, mainly of IgG class, cross the placental barrier to produce hemolysis of fetal RBCs Since the quantum of these antibodies depends on frequency of antigenic exposure, first babies are less affected than subsequent births.

Clinical spectrum of Rh-HDN varies from insignificant hemolysis to the severe hemolytic anemia in fetal life, leading to *hydrops fetalis* and stillbirth. *Severity tends to increase with increasing birth order.*

Erythroblastosis fetalis, the commonest presentation of Rh-HDN, manifest with two cardinal features: (a) moderate to severe hemolytic *anemia* at birth, and (b) appearance of *icterus* within first 24 hours. Untreated cases may rapidly progress to reach dangerously high

TABLE 12.39: Causes of hydrops fetalis

Immune hydrops: Hemolytic disease of newborn
Non-immune hydrops:
- *Severe anemia:* α-thalassemia, G6PD deficiency
- Renal malformations, e.g. agenesis, polycystic disease
- Pulmonary aplasia/hypoplasia
- *Intrauterine infections:* Syphilis, CMV
- *Chromosomal:* Down syndrome
- Placental AV malformations

bilirubin levels and consequent neurotoxicity, i.e. *kernicterus*. Other complications, e.g. hypoglycemia, CCF are common.

Hydrops fetalis: Most severe presentation, is characterized by—(a) severe anemia, (b) generalized anasarca with ascites/pleural effusion and (c) hepatosplenomegaly *at birth.* Most cases die *in utero* or soon after birth and must be differentiated from other causes of non-immune hydrops fetalis **(Table 12.39)**.

Diagnosis rests on Rh-group setting (Rh +ve baby born to Rh-ve mother), though the severity of hemolysis and extent of hyperbilirubinemia should be monitored both, antenatally as well as postnatally.

Antenatal assessment of severity is indicated in high-risk Rh-ve mothers with history of previous transfusions, abortions, stillbirths or Rh +ve delivery. This requires periodic estimation of maternal anti-D titers. Those with high titers need assessment of *optical density of amniotic fluid*, from 24th week onwards, every 2–3 weeks. An optical density difference of >0.1 from previous value *or* consistent rise on consecutive analysis, indicate severe hemolysis.

At the time of birth, cord blood should be collected in all babies of Rh–ve mothers, for grouping, Hb/Hct, direct Coombs' test and S.bilirubin levels. A positive direct Coombs' test confirms the diagnosis, though it may be false –ve, if sample is contaminated by Wharton's jelly.

Postnatally, symptomatic cases should be monitored by serial Hb, Hct and S. bilirubin levels, to decide the severity and further management. *Peripheral smear is another indicator of on-going hemolysis, showing reticulocytosis, normoblasts and other immature cells.*

Prevention of Rh-HDN involves:
- Pre-conceptional counseling with Rh-testing,
- Avoid mismatch transfusions in Rh –ve mothers,
- Anti-D immunoglobulins to mother within 72 hours of each delivery/abortion.

Although the dose of anti-D depends on the extent of expected feto-maternal leak, 250 mg is usually enough to protect against most cases with ~10 ml of feto-maternal hemorrhage.

Management of Rh-HDN aims to prevent: (a) severe anemia, and (b) bilirubin toxicity, e.g. kernicterus.
- ***Antenatal management*** of severe intrauterine HDN involves repeated fetal transfusions of 50 ml Rh-ve packed RBCs, via cordocentesis under USG guidance, till delivery.
- ***Postnatal management*** depends on the severity of hyperbilirubinemia, using two important interventions-phototherapy or exchange transfusion, discussed later in this chapter.

Apart from critical bilirubin levels **(Table 12.44)**, *early exchange transfusion* is also indicated in Rh-HDN with—(a) cord bilirubin >5 mg/dl, (b) Cord Hb <10 mg/dl, (c) bilirubin rise >1 mg/dl/hr despite phototherapy, and (d) S. bilirubin >20 mg/dl at any age.

Intravenous immunoglobulin (0.5–1.0 g/kg/dose; repeat in 12 hr) is a useful adjunctive therapy to phototherapy in Rh-HDN to reduce the need for exchange transfusion.

ABO-Hemolytic disease (ABO-HDN) is emerging as a major cause of neonatal hyperbilirubinemia after relative control of Rh-HDN by anti-D prophylaxis.

Pathogenesis: Isohemagglutinin IgG antibodies are nearly always present in mothers against the ABO antigen, which is absent on her own RBCs (Group 'O' mothers have both anti-A and B antibodies, while group 'A' and 'B' mothers have anti-B or anti-A antibodies respectively). When a fetus with different ABO group is conceived, these IgG antibodies cross placenta to cause hemolysis of fetal RBCs. However, as there is no active stimulation of maternal antibody production unlike Rh-HDN and only pre-formed antibodies are transferred, hemolysis is less severe. Although ABO incompatibility is present in >25% deliveries, only <10% manifest clinically.

Clinical manifestations are most severe in settings of 'O' mother and 'A' or 'B' baby. ABO-HDN is more common in females and more severe in first-born baby. *Unlike Rh-HDN, Severity of ABO-HDN tends to decrease in subsequent deliveries.* Jaundice usually appears after 24 hours, peaks less than in Rh-HDN and phototherapy is often enough, with less need for exchange transfusions.

Diagnosis depends on feto-maternal ABO mismatch and signs of hemolysis on peripheral smear. Direct Coombs' test is negative.

Management is same as for Rh-HDN or other causes of indirect hyperbilirubinemia, guided by serum bilirubin levels.

Breast milk jaundice is seen in ~2% of breastfed babies, who are otherwise healthy.

Etiology: Exact etiology of breast milk jaundice is unclear, though probably relates to: (a) Presence of *3–20β pregnanediol*, unsaturated fatty acids or unknown substances in human-milk, which inhibit hepatic conjugation; or (b) increased enterohepatic circulation, due to presence of β-*glucuronidase* in breast milk.

Clinically these newborns are otherwise *fullterm, healthy and active*. Jaundice develops during first week of lifelike

physiological jaundice but rather than disappearing by 7–10 day, it deepens gradually to peak by 2–3 weeks (max S. bilirubin as high as 10–30 mg/dl), followed by gradual reduction and disappearance by 3–12 weeks, even if breastfeeds are continued.

Diagnosis depends on exclusion of other causes and *typical* healthy, active baby, despite deep jaundice. In a suspected case, it may be confirmed by temporary stoppage of breastfeeds, which brings down the bilirubin levels rapidly with 48–72 hours. These levels may rise again on subsequent resumption of breastfeeding, albeit marginally and less than previous values.

Management: No specific management is required and breastfeeding should be continued even if bilirubin levels reach 20 mg/dl, though phototherapy may be necessary. Supplementing breastfeeds with top-feeds is not advisable, as mixed feeding is known to cause further rise in bilirubin.

Crigler-Najjar syndrome is an inherited enzyme defect, characterized by non-hemolytic unconjugated hyperbilirubinemia due to *Glucuronyl Transferase deficiency.*

- ***Type I** defect* (autosomal recessive), presents with rapidly progressive hyperbilirubinemia since birth and no response to phenobarbitone therapy.
- ***Type II** defect* (autosomal dominant) is a milder variant, which presents at any age with mild persistent icterus and unconjugated bilirubinemia. Family history is common. Unlike type I, These cases show rapid decline in bilirubin levels with oral phenobarbitone therapy (3–5 mg/kg/day).

Diagnosis should be considered in any case of unconjugated hyperbilirubinemia in newborn or infant, without evidence of hemolysis or infection. Enzyme estimation is diagnostic, though not easily available.

Management of type I disease is same as for other causes of unconjugated hyperbilirubinemia, i.e. phototherapy/exchange transfusion, depending on bilirubin levels. Type II disease may be controlled by long-term phenobarbitone therapy, with good prognosis.

Drug-induced jaundice in newborns may be caused by:

- Increased hemolysis and bilirubin production in G6PD deficiency (*antimalarials*),
- Displacement of conjugated bilirubin from binding sites (*sulphonamides, salicylates*),
- Competitive inhibition of Y-receptor proteins (*vitamin K*) or UDPGT (*aminoglycosides, chloramphenicol*),
- Damage to normal gut flora (*neomycin*).

Management of Unconjugated Hyperbilirubinemia

Management of unconjugated hyperbilirubinemia. Irrespective of the cause, primarily aims to keep free indirect bilirubin levels within the safe-limits of neurotoxicity, till spontaneous decline in hemolysis and maturity of liver functions. However, these *safe-limits* are not well-defined and depend on the gestational age, birth weight and co-existing problems that impair blood–brain barrier **(Table 12.45)**.

Important measures to facilitate bilirubin excretion or limit indirect hyperbilirubinemia include: (a) Phototherapy, (b) exchange transfusion, and (c) ancillary measures, discussed as follows:

I. Phototherapy is most widely used method to prevent/treat unconjugated hyperbilirubinemia and avert the need for exchange transfusion.

Principle: In phototherapy, an icteric newborn is exposed to a specific band of light frequency (425–475 nm) that leads to *photo-isomerization* of neurotoxic unconjugated bilirubin (present in skin) to non-toxic isomers, which are then excreted through normal channels. Phototherapy also reduces bilirubin levels by *photo-oxidation* as well as by enhancing *hepatic excretion* of unconjugated bilirubin into intestinal lumen.

Indications for phototherapy depends on total serum bilirubin (TSB) levels and the anticipated risk for neurotoxicity, which itself depends on the gestation, postnatal age and other risk factors **(Table 12.40)**.

American Academy of Pediatrics (2022) has recently updated separate cut-off for TSB levels in infants of different gestations 23 weeks onwards to initiate phototherapy, with or without neurotoxicity risk factors, i.e. presence of haemolytic disease, sepsis, low albumin levels <3 gm/dl, etc. and significant clinical instability in preceding 24 hours.

Procedure: Phototherapy is provided by prolonged exposure of baby to the specified frequency of photoemittance under an overhead *phototherapy unit*, usually using LED lamps at present. Important pre-requisites for effective phototherapy are:

- Light source should provide an irradiance of >30 µW/cm^2/nm within the 460–490 nm range, at the level of baby's skin (monitor with *flux meter)*. The source should also be covered with a perplex shield to cut-off harmful infra-red rays.
- Distance between baby and light source must be ~ 30–45 cm.
- Baby should be fully uncovered except eyes and genital region, to avoid radiation injury to sensitive organs. Double surface and triple surface phototherapy units are available with marginal benefits.
- Adequate breastfeeding is *must* to avoid dehydration due to insensible losses. Add 20% extra fluids to maintenance requirements, if baby is on IV fluids.
- Phototherapy is given continuously, except during BF, with intermittent bilirubin monitoring. *Intermittent Phototherapy* for 6–8 hours (with 2–3 hours gap) though

as effective as continuous phototherapy, carries potential risk of more DNA damage.
- Monitor body temperature every 2–4 hourly and TSB levels every 12–24 hours.
- Stop phototherapy only when two TSB values are below the cut-off point, though clinical monitoring should continue to check for rebound hyperbilirubinemia.

Exposure to sunlight is not an alternative to phototherapy and may be harmful due to prolonged exposure to UV rays.

Modifications to increase effectiveness of the PT include:
- *Double surface phototherapy* to expose front as well as back surface of the baby, allows faster reduction in bilirubin levels.
- *Intensive phototherapy*, i.e. lesser distance between light source and infant (15–20 cm), may be more effective.
- *Intermittent phototherapy* for 6–8 hours (with 2–3 hours gap) is as effective as continuous phototherapy, though with potential risk of more DNA damage.

Effectiveness of phototherapy depends on: (a) initial bilirubin levels, (b) surface area of exposed skin, (c) gestation/weight of baby, and (d) quality and distance from the light source. Although riboflavin supplements appear to increase its effectivity, it is not commonly used due to probable risk of DNA toxicity.

Complications: Although phototherapy is a safe and non-invasive intervention, following complications may develop in some cases:
- Dehydration due to insensible water loss,
- Loose-green stools due to bilirubin catabolites,
- Hypo/hyperthermia,
- Phototherapy rash,
- Bronze skin discoloration, if erroneously given to a case of conjugated hyperbilirubinemia, due to formation of an isomer - *bilifuscin*;
- Late effects due to cellular damage to eyes, genitals (sterility) and skin (cancers).

II. Exchange transfusion is the most effective method to reduce indirect bilirubin levels, indicated only in severe hyperbilirubinemia.

Principle: Exchange transfusion aims to: (a) remove partially hemolysed, antigen-coated RBCs as well as unattached antigen from recipient's circulation, (b) replace them by unsensitized donor's RBCs, and (c) reduce circulating bilirubin metabolites.

Indications for exchange transfusion include critical TSB levels **(Table 12.40)**, though pre-emptive exchange transfusion may also be considered if *cord bilirubin is > 5 mg/dl or rising at the rate of > 1 mg/dl/hour despite phototherapy*.

American Academy of Pediatrics (2022) has recently updated separate cut-off levels for total serum bilirubin in infants of different gestations 23 weeks onwards to consider exchange transfusion, with or without neurotoxicity risk factors.

TABLE 12.40: Cut-off unconjugated bilirubin levels for phototherapy and exchange transfusion (mg/dl)*

	Phototherapy	**Exchange**
Uncomplicated fullterms *(according to age)*		
<24 hours	Any	–
25–48 hours	12–15	20–25
49–72 hours	15–18	25–30
>72 hours	17–20	25–30
Preterms/sick fullterms** *(according to birth weight)*		
<1000 gm	Any	10–12
1000–1500 gm	7–9	12–15
1500–2000 gm	10–12	15–18
>2000 gm	13–15	18–20

*Lower values of range indicate *need to consider*, while higher value indicate *absolute need for intervention*.
**For example, asphyxia, sepsis, hypoglycemia

Exchange transfusion is also used for other indications, e.g. severe septicaemia, severe anemia with CCF and severe polycythemia (Hct >65) as well as to remove toxins in some cases of inborn errors of metabolism, e.g. hyperglycinemia.

Choice of Blood
- *Rh-HDN:* Rh-ve blood with ABO group of *baby*, *or* O-ve blood cross-matched with *mother and baby.*
- *ABO-HDN:* 'O' Rh specific (with low anti-A or B-titers)
- *Other indications:* ABO and Rh group of *baby*.

Volume of exchange: Usually double of the baby's blood volume (80 ml/kg) needs to be exchanged for effective results, which replaces >85% of baby's blood and brings down bilirubin levels to ~ 50% of pre-exchange values.

Route: Usually umbilical vein is cannulized for exchange transfusion due to its size, though peripheral veins may be used, if umbilical cannulation is not possible or umbilical sepsis is present. Normally, umbilical vein may be cannulized till 5–7 days.

Methodology: While detailed discussion is beyond the scope of this book, basic steps include:
- Obtain a free-flowing venous access and connect with a three-way cannula,
- Draw 10 cc of baby's blood for pre-exchange serum bilirubin and electrolyte levels.
- Withdraw 10–20 ml aliquot of baby's blood and then replace it with equal volume of donor's blood. Repeat the cycles till desired volume is exchanged.
- Monitor for complications. After each 50 ml exchange, 1 ml 10% calcium gluconate should be infused if ACD/CPD blood is used, to prevent bleeding tendency.
- Send last baby's blood sample at the end of exchange transfusion, for post-exchange bilirubin/electrolyte estimation.

Complications: Exchange transfusion needs expert hands and common complications include:

- *Metabolic:* Hypocalcemia, hypoglycemia, acidosis
- *Infections:* Umb. sepsis, peritonitis, septicemia, NEC
- *Traumatic:* Cord bleeding, catheter injury
- *Volume overload*
- *Hypothermia*
- *Late anemia*, due to shorter life-span of infused RBCs that necessitates top-up transfusion.

III. Ancillary measures: Following measures, though of limited efficacy, are useful adjunct to phototherapy/exchange transfusion in neonatal hyperbilirubinemia:

- *IV albumin* infusion (0.5 gm/kg) to bind free bilirubin, which is neurotoxic.
- *IV immunoglobulins* (0.5–1.0 gm/kg over 2–4 hours to reduce immune mediated hemolysis in Rh-HDN due to blocking the Fc receptors of reticuloendothelial cells which destroy antibody coated RBCs.
- *Adequate breastfeeding* to facilitate growth of gut flora.
- *PO bilirubin-binders*, e.g. agar, to prevent enterohepatic circulation.
- *Management of BBB impairing conditions*, e.g. hypoxia, acidosis and sepsis.
- *Avoidance of drugs*, known to displace bilirubin from albumin-binding sites, e.g. sulfa-drugs.
- Other modalities with equivocal results include use of phenobarbitone as microsomal enzyme inducer to enhance the conjugation of bilirubin, and synthetic metalloporphyrins to competitively inhibit heme oxygenase—a limiting enzyme for bilirubin synthesis. Use of oral bilirubin binders, e.g. agar, to prevent enterohepatic circulation is of limited value.

12.14.4 KERNICTERUS

Kernicterus is the rare but most severe complication of bilirubin toxicity in indirect hyperbilirubinenia, characterized by acute neurological signs mainly involving *extrapyramidal system*, with high mortality or long-term sequelae.

The term *"Bilirubin encephalopathy"* or *"Bilirubin-induced neurological dysfunction"* (BIND) is also used to encompass wider range of clinical presentations of bilirubin toxicity, including kernicterus.

Etiopathogenesis: Bilirubin is neurotoxic. However, following factors determine risk of kernicterus:

- *Severity of bilirubinemia:* Kernicterus develops only after a critical serum bilirubin level has reached.
- *Type of bilirubin:* Conjugated bilirubin is not neurotoxic, as it is water-soluble and does not cross BBB. In contrast, unconjugated bilirubin is fat-soluble and readily crosses the BBB, to cause neurological damage.
- *Albumin binding of unconjugated bilirubin:* In plasma, unconjugated bilirubin is circulated in free form as well as albumin-bind form. Only free-form is neurotoxic.
- *Integrity of BBB,* which may be damaged by hypoxia, acidosis and sepsis to permit bilirubin crossing at lower serum levels and development of kernicterus.

Fig. 12.17: **Kernicterus.**

Pathology: Entry of free unconjugated bilirubin into brain leads to selective and irreversible destruction of neuronal cells. *Basal ganglia is the primary site of bilirubin staining/toxicity*, apart from dentate nucleus, auditory nucleus and hippocampus.

Clinically, kernicterus presents with following features in a deeply icteric baby:

- ***Early kernicterus*** (stage I) during first 24–48 hours, with poor sucking, lethargy and high-pitched shrill cry. These features indicate impending bilirubin encephalopathy and need for exchange transfusion, irrespective of bilirubin levels.
- ***Established kernicterus*** (stage II) with generalized hypotonia/rigidity, depressed Moro's and other neonatal reflexes, *sun-set sign* (visible upper sclera due to persistent downward gaze), opisthotonus and seizures **(Fig. 12.17)**.
- ***Terminal kernicterus*** (stage III) with generalized hypotonia, absence of cry and stupor in deeply icteric baby.

Mortality and risk of long-term neurological damage is very high in stage II/III disease, despite exchange transfusion, as irreversible neurological damage has already occurred.

Late complications of kernicterus include—(a) *cerebral palsy*, usually of choreo-athetoid or extra-pyramidal type, (b) sensory-neural *deafness*, and (c) *mental retardation* or learning disabilities. Brownish discoloration of teeth is common in severe neonatal hyperbilirubinemia.

Management: Prevention is the key of management in kernicterus with early phototherapy and exchange transfusion in indirect hyperbilirubinemia and prompt treatment of BBB impairing factors. However, once the neurological damage has developed, it is irreversible and management aims to improve quality of life.

12.14.5 NEONATAL CHOLESTASIS

Neonatal cholestasis, i.e. persistent elevation of conjugated bilirubin > 1 mg/dl or (> 20% of total serum bilirubin if it exceeds > 5 mg/dl) beyond 14th day of life, denotes inadequate excretion of conjugated bilirubin from hepatocytes into duodenum.

Etiology: Depending on the site of obstruction, neonatal cholestasis may be divided into: (a) neonatal hepatitis, (b) intrahepatic biliary atresia (IHBA), and (c) extrahepatic biliary atresia (EHBA)

While ~30–40% cases are idiopathic, two most common basic pathogenic mechanisms for neonatal cholestasis are *virus-induced liver cell injury* and *metabolic liver disease* **(Table 12.41)**.

It appears that neonatal hepatitis and EHBA are different manifestations of same pathological process, the difference being the timing of insult. Hepatic injury in early fetal life probably leads to EHBA, while late disease presents as neonatal hepatitis.

Clinically, these cases present with:

- Progressive obstructive jaundice from 2nd week of life.
- Typical *clay-colour* stools, which may be intermittently coloured due to incomplete obstruction in neonatal hepatitis *or* shedding of bilirubin-laden gut mucosa in stools.
- Hepatosplenomegaly with or without signs of hepatocellular dysfunction.
- Signs of primary etiology, e.g. intrauterine infections, metabolic disorders, etc.

Diagnosis rests on persistent conjugated hyperbilirubinemia with elevated S. alkaline phosphatase levels, though etiological evaluation needs USG to detect biliary tree anomalies, liver (HIDA) scan to detect excretory functions, liver biopsy and cause-specific investigations. While d/d between neonatal hepatitis and EHBA is not always easy, **Table 12.42** compares important distinguishing features of two entities.

Management of neonatal cholestasis includes: (a) general supportive measures, and (b) specific surgical interventions, e.g. modified *Kasai's procedure* for EHBA.

General Supportive therapy includes:

- *High caloric (125% of normal) low-fat, high-protein diet* with medium chain triglycerides, (e.g. coconut oil), which do not require bile acid for their absorption.
- *Fat-soluble vitamin* supplements with vitamin A (5000–25000 IU/day), vitamin D (2500–4000 IU/day), vitamin E (PO 50–400 IU/day) and vitamin K (IM 2.5 mg biweekly), along with other micronutrients in usual doses.
- *Anti-cholestatic agents*, e.g. cholestyramine (0.25–0.5 gm/kg/d q8hr) or ursodeoxycholic acid or UDCA (10–20 mg/kg/d q8hr) with/without phenobarbitone (3–5 mg/kg/d), to enhance bilirubin excretion, reduce cholesterol levels and reduce pruritis. Rifampicin 10 mg/kg/day may also be used to also reduce itching.
- *Treatment of complications*, e.g. ascites (salt/fluid restriction, diuretics) and hepatic failure.
- *Liver transplant* is the only definite treatment in severe cases, with success rate of >75% at good centers.

Some common cholestatic disorders in newborns are as follows:

Neonatal hepatitis denotes a heterogeneous group of conditions, all characterized by common histopathological features on liver biopsy, i.e. *distorted lobular architecture with massive giant cell transformation and canalicular cholestasis.*

Etiology: Nearly 40% cases are idiopathic, while remaining may be due to intrauterine infections or more rarely, metabolic disorders **(Table 12.47)**.

Clinically most of these babies are IUGR and present with slowly progressive jaundice beyond first week of life (as late as 3 months). Stools are *intermittently clay coloured*, signifying incomplete biliary obstruction.

TABLE 12.41: Neonatal cholestasis disorders

- **Intrahepatic cholestasis**
  - ***Neonatal hepatitis***
    - Idiopathic neonatal hepatitis (~50%)
    - Intrauterine (TORCH) Infections (45%)
    - Metabolic disorders (5–8%):
      - Cystic fibrosis
      - *Others:* Galactosemia, α_1-antitrypsin deficiency
    - *Others:* Hypothyroidism, total parenteral nutrition
  - ***Intra-hepatic biliary atresia (IHBA)***
    - Watson-Alagille syndrome
    - Caroli disease *(cystic dilatation of IHB ducts)*
    - Progressive familial intrahepatic cholestasis
- **Extrahepatic cholestasis**
  - Extra-hepatic biliary atresia (EHBA) (25–40%)
  - Choledochal cyst
  - Inspissated bile syndrome
  - Hypertrophic pyloric stenosis

TABLE 12.42: D/D Neonatal hepatitis *vs* EHBA

	Neo. Hepatitis	***EHBA***
Appearance	IUGR	Normal
Onset of icterus	Early	Late (>2 weeks)
Severity of icterus	Fluctuating	Progressive
Clay-Stools	Intermittent	Continuous
HSmegaly	Early	Late
U. urobilinogen	+/–	–
Alk phosphatase	↑	↑↑↑
SGOT/PT	↑↑	N/↑
α-fetoproteins	↑/N	N
IMIDA scan	Excretion	No excretion
Liver biopsy	Giant cells	Canal. hypoplasia
*Op.Cholangiogram**	Excretion	No excretion

Hepatosplenomegaly is invariably present, as also other features of intrauterine infections or metabolic disease.

Hepatic damage is usually progressive with ultimate development of *micronodular cirrhosis*, though some cases of idiopathic etiology may recover spontaneously.

Diagnosis rests on—(a) conjugated bilirubinemia, (b) liver biopsy, and (c) etiological investigations, e.g. serology for intrauterine infections, screening for metabolic errors, etc.

Management is largely supportive, as discussed earlier, unless the specific cause is identified and treatable. *Corticosteroids are of no benefit and not recommended*.

Extra-hepatic biliary atresia (EHBA) is the commonest anatomical cause of neonatal cholestasis, ~10 times more common than IHBA.

Clinical features: *Unlike neonatal hepatitis*, in EHBA: (a) most babies are apparently healthy with good birth weight, (b) stools are consistently clay-colored or 'cheesy-white' (except intermittent color due to shedding of bilirubin-laden gut mucosa), and (c) associated malformations, e.g. intestinal atresia, dextrocardia or polysplenia may be present. Untreated cases progress rapidly to develop biliary cirrhosis, as early as by 8th week of life.

Diagnosis rests on: (a) consistent rise in direct bilirubin and serum alkaline phosphatase levels, (b) USG for anatomical biliary tree status, (b) liver (HIDA) scan to demonstrate poor hepatic excretion, and (c) *confirmatory per-operative cholangiography.*

On biopsy, presence of ductal/ductular proliferation, ductular bile plug and fibrosis are more suggestive of EHBA than neonatal hepatitis.

Management: *Modified Kasai's procedure* (hepato-portoenterostomy) is the surgery of choice in EHBA, to use minute bile duct remnants in fibrous tissue of porta hepatis for bile drainage, which may be in direct continuation of intrahepatic ductules.

Success of the surgery depends on its timing, extent of bile-duct remnants and pre-existing liver damage. These cases must be operated as soon as possible to prevent irreversible hepatic damage. Kasai's procedure is successful in >80% cases if performed before 8th week, though long-term outcome is poor due to secondary complications, e.g. cholangitis.

Intra-hepatic biliary atresia (IHBA) is less common than neonatal hepatitis and EHBA. Among various types of IHBA, the commonest is ***Watson-Alagille syndrome,*** characterized by:

a. *Typical facial dysmorphism* with prominent forehead, hypertelorism, anti-mongoloid slant of eyes and flat nasal bridge,
b. *IHBA* with direct hyperbilirubinemia that usually presents later than EHBA/neonatal hepatitis (3rd–4th week), and
c. *Co-anomalies*, e.g. pulmonary stenosis, vertebral arch defects and tubulointerstitial nephropathy.

Treatment is largely supportive and long-term survival is relatively better than in EHBA, though pruritis, xanthomas and malabsorption is common.

Inspissated bile syndrome is usually a consequence of Rh-HDN, due to clogging of bile canaliculi by thick viscid bile, containing large amount of bile pigment.

Clinically, these cases present with persistent conjugated hyperbilirubinemia following severe hemolysis in neonatal period, which gradually recovers in next few months without any treatment.

12.15 PERINATAL INFECTIONS

Infections are major cause of perinatal morbidity, responsible for >40% neonatal deaths in India. Newborns are highly susceptible for infections due to immature defense mechanisms **(Table 12.43)** as well as exposure to variable bacterial flora during delivery or postnatal stay in the hospital. Various diagnostic/therapeutic interventions in intensive care units are further source of nosocomial infections in sick babies. Interestingly, male newborn is more prone for infections, perhaps due to possible locus of gene for immunoglobulin synthesis on X chromosome (?).

12.15.1 SUPERFICIAL NEONATAL INFECTIONS

Superficial skin infections, discussed in this section, are not only more common, but also serves as a portal of microbial entry for serious deep-seated infections or septicaemia

Umbilical sepsis *(omphalitis)* is one of the commonest superficial infection and potential source of septicaemia in newborns.

Etiologically, umbilical sepsis is usually due to *Staph. aureus* or *E.coli*, depending on local nursery profile and antiseptic practices.

Clinically, it presents with—(a) purulent, foul-smelling discharge, (b) peri-umbilical redness and induration, and (c) delayed separation of stump >7–10th day **(Fig. 12.18)**.

TABLE 12.43: Immature host-defenses in newborn

- Immature skin/mucus membrane barriers
- Immature physiological clearance, e.g. cough
- Immature immune mechanisms
  - Poor phagocytosis for innate immunity
  - Low IgM and secretory IgA levels*
  - Low IgG in preterms**
  - Low complement/opsonin activity
  - ↓ NK-cell activity
  - Lack of specific acquired immunity
- Antibiotic/drug therapy altering normal flora

*Only IgG is transferred transplacentally,
**as IgG transfer is maximum in last trimester.

Fig. 12.18: **Umbilical sepsis.**

Complications: Untreated umbilical sepsis may lead to three important complications: (a) local abdominal cellulitis, (b) neonatal septicemia, and (c) portal vein thrombosis, with extrahepatic portal hypertension in later life.

Diagnosis is clinical though umbilical swab should be sent for microbial diagnosis. However, a positive culture from umbilical site without clinical signs of sepsis indicates colonization and needs no treatment. However all cases need sepsis screening (*see* **Table 12.45**) to exclude neonatal septicaemia.

Treatment: Mild, uncomplicated umbilical sepsis only requires periodic cleaning of the discharge with a sterile wet/alcohol gauze, followed by topical application of an antibiotic (neomycin or bacitracin) or 0.5% gention violet 6-hrly.

Systemic antibiotics are indicated only in cases with severe umbilical sepsis or suspected neonatal septicemia. Umbilical catheterization should never be attempted in cases with umbilical sepsis.

Prevention of umbilical sepsis includes: (a) general maternal/neonatal hygiene, to reduce pathogenic colonization, (b) hand washing by nursery personnel before handling the baby.

Conjunctivitis *(ophthalmia neonatorum)*: Slight sticky eye discharge is common during first few days of life, which clears spontaneously and needs no treatment except intermittent cleaning with sterile wet cotton. However, presence of persistent/purulent discharge indicates neonatal conjunctivitis.

Etiologically, neonatal conjunctivitis is caused by organisms from: (a) maternal birth canal, e.g. *N. gonorrhoeae* or *C. trachomatis*, *or* from (b) hospital environment, e.g. *pseudomonas* or *staphylococci*, i.e. nosocomial conjunctivitis.

Clinically, gonococcal conjunctivitis presents within first 48 hours, chlamydial conjunctivitis after 5th day (usually unilateral) and nosocomial conjunctivitis at any age (usually purulent). Severity may vary from superficial conjunctivitis to secondary complications, e.g. keratitis, iridocyclitis and panophthalmitis.

Diagnosis is clinical, though gram staining and culture of discharge as well as microscopic examination of scrapping from tarsal conjunctiva (inclusion bodies in chlamydial disease) is essential for rational therapy.

Treatment: Regular eye wash with warm saline and topical antibiotics (Erythromycin 0.5% or Chloramphenicol 1.0%) are enough for mild conjunctivitis, while severe cases need organism-specific systemic antibiotics. A single dose of IV/IM ceftriaxone 25–50 mg/kg at birth is enough for gonococcal conjunctivitis while chlamydial infection must be treated with oral Azithromycin 20 mg/kg OD for 3 days, along with local eye irrigation. Topical antibiotic drops, e.g. Tobramycin is required in cases of other bacterial conjunctivitis.

Crede's method to instill 1% silver nitrate in eyes at birth to all newborns to prevent gonococcal conjunctivitis is no longer practiced due to low incidence and risk of chemical conjunctivitis.

Pyoderma are usually *staphylococcal* in origin and commonly seen over scalp, neck, groin, back and axilla in newborn. Occasionally, the focal lesion may spread *locally* to form abscess, cellulitis or pemphigus neonatorum (extensive bullous lesions with exfoliation) or *hematogenously* to cause neonatal septicemia or deeper infections, e.g. osteomyelitis.

Uncomplicated pyoderma may be punctured for gram staining/culture of pus, followed by topical antibiotics, e.g. *mupirocin*, 2–3 times a day. Systemic antibiotics are indicated only in extensive superficial lesions with cellulitis/abscess *or* suspected septicemia.

Oral thrush, due to transient and self-limiting *C. albicans* infection is very common even in normal newborns. Infection is usually acquired during passage from infected birth canal or from a nosocomial source.

Clinically, *oral thrush* presents as a white, adherent plaque with erythematous base on oral mucosa, tongue and palate that leaves punctate areas of bleeding on removal. *Invasive candidiasis* may develop in extreme preterms, critically sick newborns or after prolonged antibiotics.

Diagnosis is clinical, to be differentiated from *milk patch*—easy removable without leaving bleeding points.

Treatment includes topical application of antifungal agents, e.g. miconazole, clotrimazole, nystatin (2 lac U/5 ml glycerine) or 0.5% gention violet. Systemic antifungal therapy is not required for superficial candidiasis.

Napkin rash is a common problem associated with use of synthetic diapers, due to contact dermatitis, chemical irritation by urine/stools, and occasionally, secondary infection, e.g. candidiasis.

Clinically, it presents with well-demarcated confluent erythema over diaper region. Presence of red satellite pustules indicates candidal infections.

Management: Napkin rash is easily preventable by use of cotton diapers and frequent change of diapers to avoid excessive wetness and skin maceration. Uncomplicated cases respond well to topical application of coconut oil or a bland ointment, e.g. zinc calamine, while those with suspected candidal infection need topical antifungals, e.g. clotrimazole/miconazole. Mild steroid cream, e.g. clobetasone, may be used on acute irritating lesions.

Noma neonatorum (cancrum oris) is a rare but serious anaerobic infection in newborns (and in severely malnourished infants), characterized by acute, *rapidly progressive gangrene of buccal mucosa* that rapidly turns into perforating cheek ulcer. Secondary infection with pseudomonas is common.

Diagnosis is clinical and therapy includes intensive antibiotic therapy, though reconstructive plastic surgery is required in survivors.

12.15.2 NEONATAL SEPTICEMIA

Neonatal septicemia is a clinical diagnosis with *features of sepsis with or without positive blood/CSF cultures during first month of life*.

According to the time of onset, it may be divided in *early onset sepsis* (EOS) manifesting <72 hours of delivery *or late-onset sepsis* (LOS), with different predisposing factors and microbial etiology.

Risk factors: Neonatal sepsis is the commonest cause of neonatal mortality in India, with an estimated incidence of ~2–10%, depending on risk factors **(Table 12.44)**. Premature rupture of membranes, foul-smelling liquor amnii and complicated delivery with neonatal resuscitation are most important risk factors for EOS, while LOS is predominantly associated with prematurity/low birth weight, umbilical sepsis and nosocomial infections.

Table 12.44: Risk factors for neonatal septicemia

Early-onset sepsis
- ***Maternal factors***
  - Maternal fever <14 days before delivery
  - Foul smelling/meconium stained L. amnii
  - Prolonged rupture of membranes >24 hours
- ***Obstetrical factors***
  - Prolonged, difficult or instrumental delivery
  - Repeated unclean vaginal examinations

Late-onset sepsis
- ***Neonatal factors***
  - Preterm or small-for-date delivery
  - Superficial infections, e.g. umblical sepsis
  - Postnatal (milk) aspiration
- ***Nosocomial factors***
  - Neonatal resuscitation procedures
  - Invasic Intensive care procedures
  - Prolonged antibiotic therapy

Microbial etiology depends on the source and timing of infection.

EOS is usually caused by maternal flora of the genital tract, e.g. *E. coli, Klebsiella, Enterobacter, Listeria,* etc. Group B streptococci—the commonest cause of EOS in developed countries, is relatively uncommon in India.

LOS is usually a nosocomial infection due to organisms prevalent in hospital environment, e.g. *Staph. aureus, Klebsiella, Pseudomonas, Acinetobacter, enterococci, coagulase negative staphylococci* (CONS), etc. Fungal infections (*C. albicans*/non-albicans) are emerging as important cause of nosocomial LOS in NICUs.

Microbial profile of neonatal septicemia also depends on locally prevalent flora and infection-control practices. In general, *Klebsiella (~30%), S. aureus (~15%) and pseudomonas (~15%) are common pathogens in India*, with rising incidence of acenobactor, enterococci and CONS.

Clinical presentation of neonatal sepsis extends from silent bacteremia to multi-organ dysfunction, though most cases present with:
- ***Early clinical indicators***, e.g. refusal to feed, sluggish activity or irritability, excessive or high-pitched cry, respiratory distress or apneic spells, seizures, diarrhoea and/or vomiting.
- ***Signs of systemic stress,*** e.g. hypothermia, sclerema, pallor, cold-clammy skin, circumoral cyanosis, exaggerated icterus and purpuric spots. Peripheral perfusion may be poor with capillary filling time exceeding 3 seconds.
- ***Signs of localized infection***, e.g. umbilical sepsis or pyoderma, pneumonia, meningitis (~20–30%), necrotizing enterocolitis and bleeding diathesis, e.g. DIC. Pneumonia and meningitis is more common in EOS and LOS respectively.

Diagnosis of neonatal septicemia usually rests on clinical suspicion and presence of high-risk *factors.*

However, laboratory confirmation requires:
- ***Indirect evidences,*** e.g. peripheral smear, are useful screening tests for early diagnosis of neonatal septicemia. A combination of indirect evidences is often termed *sepsis screen* **(Table 12.45)**, with specificity

Table 12.45: Sepsis screen in newborns

- **Hematological findings (criteria)**
  - Leukopenia (<5000 cells/mm^3)
  - Absolute neutropenia (<1800 cells/mm^3)
  - Immature (Band) cell count >20% (I:T Ratio > 2)
  - Thrombocytopenia <1,00,000 cells/mm^3
- **Positive acute phase reactants**
  - C-reactive protein (CRP) >8 mg/L
  - Micro ESR > 15 mm/FHR

I:T ratio: Immature to total neutrophil count ratio.

and sensitivity of >90%, if at least two parameters are fulfilled. Two negative sepsis screens 24 hours apart, practically exclude neonatal sepsis. CRP alone has a sensitivity and specificity of 87% and 83% respectively.

- ***Direct evidences,*** i.e. positive culture from blood, CSF, pus, etc. is the gold standard for diagnosis of neonatal sepsis. However, a sterile culture does not exclude the diagnosis, specially if empirical antimicrobial therapy was started before sample collection. BACTEC radiometry, though costly, is very useful for earlier microbial identification than conventional culture.
- ***Antigen-detection tests*** (Latex-agglutination test, ELISA) or polymerase chain reaction (PCR) are specially useful to identify causative pathogens in culture-sterile cases.
- ***Evidence of focal infections,*** e.g. abnormal CSF findings, urine-analysis, pus cells in umbilical discharge, gastric wash, etc. *CSF examination is indicated in all cases of severe sepsis,* though reports should be interpreted carefully, as newborns, specially preterms, have higher protein and cell content in CSF, than in older children.

Management of neonatal septicemia may be divided into antimicrobial therapy and supportive management.

- ***Antimicrobial therapy*** should be started empirically after collection of cultures and modified after culture/sensitivity reports. Choice for empirical therapy may vary in different centers, based on local flora and sensitivity patterns **(Table 12.46)**. In all cases, antibiotics should be given via IV route and continued for minimum 10 days in cases without meningitis and for minimum 21 days in presence of meningitis.
- ***Supportive therapy*** depends on individual needs and includes:
  - Maintenance of temperature with warmer care,
  - Oxygen/ventilatory support
  - Circulatory support with IV fluids, volume expanders (blood/plasma) and vasopressors.
  - Fluid and electrolyte correction
  - Adequate oral or parenteral nutrition
  - Treatment of complications, e.g.
    - Hypoglycemia (IV dextrose 10% 2 ml/kg stat)
    - Apneic spells (stimulation, aminophylline)
    - Hyperbilirubinemia (phototherapy/exchange)
    - Bleeding tendency (vitamin K, FFP, platelets)
    - Seizures (anticonvulsants)
  - Surgical interventions, e.g. drainage of pus, etc.

Role of immunoglobulins and exchange transfusion in neonatal septicemia is controversial but may be useful in some critically sick cases.

Prevention of neonatal septicemia involves: (a) early detection and management of high-risk factors, (b) six *"cleans"* at the time of delivery (*clean hands, clean delivery surface, clean perineum, clean blade to cut the cord, clean/dry cord and clean towels),* and (c) prevention of nosocomial infections.

Role of prophylactic antibiotics is controversial though may be indicated in presence of high-risk factors for neonatal septicemia. However, intrapartum antibiotic prophylaxis with a single dose Penicillin or cefazolin, 4 hours before delivery is indicated to prevent GBS sepsis in cases of PROM, maternal fever and antenatal GBS colonization in rectovaginal swabs.

Listeriosis (L. monocytogenes) is an emerging cause of meningitis/septicemia in newborns (or immunodeficient children). It is primarily an epizootic infection, transmitted to humans via consumption of infected animal products, e.g. milk or faeces-contaminated vegetables. *Maternal listeriosis* is asymptomatic, but with higher risk of abortion, stillbirth or premature delivery.

Neonatal listeriosis is acquired during delivery via infected birth-canal or as nosocomial infection and typically presents as meningitis with septicemia. *diagnosis* rests on blood and CSF cultures, along with simultaneous cultures from maternal genital tract. *Treatment* of choice is Ampicillin alone or with an aminoglycoside, followed by vancomycin in non-responders. Listeria is not susceptible to third-generation cephalosporins.

TABLE 12.46: Antimicrobial therapy in neonatal septicemia

Empirical therapy	
NS without meningitis (minimum 7–10 days)	
First-line	: Ampicillin + Aminoglycoside
Second-line	: Piperacillin tazobactam + Aminoglycoside
NS with meningitis (minimum 21 days)	
First-line	: Cefotaxime + Aminoglycoside **or** Vancomycin + Aminoglycoside
Second line	: Meeropenem + Aminoglycoside **or**
Specific therapy	
E. coli/Klebsiella	: Cefotaxime + Aminoglycoside
Pseudomonas	: Ceftazidime + Aminoglycoside
Staph. aureus	: Cloxacillin/vancomycin
Listeria	: Ampicillin

Daily IV doses in newborn (in 2–3 divided doses):
Ampicillin/Cloxacillin/Piperacillin all (100–150 mg/kg/d),
Cefotaxime/Ceftazidime/Ceftriaxone all (100–150 mg/kg)
Gentamycin (5–8 mg/kg), Amikacin (15 mg/kg),
Meropenem (120 mg/kg), Vancomycin (30 mg/kg)

12.15.3 NEONATAL NECROTIZING ENTEROCOLITIS

Neonatal necrotising enterocolitis (NEC) is a serious GIT complication in *preterm and critically sick or septic newborns*, characterized by *progressive abdominal distension, hematochezia and vomiting or retention of nasogastric feeds.*

Incidence: NEC may develop in ~3–5% of NICU cases, most common in: (a) extreme preterms (<32 weeks), and (b) critically sick newborns, e.g. birth asphyxia, sepsis, shock and acidosis. Early enteral feeding in these cases is an additional risk factor.

Pathogenesis is still evolving, but two factors are most important and inter-related:

a. *Ischemic gut mucosal injury* due to shock or hypoxia, leading to stasis and infection, and
b. *Local enteral Infection* due to early feeding or septicemia, aggravating the mucosal injury.

Irrespective of primary event, the net result is intestinal stasis and infection, further complicated by necrotizing mucosal injury, perforation and peritonitis.

Clinically, NEC usually presents on 3–4th day, with a triad of:

- Gross, tender, tympanic abdominal distension suggestive of paralytic ileus.
- Retention of nasogastric feeds (>25% of previous feed) or vomiting,
- Hematochezia, i.e. per-rectal bleeding, with/without upper GIT bleeding

In addition, systemic signs of sepsis, shock or other perinatal complications are often present.

Diagnosis is largely clinical, supported by radiological findings **(Fig. 12.19)**. *Pneumatosis intestinalis*, i.e. presence of intramural gas bubbles in intestinal wall is pathognomic radiological feature of NEC, though frequently missed. *Other X-ray features* include fixed-loop pattern, bowel-wall edema, air in portal/hepatic vein *or* pneumoperitoneum, suggestive of intestinal perforation.

Supportive investigations include stool examination for hematochezia, blood/stool cultures and other relevant investigations, e.g. serum electrolytes.

Severity of NEC may be staged (***Bell's criteria***) as:

- ***Stage I (Suspected NEC)*** with mild distension, retention of feeds/vomiting, minimal X-ray abnormality.
- ***Stage II (Definite NEC)***, with marked distension, hematochezia, absent bowel sounds and/or pneumatosis intestinalis on X-ray.
- ***Stage III (Advanced NEC)*** with DIC, shock, peritonitis and radiological signs of pneumoperitoneum or extraintestinal (portal vein) gas.

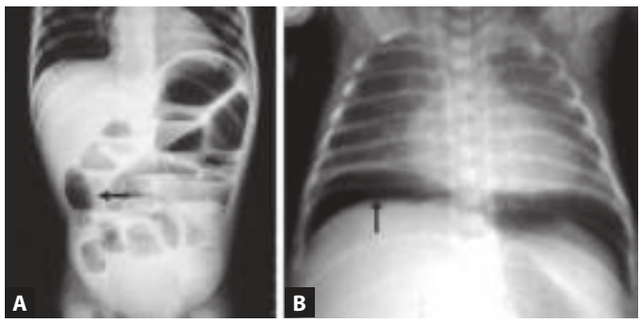

Fig. 12.19: Neonatal necrotizing enterocolitis: (A) Pneumatosis intestinalis; (B) Gas under diaphragm.

Management of these cases include:

- Management of primary causative factor, i.e. perinatal complications.
- Nil orally with continuous nasogastric drainage to rest the bowel and drain gastric secretion/bleeds.
- IV fluid therapy, to provide nutrition and maintain fluid and electrolyte balance.
- Systemic antibiotics to control infection. Local gut sterilization is not routinely indicated.
- Blood/packed cell transfusions, in cases with severe GIT bleeding.
- Constant monitoring of abdominal girth and other vital/laboratory parameters
- Surgical intervention in perforation or peritonitis.

Enteral feeding may be restarted gradually after 48–72 hours of the control of GIT bleeding, absence of abdominal distension and appearance of bowel sounds; though recurrences are not uncommon.

Outcome: With best possible treatment, mortality is nil in stage I, 5–10% in stage II and >50% in stage III disease.

12.15.4 INTRAUTERINE INFECTIONS

Term intrauterine (IU) infections denotes *in utero fetal infection, either transplacentally or as an ascending infection from maternal birth canal*.

IU infections are the commonest cause of fetal loss (abortions/stillbirths), congenital malformations and intrauterine growth retardation (IUGR) in India. While infection in first trimester usually results in fetal loss or congenital malformations, later infections cause IUGR.

Etiology: IU infections are usually viral, though may also be caused by many bacterial, protozoan and spirochetal agents **(Table 12.47)**. In clinical practice, common IU infections are popularly referred with an acronym TORCH—***T***oxoplasma Gondi, ***O***thers, ***R***ubella, ***C***ytomegalovirus disease (CMV) and ***H***erpes simplex infections.

Clinical presentation: Live born babies with IU infections usually present with following features at birth **(Table 12.48)**, though some manifestations may develop or diagnosed at a later age.

- ***History of maternal illnesses***, e.g. fever, rashes, lymphadenopathy, jaundice and vaginal lesions

TABLE 12.47: Common intrauterine infections

a.	**Viral**	Rubella, CMV, HSV, HBV, HIV Varicella, mumps, parvovirus B19
b.	**Bacterial**	Tuberculosis, gonococci gram-ve organisms, listeriosis
c.	**Spirochetal**	Syphilis
d.	**Protozoal**	Toxoplasmosis, malaria
e.	**Others**	Mycoplasma, chlamydia

TABLE 12.48: Clinical indicators of intrauterine infections

- History of maternal infection
- Intrauterine growth retardation (IUGR/LBW)
- Hepatosplenomegaly and/or Jaundice
- Purpura
- *CNS:* Microcephaly, hydrocephalus, mental retardation
- *Ocular:* Microphthalmia, cataract, chorioretinitis
- Hearing impairment
- Congenital malformations, e.g. CHDs
- *Others:* Skin rash/vesicles, pneumonia, etc.

during pregnancy is present in >50% cases, though missed frequently.

- ***Low birth weight*** *(IUGR)* is the commonest manifestation in 60–70% babies. However, babies with congenital syphilis tend to be large-sized due to hydrops fetalis.
- ***Hepatosplenomegaly*** is present in 50–60% cases, with/without evidence of active liver disease. Neonatal *jaundice* is common in Toxoplasmosis and CMV infection.
- ***Purpuric lesions*** due to thrombocytopenia are common in CMV and congenital rubella, though serious internal bleeds are rare.
- ***Meningoencephalitis,*** is usually sub-acute and presents with microcephaly (rubella or CMV), hydrocephalus (toxoplasmosis) intracranial calcifications (CMV, rubella), mental retardation and seizure disorders. Intracranial calcifications are typically periventricular in CMV and diffusely nodular in toxoplasmosis.
- ***Ocular abnormalities:*** Extrinsic abnormalities, e.g. micropthalmia, microcornea, corneal opacities and cataracts are more common in congenital rubella. Presence of uveitis or interstitial keratitis indicates CMV and congenital syphilis respectively. Chorioretinitis is present in many infections and typically *central in toxoplasmosis, peripheral with normal macula in CMV* and *salt-pepper type in rubella* infections. Chronic retinopathy may leads to optic atrophy, strabisumus and searching nystagmus in older children.
- ***Hearing impairment*** is common in congenital rubella and CMV infections.
- ***Congenital heart diseases*** are common in congenital rubella, specially PDA or sub-valvular PS.
- ***Other manifestations*** include skin vesicles in herpes simplex, rash or snuffles in congenital syphilis, pneumonia and neonatal septicemia.

Diagnosis of IU infections depends on:

- *Presence of clinical indicators* **(Table 12.48)** or antenatal history suggestive of maternal infection.
- *Non-specific cord IgM levels* of >20 mg/dl indicate possibility of IU infection and may be used as a screening test. However, it has no differentiating value between various causes.
- *Specific serology* ***(TORCH screen)*** for organism specific IgG and IgM antibodies. Single IgG titers are unreliable due to passive transplacental transfer from mother. IgM titers are more reliable and indicate actual fetal infection.
- Serodiagnosis of any IU infection requires positive IgM titers *or* IgG titers multi-fold higher than maternal values *or* rising IgG values after 3–4 weeks.
- *Isolation of specific etiological agent* by microbiology or PCR testing is confirmatory, though rarely possible.
- *Relevant investigations:* X-ray skull and long bones, e.g. knee are indicated in all cases to detect, e.g. intracranial infections (CMV, toxoplasmosis), osteochondritis, periosteal reaction, and metaphysitis in long bones (congenital syphilis), longitudinal linear radiolucent areas with increased bone density (congenital rubella).

D/D of common IU infections is given in **Table 12.49**, while some are discussed in detail, as follows.

Congenital rubella syndrome (CRS) is consequence of rubella infection in previous non-immune pregnant mothers, which produces mild viral illness in pregnant mothers, but with devastating effect on fetus. For acquired infection, *see Ch 10.18.*

Mode of infection: Fetal infection is acquired transplacentally and risk of transmission is highest (~90%) when mother is infected in first trimester. Infection beyond 20th week is rarely associated with CRS, except sensory-neural deafness.

Clinical features of CRS include—(a) IUGR, (b) neurological signs, e.g. microcephaly and mental retardation, (c) ocular signs, e.g. congenital cataract, microphthalmia, microcornea, salt-pepper retinopathy, etc., (d) sensorineural hearing loss, (e) hepatosplenomegaly with/without jaundice, (f) anemia and thrombocytopenic purpura and (g) congenital heart diseases, specially *PDA or subvalvular PS* **(Fig. 12.20)**.

Diagnosis usually rests on specific serology, i.e. (a) elevated IgM titers in cord/neonatal blood, or (b) >4-fold higher IgG titers in newborn than in mother, or (c) rising IgG titers after one month. Viral isolation from nasopharynx or urine is confirmatory, but rarely feasible.

Management: Prevention of CRS revolves around prevention of maternal infection during pregnancy by (a) MMR immunization in childhood or unimmunized women in reproductive age, (conception should be avoided at least 3 months after immunization), or (b) avoidance of contact with suspected case during pregnancy, including a case of CRS (as virus may be shed up to 1 year).

TABLE 12.49: Comparative features of important intrauterine (TORCH) infections

	Rubella	*CMV*	*Toxoplasmosis*	*HSV*	*Syphilis*
Mode of transmission	TP	TP + PP + BM	TP + PP	PP + TP	TP + PP

TP: Transplacental infection, **PP:** Peripartum infection during vaginal delivery, **BM:** Infection via breast milk,
*in primary infection during pregnancy, < 1% in recurrent infection. ** *See* text for details

Fig. 12.20: Congenital Rubella Syndrome: (A) Microphthalmia with microcornia (*Inset:* Corneal opacity); (B) Celery-stalk appearance on X-ray knee.

Accidentally exposed and unimmunized pregnant mothers should be screened serologically, immediately and after 4 weeks of exposure. Risk of CRS is negligible in seropositive mothers at the time of exposure. However, those who seroconvert after exposure have maximum risk of CRS and should be counselled accordingly. If abortion is not an option, immunoglobulin prophylaxis is advisable immediately after exposure, to reduce risk of CRS.

Cytomegalovirus disease: Neonatal CMV infection is a consequence of primary maternal infection during pregnancy with risk of transmission being ~40%. Maternal reinfection or reactivation of previous infection is unlikely to produce neonatal disease. For acquired infection, *see Ch* 10.24.3.

Mode of infection: Neonatal CMV infection may occur: (a) *in utero* during maternal viremia after primary infection in pregnancy, (b) *during delivery*, by the virus present in genital passage, or (c) *post-natally* by infected breast milk or blood products. Maternal infection in

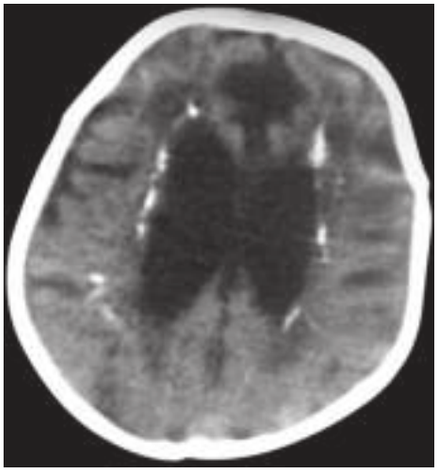

Fig. 12.21: **Periventricular calcification in congenital CMV infection.**

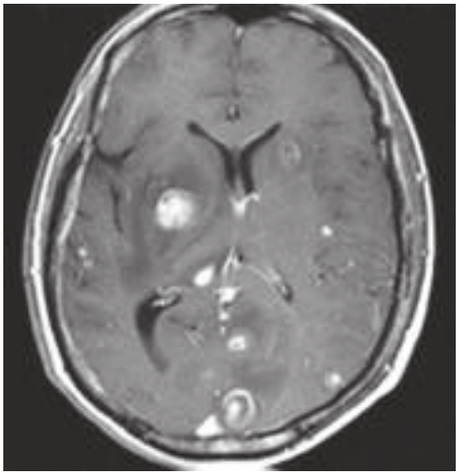

Fig. 12.22: **Diffuse intracranial calcifications and lesions in toxoplasmosis.**

early pregnancy is usually associated with more severe fetal disease.

Clinical manifestations depend on timing of infection and divided into three categories:

a. *Asymptomatic infection*, but with late developmental abnormalities (15%), e.g. deafness, mental retardation, spasticity and microcephaly.
b. *Symptomatic but not life-threatening infection*, with – (a) IUGR, (b) neurological signs, e.g. microcephaly, intracranial periventricular calcification **(Fig. 12.21)**, hearing deficit, mental retardation, etc., and (c) ocular signs, e.g. peripheral chorioretinitis without macular involvement.
c. *Acute sepsis-like manifestations* with—(i) hepato-splenomegaly, (ii) thrombocytopenic purpura, (iii) severe jaundice, and (iv) pneumonitis.

Diagnosis usually rests on serology though d*efinitive diagnosis* is possible by virus isolation or PCR testing in urine or saliva.

Treatment: *IV Ganciclovir* (6 mg/kg/dose q12hr) or PO Valganciclovir (16 mg/kg/dose q12hr) for 20 days is the drug of choice for acute manifestations, e.g. preumonitis or chorioretinitis, along with standard/hyperimmune *IVIG* (500 mg/kg/alternate day 10 doses). However, its utility in CNS disease is not established. *Foscarnet* is another alternative, under evaluation.

Congenital toxoplasmosis is a consequence of maternal infection during pregnancy, specially in last trimester. Fetal infection due to pre-pregnancy infection is extremely rare.

Mode of infection: Fetal infection is acquired trans-placentally, with risk of transmission being ~60% in last trimester infection, ~3–4 times higher than in first trimester infection.

Clinically, congenital toxoplasmosis may present with: (a) prematurity and IUGR, (b) neonatal disease with anemia, purpura, jaundice, and neurological disease, or (c) neuro-ocular sequelae of untreated infections in later life.

Characteristic features include—(a) *neurological disease* with hydrocephalus, diffuse intracranial calcifications **(Fig. 12.22)** and seizures; or (b) *ocular disease* with central choreoretinitis and secondary optic atrophy.

Diagnosis usually rests on elevated Toxo-IgM levels, though presence of tachyzoites in placenta on immuno-fluorescent staining) *or* positive CSF-PCR is confirmatory.

Treatment is of limited value in severely affected newborns, as the damage has already occurred. It should begin as early as possible and includes:

- ***Severe disease*** are treated with PO Pyrimethamine (1 mg/kg/day for 6 months than 0.5 mg/kg/day for next 6 months) and Sulfadiazine (100 mg/kg/day for 12 months, along with Folinic acid 10 mg alternate days. Steroids are indicated for 8–12 weeks in cases with acute inflammatory injury, e.g. chorioretinitis or elevated CSF protein > 1 gm.
- ***Mild or subclinical cases b***orn to a mother with definite primary infection may be treated less intensive regimens for shorter duration.

Prevention involves treatment of maternal infection during pregnancy with PO Spiromycin (2 gm/day) from 20th week onwards, along with Sulfadiazine (75 mg/kg/day) and Pyrimethamine (25 mg BD for 2 days, than OD for 7 days than biweekly). Folinic acid (5 mg bi-weekly) should be given with Pyrimethamine to prevent folic acid deficiency.

Congenital syphilis is a rarity in recent years due to early recognition and treatment of maternal disease.

Mode of infection: *Congenital syphilis* is usually acquired as transplacental infection during spirochetemia in mother, or rarely at the time of delivery through infected

TABLE 12.50: Late clinical stigmata of congenital syphilis

Bony changes (due to chronic periosteitis)
- Frontal bossing
- *Olympian brow* (prominent forehead)
- *Saddle nose* (depressed nasal bridge)
- *Perforated nasal septum* (due to snuffles)
- *Higouménaki's sign* (thick sternoclavicular joints)
- *Saber shins* (anterior bowing of Tibia)
- *Scaphoid scapula* (convex medial border)

Dental abnormalities (manifests ~6 years of age)
- *Hutchinson teeth* (barrel-shape upper incisors)
- *Notched teeth* with abnormal enamel and severe caries
- *Mulberry molars* (multi-cuspid lower first-molars)

Residual mucocutaneous lesions
- *Rhagades* (Spoke-like perioral/perianal scars)

Hypersensitivity manifestations
- Interstitial keratitis with/out corneal opacities
- *Clutton joints** (painless joint swellings)

*due to intermittent syonovitis, specially at knee

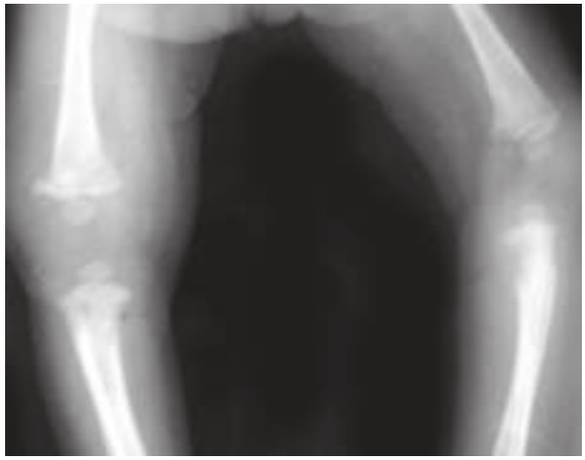

Fig. 12.23: Congenital syphilis : Periosteitis and osteochondritis at the ends of long bones.

birth canal. Infection is usually transmitted in last trimester, though spirochetes may cross placenta at any stage.

Risk of transmission is highest (~100%) in mothers with recent infection, decreases gradually and unlikely after 5 years of maternal infection.

Clinical manifestations: Early trimester infections often lead to abortions, stillbirths (40%) or hydrops fetalis due to severe anemia, while late trimester infections are often associated with *large placenta* and present as follows (IUGR is rare).

a. ***Early manifestations*** during first 2 years of life, are analogous to secondary syphilis, including Failure to thrive, generalized erythematous rash, Nasal snuffles, painful and restricted limb movements (pseudoparalysis), hepatosplenomegaly and pan/bicytopenia. Pneumonia and meningitis may be present.
b. ***Late manifestations (stigmata)*** after 5–10 years, due to chronic inflammatory changes in skin, bones and teeth, *or* hypersensitivity **(Table 12.50)**.

Diagnosis may be confirmed by dark field microscopy, FTS-ABS IgM or serial VDRL with rising titers after one week. A single VDRL titer >4 times of the mother or Positive VDRL in CSF may also be considered as diagnostic. VDRL may be false-positive in babies of infected mothers due to transplacental transfer of antibodies. *X-ray knee joint* may be diagnostic in a suspected case, showing periostitis and osteochondritis at the ends of long bones **(Fig. 12.23)**.

CSF examination is indicated in all cases for biochemistry and VDRL test, as longer penicillin therapy is required in cases with CNS involvement. However, CNS involvement is possible without CSF abnormalities.

Treatment of a baby born to VDRL positive mother depends on anticipated risk of infection. Adequate maternal therapy, if received at least 30 days prior to delivery, virtually eliminates the risk of transmission.

All other cases must be treated either with IV Crystalline Penicillin G (50,000 IU/kg/dose 8–12 hourly) *or* IM Procaine penicillin (50,000 IU/kg once a day) for 10–14 days. Longer therapy (3 weeks) is necessary in cases with CNS involvement.

Perinatal HSV infection is a consequence of primary or re-activation HSV infection in mother with active disease during pregnancy. For acquired infection, *see* Chapter 10.24.1.

Mode of infection: HSV infection is usually acquired during delivery through infected birth canal (peripartum). Rarely, baby may be infected *in utero* (<5%) or as postnatal nosocomial infection.

Clinically, peripartum infection presents with signs of active disease, e.g. typical skin/mucosal lesions (grouped vesicles), meningitis and respiratory distress during 1st week. However, early *in utero* infection may present with sequelae, e.g. microcephaly, microphthalmia, chorioretinitis and old skin scars (suggestive of *in utero* vesicles).

Diagnosis is largely clinical but may be confirmed by the viral culture or PCR from urine or saliva in first two weeks of illness. *Tzanck* cells are also present in vesicular scrapping.

Treatment: Acyclovir therapy (IV 20 mg/kg/dose TDS for 14–21 days) is the mainstay of treatment in perinatal HSV infection, apart from supportive and symptomatic care.

Prevention: Obstetrical care in mother with genital HSV includes—(a) elective LSCS to avoid vaginal passage, (b) Viral cultures from eyes, nose, mouth, urine and stools of baby at 48 hours, and (c) prophylactics acyclovir therapy to baby, if mother is symptomatic at the time of delivery.

Some other important intrauterine infections, e.g. congenital tuberculosis, congenital malaria and perinatal HIV infection have been discussed in respective chapters.

12.16 NEONATAL SEIZURES

Seizure is a common neonatal emergency, seen in ~0.5% of term and ~2.0% of preterm newborns. Apart from sudden death due to choking or aspiration, seizures may also lead to persistent hypoxic brain damage and long-term sequelae.

Clinical types: Neonatal seizures often present differently than in older children and adults with atypical manifestations, e.g.

- *Subtle seizures,* either with *minimal motor activity* involving eyes (vacant stare, upward gaze), face (chewing, tongue thrusting, lip smacking), or limbs (paddling, cycling, boxing); *or sudden autonomic disturbances*, e.g. apnea, tachycardia/bradycardia, etc.
- *Clonic seizures* with associated EEG abnormality, which carry best prognosis.
- *Tonic seizures* or decerebrate posture, usually without EEG changes.
- *Myoclonic seizures* with jerky movements of limbs or trunk, carry worst prognosis in terms of neurodevelopmental outcome.

Neonatal seizures may also be classified as: (a) Electroclinical seizures with clinical as well as EEG changes, (b) Clinical seizures without EEG changes, and (c) Electric seizures with abnormal EEG but no clinical presentation.

Etiology: Metabolic seizures are most common in previously healthy newborn, while sick babies may convulse due to many causes, as follows:

- *Hypoxia:* HIE or intracranial hemorrhage.
- *Infections:* Meningitis, intrauterine infections, etc.
- *Metabolic:*
  - Hypoglycemia
  - Hypocalcemia with/without hypomagnesemia
  - Pyridoxine dependency
  - Dyselectrolytemia
  - Inborn errors of metabolism (rare)
- *CNS malformations:* Microcephaly, hydrocephalus
- *Kernicterus*
- *Vascular:* Polycythemia, severe dehydration
- *Iatrogenic:* Narcotic withdrawal, aminophylline, accidental injection of local anaesthetics over fetal scalp during delivery—analgesia.

Diagnostic approach: Immediate control of seizures is more important than to identify its etiology. However, subsequent clinical evaluation and relevant investigations are necessary for etiological diagnosis and rational treatment, to prevent further attacks.

Diagnostic approach in these cases involves:

- ***Careful history*** regarding
  - Age of onset **(Table 12.51)**.
  - Antenatal maternal infections or medications, etc.
  - CNS anomalies or metabolic errors in family.
  - Birth asphyxia, risk factors of neonatal sepsis.
  - Delayed feeding (hypoglycemia), etc.
- ***Clinical examination*** *for signs of*:
  - Sepsis/meningitis, e.g. sick child, bulging AF, etc.
  - Neural tube defects, abnormal head size
  - Intrauterine infections, e.g. low birth weight, hepatosplenomegaly, etc.
  - *Apparently well child* (metabolic seizures).
- ***Laboratory investigations,*** including:

  Step I. Base-line investigations
  - Sepsis screen: Blood counts, CRP, etc.
  - Metabolic screen: B. Sugar, S. Ca^{++}, Mg^{++}
  - CSF examination including bacteriology
  - Cranial USG for malformations or bleeds

  Step II. Second-line investigations
  - *Neuroimaging:* CT/MRI, EEG
  - Serological (TORCH) screening

  Step III. Select cases with unexplained seizures
  - Screening tests for inborn errors of metabolism, e.g. arterial blood gas analysis, serum ammonia, lactate/pyruvate, etc.

TABLE 12.51: Causes of neonatal seizures with age of onset

Day 1 seizures
- Birth asphyxia/hypoxic ischemic encephalopathy (HIE)
- Pyridoxine dependency
- Local anaesthetic injection in fetal scalp

Day 2–3 seizures
- *All of the above,* ***plus***
- *Metabolic:* Hypoglycemia, hypocalcaemia, hypomagnesemia
- Birth injuries, e.g. Intracranial haemorrhage
- Developmental CNS malformations
- Tetanus neonatorum
- Narcotic withdrawal

Day 3–28 seizures
- *All of the above except narcotic withdrawal,* ***plus***
- Infections, i.e. septicemia, meningitis
- *Metabolic:* Late-onset hypocalcemia
  Pyridoxine dependency/deficiency
  Inborn errors of metabolism
- Benign familial neonatal seizures (5^{th} day fits)
- *Others:* Kernicterus

Differential diagnosis: Apart from etiological differentiation, neonatal seizures should also be differentiated from seizure mimics, e.g. jitteriness and being neonatal myoclonus.

Jitteriness is common in normal newborns during first 48 hours, characterized by fast, symmetrical and rhythmic movement of limbs without gaze abnormality, which can be easily stimulated by just touching the baby and can be rapidly abolished by mild restrain or passive flexion of limbs. Persistent and severe jitteriness may be a sign of: (a) cerebral hypoxia, (b) metabolic problems e.g. hypoglycemia, hypocalcemia, etc., (c) narcotic withdrawal, and (d) congenital thyrotoxicosis.

Benign myoclonus is sudden jerky movement of limbs in a newborn while asleep, which disappear on waking. Baby is otherwise normal and myoclonus subsides by 2–3 months without any treatment, with long term adverse outcome.

Management: All neonatal seizures need emergency hospitalization and the first priority lies in immediate control of seizures, irrespective of cause. Important steps in management include:

Step I. Ensure airway patency and adequate ventilation by cautious low-pressure suction, proper positioning (lateral/prone) to prevent aspiration and oxygen supplementation.

Step II. Establish an IV line for anticonvulsants, drugs and fluid-electrolyte correction. An IV anticonvulsant (as in step V) may be given at this stage, if seizures are life-threatening and unlikely to be metabolic.

Step III. Collect blood samples for *metabolic screen*, i.e. B. sugar, calcium and magnesium, as well as quick clinical evaluation.

Step IV. Empirical correction for common metabolic causes, specially in apparently healthy and term babies. This step involves step-wise correction of problems, as follows:

- IV Dextrose 10%, 2 ml/kg as bolus, followed by continuous infusion (6–8 mg/kg/min). If seizures are not controlled, then–
- IV Calcium gluconate 10%, 2 ml/kg (1:1 dilution in distilled water), slowly over 5–10 minutes with cardiac monitoring for bradycardia. If seizure are not controlled, then–
- IM Magnesium sulphate 50%, 0.2 ml/kg as bolus. If seizure are not yet controlled, then–

Step V. Specific anticonvulsant therapy should begin as early as possible, if metabolic cause is unlikely *or* no response to metabolic corrections (Step IV). Various anticonvulsants are used in step-wise manner with monitoring of response, as follows:

- IV Phenobarbitone 20 mg/kg, slowly over 20 minutes. Doses may repeated as 5–10 mg/kg twice after every 30 minutes (Total 40 mg/kg) in non-responders. Still, if seizures continue.
- IV Phenytoin 20 mg/kg, diluted in distilled water, slowly (<1 mg/kg/min) over 10–15 minutes IV **or** preferably IV Levetiracetam 50 mg/kg over 20 minutes. Fosphenytoin is preferred to Phenytoin in equivalent doses, if available. Still, if seizures continue.
- IV Midazolam (0.15 mg/kg as bolus followed by continuous infusion as 0.5–1 µg/kg for the ease of dosage titration. However, considering side-effects, e.g. sedation, benzodiazepines should not be used for long-term control. IV Lidocaine 2 mg/kg bolus followed by 6 mg/kg/hour may also be used to control refractory seizures, titrated down gradually

  IV Pyridoxine 50–100 mg slowly under EEG monitoring may be tried in some refractory cases with dramatic response in cases of pyridoxine deficiency/dependency seizures, which are common in newborns whose mothers have received high-dose pyridoxine therapy for hyperemesis gravidarum.

Step VI. Maintenance anticonvulsant therapy with Phenobarbitone (3–6 mg/kg/day q12h) or Phenytoin (4–8 mg/kg/day q12h) or Levetiracetam 40 mg/kg/day q12h for 6–8 weeks is necessary in all non-metabolic seizures, the choice depending on the response in bolus therapy. Maintenance therapy should be started after 24 hours of last bolus dose. Unlike adults, prolonged anticonvulsant therapy is not required in most newborns due to little risk of recurrence in neonatal seizures and significant side effects on growth and development.

Specific therapy is needed for primary disease, e.g. meningitis, narcotic withdrawal, etc. apart from anticonvulsants.

Outcome of neonatal seizures depends on primary cause, though ~ 10–20% of untreated convulsing infants may die due to asphyxia and choking. Risk of long-term neurological deficit depends on the primary cause, though high-risk factors include—(a) onset of seizures on first day of life, (b) persistence beyond 48 hours despite anticonvulsant therapy and (c) myoclonic seizures. *Metabolic seizures have best prognosis with very rare long-term neurological damage.*

12.17 HEMATOLOGICAL DISORDERS IN NEWBORN

Hematological status *at birth* is characterized by:

- Higher hemoglobin levels (~14–16 gm/dl) with predominance of HbF (~70%),
- Higher reticulocyte count (>5%), suggestive of rapid bone marrow turnover,
- Higher TLC (~18,000 cells/mm^3), with lymphocytic predominance (>60%), and
- Relative thrombocytopenia with immature hemostatic mechanisms. All clotting factors are low in newborns except factor $_f$V, VIIIs and XIII as also Antithrombin III, plasminogen and protein-C levels.

These developmental features change rapidly in neonatal period to reach adult values and should always be considered while assessing a neonatal blood reports. This chapter deals with common hematological problems in newborns, i.e. bleeding, anemia and polycythemia.

12.17.1 BLEEDING NEONATE

Newborns are prone for bleeding tendencies due to: (a) developmental thrombocytopenia, (b) developmental deficiencies of clotting factors, (c) vitamin K deficiency

due to inadequate endogenous synthesis by immature gut flora, and (d) higher vascular permeability. Coagulation proteins do not cross placenta and synthesized in fetus from 10th week of gestation.

Etiology: Bleeding problems in newborn vary from mild/moderate bleeds in an apparently healthy child, e.g. *hemorrhagic disease of newborn* (HDN), to life-threatening hemorrhage, e.g. DIC in critically sick babies **(Table 12.52)**.

Diagnostic approach: A bleeding newborn may bleed *externally* from umbilical cord, skin, gastrointestinal; tract and IV sites etc; or *internally*, e.g. intracranial hemorrhage. Severity of clinical signs depends on the site and severity of bleed as well as primary cause.

Important diagnostic clue include:

- ***Detailed history,*** with special reference to:
  - Age of onset **(Table 12.53)**
  - Family history of bleeding disorders
  - Antenatal maternal infections
  - Obstetric complications, e.g. APH (swallow-blood),
  - Postnatal feeding, (e.g. HDN in breastfeds)
- ***Clinical examination,*** with special reference to:
  - *General appearance*: term and healthy (HDN) or preterm and sick (DIC).
  - *Site of bleed*: IV sites (DIC), cord (slipped ligature, hemophilia), vagina (withdrawal bleeding, HDN).
  - Associated sepsis, asphyxia, hypothermia (DIC).
  - Hepatosplenomegaly (IU infections).

  Signs of concealed/internal bleeding, e.g. *progressive pallor, deep icterus, and shock* are rare in classic HDN and usually indicate more severe etiology.
- ***Laboratory investigations:*** Need for investigations **(Table 12.54)** depends on severity of bleed and probable etiology.

No investigations are necessary in healthy breastfed term newborn with minor bleeding, who has not received vitamin K at birth and responds rapidly to single dose of vitamin K (suggestive of HDN).

Apt and Downey test is used to distinguish swallowed maternal blood from fetal blood in babies with blood mixed vomiting/melena. Mix 1 part of vomitus/stool with 5 parts of distilled water > centrifuge > add 1 ml of 1% NaOH > a change of color to yellowish-brown indicates swallowed maternal blood, due to denaturation of adult Hb. Fetal Hb is resistant to alkali denaturation.

A step-wise approach is preferred in other cases, beginning with three base-line investigations: (a) platelet count, (b) prothrombin time, and (c) partial thromboplastin time; to differentiate common causes of bleeding neonate **(Table 12.55)**. Detailed investigations may be necessary to confirm the diagnosis or detect uncommon defects.

TABLE 12.52: Causes of bleeding neonate

- **Coagulation disorders**
  - Hemorrhagic disease of newborn (HDN)
  - *Inherited:* hemophilia, von-Willebrand disease
  - *Hepatic injury:* hypoxia, infections
  - *Maternal drugs:* anticoagulants, salicylate, phenytoin
- **Platelet disorders (purpura)**
  - *Increased destruction:*
    - *Immunological:* Neonatal ITP
    - *Mechanical:* Hemagioma, NEC
  - *Decreased bone marrow production:*
    - BM depression—infections, hypoxia, drugs
    - BM infiltration—leukemia, Gaucher disease
  - *Hereditary disorders:*
    - Wiskott-Aldrich syndrome
    - Function defects—Glanzmann thrombasthenia
- **Vascular immaturity/injury**
  - Intra-ventricular hemorrhage
  - *Trauma:* Birth trauma, slipped cord ligature
- **Disseminated intravascular coagulation (DIC)**
- **Swallowed maternal blood**

TABLE 12.53: Causes of N. bleeding with age of onset

<24 hour	:	Swallow' blood, *early HDN*, hemophilia
>24–72 hour	:	*Classic HDN*, DIC, neonatal ITP
>72 hour	:	Sepsis, hypoxia/acidosis, DIC, IU infections
>7 day	:	*Late HDN*, inherited clotting disorders

TABLE 12.54: Lab. investigations in bleeding neonate

Step I. Baseline investigations

- Apt test (swallowed blood)
- Platelet count (thrombocytopenia)
- Peripheral smear (sepsis, leukemia)
- Basic clotting profile (BT, CT, PT, PTT)

Step II. Relevant investigations

- Platelet function tests
- Clotting factor assays
- FDP or D-dimer assay (DIC)
- Maternal platelet count (for neonatal ITP)
- Coomb test (platelet isoimmunization)
- Liver function tests

TABLE 12.55: Diagnostic approach to bleeding neonate

Plc	*PT*	*PTT*	*Diagnosis*
		Clinically well neonate	
N	N	N	Trauma, platelet function defects
N	N	↑	Inherited clotting factor deficiency
N	↑	↑	Hemolytic disease of newborn
↓	N	N	Immune thrombocytopenia (ITP)
		Clinically sick neonate	
N	N	N	Vascular purpura*
N	↑	↑	Liver disease, heparinization
↓	N	N	Mechanical purpura**
↓	↓	↓	DIC

Plc: Platelet count. *e.g. in preterms, acidosis, asphyxia
**excessive platelet destruction, e.g. in sepsis, NEC, hemangioma

Hemorrhagic disease of newborn (HDN) is the commonest cause of bleeding in newborns, due to transient *Vitamin K deficiency*—required for synthesis of coagulation factors—II, VII, IX and X. The term ***Vitamin K deficiency bleeding*** **(VKDB)** is preferred by some workers, as HDN is not limited to newborns and neonates may bleed due to other causes rather than vitamin K deficiency.

According to the age of presentation and etiology, HDN may be divided into 3 types:

a. **Classical HDN,** manifests on 2–7th day and almost exclusively seen in full-term breastfed newborns with estimated incidence of ~0.5–1.0%.

   Etiologically, it is linked to—(i) marginal vitamin K content in breast milk, (ii) delayed/inadequate feeding, and (iii) inadequate endogenous vitamin K synthesis due to relatively sterile gut.

   Clinically, these newborns are apparently healthy, except mild bleeding from superficial sites, e.g. umbilical stump, nose, vagina, venepunctures, circumcision wounds, etc. Mild transient gastrointestinal bleeding is not uncommon but serious intracranial bleeds are very rare.

b. **Early HDN** presents with severe bleeding manifestations within 24 hours of birth, due to vitamin K deficiency following maternal therapy with drugs that interfere with vitamin K metabolism, e.g. anticoagulants, anticonvulsants, antitubercular drugs and salicylates.

c. **Late HDN** presents beyond 1st week of life (usually 3–8th week) due to inadequate endogenous synthesis in gut, usually in *sick babies* with cholestatic liver disease, malabsorption syndromes and prolonged antibiotic therapy, when normal gut flora is destroyed. Unlike classic disease, serious internal bleeding and intracranial hemorrhage is common.

Diagnosis of classical HDN is largely clinical (bleeding in apparently healthy newborn), supported by abnormal coagulation profile and therapeutic response to vitamin K within 30–120 minutes.

In early/late HDN, diagnosis may be confirmed by *elevated PIVKA-II levels* (proteins induced in vitamin K absence).Vitamin K levels are difficult to measure and unreliable.

Management: A single dose IV or SC vitamin K_1 (1–5 mg) is the treatment of choice for VKDB/HDN, even before laboratory confirmation. IM injections should be avoided due to risk of large hematoma formation. Severe or persistent bleeding may require repeated doses along with factor replacement therapy with fresh frozen plasma (10 ml/kg) or prothrombin complex concentrates.

Late VKDB is a chronic problem and may need regular vitamin K supplements (1 mg/months IM *or* 50–100 mg/day PO) as well as treatment of primary cause.

Prevention: Prophylactic administration of a *single dose of IM vitamin K 1mg* (0.5 mg in babies weighing < 1000 gm) at birth is an established practice to prevent almost all cases of classic/Late HDN. While oral vitamin K prophylaxis is equally effective to prevent classic HDN in fullterms, protection is inadequate against late HDN. Infants on antibiotics for > 2 weeks should receive 0.5 mg vit K per week.

Pregnant mothers on oral anticonvulsants should receive daily vitamin K supplements (PO 10–20 mg) for 15–30 days before delivery to prevent early HDN.

12.17.2 ANEMIA IN NEWBORN

Considering developmentally higher hemoglobin levels in normal newborn, neonatal anemia is defined as *Hb <13 gm in fullterm and <12 gm/dl in preterms, during first two weeks of life.*

Etiology: Transplacental iron transfer is an active process, not affected by maternal Hb levels and maternal anemia is unlikely to cause neonatal anemia. however, since maximum iron transfer through placenta occurs in last trimester, preterms are anemic.

Rh/ABO incompatibility, perinatal blood loss and *sepsis* are three most important causes of anemia in newborn, apart from others **(Table 12.56)**. Repeated blood sampling is an important cause of severe anemia in neonatal intensive care.

Fetomaternal hemorrhage, though occurs in ~50% pregnancies, is rarely enough to cause significant neonatal anemia (<1%).

Clinical evaluation of neonatal anemia includes:

- Family history of hereditary hemolytic anemia
- Maternal blood group (Rh/ABO incompatibility)
- Prenatal history of infections or invasive procedures
- History of multiple pregnancy (twin-twin transfusion) and cord clamping time.
- *Co-existing problems:* Cephalohematoma, severe edema (hydrops), hepatosplenomegaly, icterus, sepsis, etc.

TABLE 12.56: Causes of severe anemia in newborn

Increased blood loss
- *Fetal:* Feto-fetal or feto-maternal hemorrhage
- *Placental:* Placenta previa. antepartum hemorrrhage
- *Cord:* Early/late clamping, trauma, anomalies.
- *Birth injuries:* Cephalohematoma
- Bleeding neonate

Increased RBC destruction
- Hemolytic disease of newborn (Rh/ABO)
- Congenital hemolytic anemia
- *Acquired hemolysis:* Sepsis, IU infections, drugs

Decreased RBC synthesis
- Anemia of prematurity
- *Bone marrow hypoplasia:* Drugs, IU Infection
- *Bone marrow infiltration:* Leukemia, osteopetrosis

Iatrogenic
- Repeated blood sampling
- Post-exchange (low Hb content in adult blood)

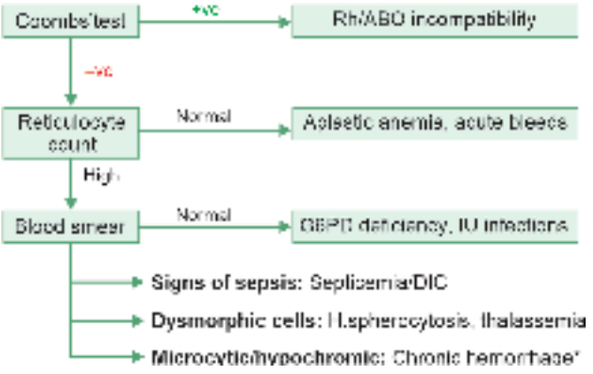

Fig. 12.24: Diagnostic algorithm for neonatal anemia.
*exclude feto-maternal or twin-twin transfusion (Kleihauer test)

Laboratory evaluation: **Fig. 12.24** provided a practical algorithm for laboratory diagnosis of neonatal anemia, though common investigations include:

- Complete hemogram including Hb, Hct, cell counts and Reticulocyte count
- P. smear for hemolysis, sepsis, abnormal cells
- Direct Coombs' test (Rh/ABO disease)
- Sepsis screen, including relevant cultures
- Serological tests for intrauterine infections
- Bone marrow examination (in selected cases)
- Coagulation profile (in bleeding disorders)
- *Kleinhauer test*

Kleihauer-Betke test is used to detect presence of fetal RBCs in maternal blood in fetomaternal hemorrhage, as follows:

Collect maternal smear along with controls from a normal newborn and adult > Fix them with 80% ethanol for 5 minutes > Rinse, dry and immerse in a buffer solution (73.4% of 0.1 M citric acid + 26.6% of 0.2 M disodium hydrogen phosphate) for 5 minutes > Hematoxylin-eosin staining > Examine under microscope. On microscopy, RBCs with acid-resistant fetal Hb remain darkly stained, while those with adult Hb appear like ghost cells, due to acid elution. *Presence of ~ 1% of fetal RBCs in maternal smear indicates ~ 50 ml of fetal blood loss to maternal side.*

Management of neonatal anemia depends on its severity, primary cause and associated problems. Packed RBC transfusion (15 ml/kg over 2–4 hours) is indicated according to the hemoglobin levels and clinical status of the newborn as follows:

- On mechanical ventilation @ Hb < 11 gm/dl
- On minimum respiratory support @ Hb < 10 gm/dl
- On oxygen or impending CCF @ Hb < 8 gm/dl
- Asymptomatic newborn @ Hb < 7 gm/dl

Anemia of prematurity may be prevented with recombinant *erythropoietin* therapy (25–100 U/kg SC alternate day) with PO iron (2 mg/kg/d) from 2nd week onwards, though rarely practiced.

12.17.3 NEONATAL POLYCYTHEMIA

Polycythemia (Hct >65%) is seen in ~1% of newborns, specially full-terms with following risk factors:

- Delayed clamping of cord,
- Twin-twin transfusion in recipient baby,
- Infants of diabetic mother,
- Cyanotic CHDs (compensatory) *or rarely in,*
- Endocrinal disorders, e.g. cong. adrenal hyperplasia,
- Chromosomal disorders, e.g. Down syndrome.

Pathophysiologically, it leads to increased blood viscosity (thromboembolic episodes), volume overload (CCF) and increased metabolic requirements for cell survival (hypoglycemia, hypocalcemia).

Clinically, visible plethora is the only indicator of polycythemia in most babies, though severe cases may develop complications, e.g. CCF, hypoglycemia, hypocalcemia and seizures.

Management: *Plasma exchange* is treatment of choice in cases with Hct >70, with an aim to bring it <55. Exchange volume may be calculated as

(Observed Hct – 55/observed Hct) × 85 × Weight (kg).
where 55 is desired Hct and 85 is blood volume/Kg.

12.18 METABOLIC DISORDERS IN NEWBORN

Some important metabolic problems in newborns are as follows:

Hypoglycemia is the commonest metabolic problem in newborn, generally defined as *blood glucose (BG) values of <25 mg/dl during first 3 hours, <35 mg/dl between 3 and 24 hours and <45 mg/dl beyond the first day,* irrespective of gestation or birth weight. BG levels of 45 mg/dl may be considered as cut-off for hypoglycaemia in symptomatic newborns.

However, there is lack of consensus on cut-off BG value and current practice is based on operational thresholds for intervention, i.e. BG should be maintained >60 mg/dl in symptomatic neonates after 48 hrs of life.

Etiology: Normal fetal glucose levels are ~2/3rd of maternal values, which drop further during first two hours before rising again to normalize by 3–4 hours of age. Poor fetal reserves in preterm/LBW babies and delayed feeding are two most common causes of neonatal hypoglycemia **(Table 12.57)**.

TABLE 12.57: Risk-factors for neonatal hypoglycemia

- Preterms, low birth weight and IUGR
- Large for date or post-term newborns
- Infants of diabetic mother (IDM)
- Delayed or inadequate feeding
- Rh-incompatibility and exchange transfusion
- *Critical illness:* Polycythemia, sepsis, hypothermia
- Inborn errors of metabolism (rare)

Clinical manifestations of hypoglycemia not necessarily correlate with blood glucose level. Most cases present on 2nd–3rd day with:

- *Abnormal movements*, e.g. jitteriness, tremors or seizures,
- *Abnormal behavior*, e.g. apathy, limpness, refusal to feeds and coma,
- *Autonomic disturbances*, e.g. recurrent apnea, tachycardia, sudden pallor, sweating, etc.

Diagnosis rests *low blood glucose levels*, preferably from laboratory. *Dextrostix*, while adequate for screening, are not reliable at very low glucose levels.

Prevention of hypoglycemia includes: (a) early breastfeeding, (b) routine glucose monitoring in high-risk newborns at 2,6,12, 24, 48 and 72 hours, and (c) prevention/ treatment of precipitating factors, e.g. hypothermia, sepsis, etc.

Routine BG monitoring is recommended for all preterms < 35 weeks, LBW < 2000 gm, infant of diabetic mothers, large-for-date babies and sick newborns.

Management depends on the severity of hypoglycemia as follows:

- ***Symptomatic hypoglycemia or BG levels < 20 mg/dl*** irrespective of symptoms, need IV bolus of Dextrose 10%, followed by slow infusion of 6–12 mg/kg/min to maintain BG levels >45 mg/dl for at least 24 hours before tapering slowly under monitoring and simultaneously ensuring oral feeds.
- ***Asymptomatic hypoglycemia with BG >20 mg/dl*** does not need urgent correction and treated with adequate feeding and additional sugar-fortified feeds, if necessary. However, BG must be reassessed after 30 minutes and must be treated with IV Dextrose 10%, if remains <40 mg/dl.
- ***Refractory hypoglycemia,*** defined as failure to maintain normal BG levels despite 12 mg/kg/min of Dextrose 10% infusion for 48 hours must be investigated for endocrinal disorders, (e.g. adrenal insufficiency), hyperinsulinemic states, (e.g. Islet cell hyperplasia) and inborn errors of metabolism, (e.g. glycogen storage disorders). Some of them may benefit with IV hydrocortisone (5 mg/kg), IV Glucagon (300 mg/kg) or IV Diazoxide (25 mg/kg/d q8hr) therapy. Glucagon is more useful in high-insulin hypoglycemia, e.g. infants of diabetic mothers and hemolytic disease of newborn.

Outcome: Untreated symptomatic hypoglycemia may be fatal, though timely intervention ensures dramatic recovery. Persistent hypoglycemia in newborn may leave neurodevelopmental problems in 30–70% cases.

Hypocalcemia is second commonest metabolic disorder in newborns, defined as *S. calcium <7 mg/dl in preterms and <8 mg/dl in term newborns or ionic fraction < 4 mg/dl.*

TABLE 12.58: Causes of neonatal hypocalcaemia

- **Early-onset *(with 24–72 hours)***
  - Preterms and VLBWs
  - Infants of diabetic mothers
  - Perinatal complications, e.g. prolonged labor
  - Maternal medications, e.g. nifedipine
- **Late-onset *(classic tetany)***
  - Formula-fed newborn (wrong Ca:P ratio)
  - Iatrogenic—ET, rapid acidosis correction
  - Maternal hyperparathyroidism
  - Hypoparathyroidism, e.g. DiGeorge syndrome

ET: Exchange transfusion

Etiology of hypocalcemia differs with age of presentation **(Table 12.58)**.

- *Early-onset hypocalcemia* (<72 hour) is common in preterms due to poor storage and immature renal functions to conserve calcium.
- *Late-onset hypocalcemia* is common in formula-fed newborns, due to high phosphorus content that prevents calcium absorption.

Clinical features of hypocalcemia include:

- *Seizures*, usually on 3rd day, in otherwise alert and active newborn,
- *Neuromuscular irritability*, e.g. jitteriness, sustained clonus and high-pitched cry. Well-defined tetany is uncommon in newborns.

Diagnosis depends on S. Calcium levels including ionic fraction, drawn before the therapy and therapeutic response to IV calcium infusion. Parathyroid studies are indicated in refractory hypocalcemia.

Management of hypocalcemia includes:

- ***Symptomatic cases*** should be treated by IV Calcium gluconate 10%, 2 ml/kg (half-diluted in DW 5%), infused slowly at the rate of <1 ml/min with cardiac monitoring for bradycardia. Maximum dose is 10 ml in term newborns and 5 ml in preterms. Post-bolus, a maintenance dose of 2 mg/kg 6-hrly must be continued for next 24–48 hours, before switch-over on oral maintenance. IV site should also be observed for extravasation.
- ***Asymptomatic hypocalcemia*** *or* symptomatic cases after initial therapy as above, should receive oral elemental calcium supplements as 40–80 mg/kg/d for next 3 days.
- ***Unresponsive hypocalcemia*** may be associated with hypomagnesemia, which needs to be corrected along with calcium therapy (as discussed below).

Outcome is excellent in hypocalcemic seizures, with no neurodevelopmental sequelae, unless due to primary cause.

Hypomagnesemia, defined as serum magnesium levels *< 1.2 mEq/L*, is relatively uncommon, usually seen along

with hypocalcemia in IUGR babies, infants of diabetic mothers and after diarrhea.

Clinically Hypomagnesemia *per se* rarely produces seizures, but in its presence, hypocalcemic seizures do not respond to calcium therapy.

Treatment includes IM magnesium sulphate 50% (0.2 ml/kg), two doses at 12-hour interval, followed by oral supplements (30 mg/d) for 3–5 days.

Late metabolic acidosis is common in top-fed preterms (5–10%), due to high solute load in formula milks and immature renal acidification.

Clinically, these cases present in 2nd–3rd week, with failure to thrive, tachypnea without lung signs, circumoral pallor and sluggish activity.

Diagnosis rests on blood gas analysis showing: (a) persistent metabolic acidosis, (b) increased anion gap, (c) normal/low pCO_2, and (d) base excess <5 mmol/L.

Treatment includes oral $NaHCO_3$ therapy for 2 weeks or till 35 weeks of conceptional maturity, with suitable modifications in formula-feeds.

Infant of diabetic mother (IDM): Diabetes mellitus, including gestational diabetes, is the commonest metabolic disorder in pregnancy with significant effects of fetal outcome.

Pathological effect on fetus: Hyperglycemic state in mother leads to fetal hyperglycemia with compensatory rise in fetal insulin levels and islet cell hyperplasia. In presence of fetal hyperglycemia, insulin acts as an anabolic hormone-leading to *macrosomia*. Post-birth, with sudden cut-off of transplacental glucose supply, this high insulin-state may precipitate *severe hypoglycaemia in early neonatal period*.

Clinically IDMs present with:

- *Typical physical features*, i.e. macrosomia, moon facies, hypertrichosis and hairy pinna.
- *Complications*, e.g.
  - Obstructed labor and birth trauma due to large size,
  - Hypoglycemia and hypocalcemia (on 2nd–3rd day),
  - Hyaline membrane disease (surfactant maturity),
  - Polycythemia, leading to hyperbilirubinemia and renal vein thrombosis.

Congenital malformations, e.g. CHDs (specially asymmetric septal hypertrophy), neural tube defects and small left-colon syndrome, are also common in IDMs.

Management of IDMs include:

- ***Antenatal management:*** Oral hypoglycemic agents are contraindicated in pregnancy due to teratogenic effects and intractable hypoglycemia in newborn and near-normoglycemic state should be maintained with insulin. Periodic monitoring of amniotic fluid surfactant activity by L:S ratio is advised to ensure adequate maturity at birth.
- ***Obstetrical care:*** Planned delivery is preferable in most cases and those with large fetal size may be taken for elective caesarean section.
- ***Postnatal management*** includes: (a) early feeding within 30 minutes to prevent hypoglycemia, (b) glucose monitoring at 2, 6, 12, 24, 48 and 72 hours, (c) detection and treatment of hypoglycemia as well as other complications, e.g. HMD, polycythemia, hyperbilirubinemia and other metabolic disturbances, and (d) management of co-existing malformations, e.g. cardiac disease. All IDMs with respiratory distress must undergo echocardiography to exclude asymmetric septal hypertrophy.

12.19 CONGENITAL MALFORMATIONS

Congenital malformations are defined as "*anatomical or structural defects, present at birth, with/without functional impairment*." Although used interchangeably, the term congenital anomaly has wider connotation, i.e. *structural, functional, biochemical or physiological disorders of prenatal origin*.

Structural malformations may be broadly divided into *major malformations* with significant functional impairment, e.g. CHDs or neural tube defects; and *minor malformations* without direct functional implications, e.g. pre-auricular skin tags.

Incidence: Congenital malformations are third commonest cause of perinatal mortality in India, estimated to be present in ~2.5% of newborns at birth and incidence may rise to 4–5% by 5 years, as many defects manifest in later life.

Etiology: Over 60% of congenital malformations are idiopathic, rest due to various intrinsic (genetic) defects or extrinsic (environmental) factors **(Table 12.59)**. Term *teratogens* is applied to those environmental influences, which are known to have definite exposure-risk relationship with a congenital anomaly, e.g. maternal infections, drugs, radiation and alcohol/ smoking. Only 10% malformations are due to recognizable teratogens.

Classification: Congenital malformations may be single primary defects or multiple malformation syndromes.

TABLE 12.59: Common causes of congenital malformations

- **Idiopathic (~60%)**
- **Intrinsic or inherited (~ 25–30%)**
  - *Chromosomal:* Down syndrome, Turner syndrome
  - *Single gene:* Achondroplasia, Holt-Oram syndrome
  - *Polygenic:* Cleft palate, neural tube defects, CHDs
- **Extrinsic *or environmental* (~10–15%)**
  - *Maternal infections:* Rubella, CMV, toxoplasmosis
  - *Maternal diseases:* Diabetes, iodine deficiency
  - *Drugs/toxins:* Antiepileptics, alcohol, hormones
  - *Maternal smoking, irradiation*
  - *Maternal malnutrition,* e.g. folic acid deficiency
  - *Uterine anomalies or oligohydramnios*

Depending on the etiology and secondary effects, various terms are used to denote these defects, as follows:

- **Malformation,** i.e. a single morphological defect due to intrinsic error in embryogenesis and organ differentiation, e.g. cleft lip or CHD.
- **Deformation,** i.e. abnormal shape/position of normally-formed body part due to abnormal uterine pressure/posture, e.g. congenital dislocation of hip or congenital talipes equinovarus. Abnormal posture may be due to extrinsic uterine pressure, e.g. *oligohydramnios*, or intrinsic fetal hypotonia, e.g. *neuromuscular disorders*.
- **Disruption,** i.e. destruction of a normally-formed body part in late gestation, due to: (a) tearing/amputation of a structure by floating strands of amnion, e.g. amniotic band syndrome, loss of a digit or limb, etc.; or (b) interruption of blood supply due to infection, trauma or other teratogens, leading to distal infarct, necrosis or resorption, e.g. intestinal atresia, porencephaly, etc.
- **Dysplasia** denotes abnormal organization of constituent cells in a structure, leading to abnormal growth. Dysplasias may be *localized*, e.g. hemangioma, or *generalized*, e.g. skeletal dysplasia. Being growth-dependent, clinical appearance in these defects tend to change with age, e.g. hemangiomas may regress or skeletal dysplasias may deteriorate, postnatally.
- **Sequence** denotes a spectrum of multiple malformations due to cascading effect of a single primary defect in morphogenesis. Depending on the primary error, a sequence is further classified as malformation, deformation or disruption sequence. Some common sequences include:
  - *Robin malformation sequence,* with primary defect of mandibular hypoplasia, leading to macroglossia, glossoptosis and high-arched palate.
  - *Breech deformation sequence* due to abnormal uterine pressure in breech position, leading to abnormal skull shape, facial asymmetry, torticollis, CDH and CTEV. Similar abnormalities are also seen *Potter's sequence,* due to oligohydramnios.
  - *Amniotic band disruption sequence*, due to disruption of normally formed amniotic membrane, leading to defects, e.g. cleft lip, limb defects, aplasia cutis, etc. Sequences need to be differentiated from multiple malformation syndrome, as the recurrence risk in them depends on the primary defect.
- **Multiple malformation syndrome** denotes presence of one or more development abnormality involving at least two different systems, due to an established cause. Most of these defects are chromosomal or polygenic in origin, e.g. Down syndrome, though others may be due to single gene defects or environmental factors, e.g. intrauterine exposure to infection/drugs (congenital rubella syndrome, fetal hydantoin syndrome, etc.).
- **Association** denotes a non-random (more than by chance) occurrence of multiple malformations in a combination, not explained by a common etiological basis, i.e. syndrome or sequence. Two common associations are:
  - *VATER association* (***V***ertebral anomalies, ***A***nal atresia, ***T***racheoesophageal fistula, ***E***sophageal atresia and ***R***enal/Radial defects).
  - *CHARGE association* (***C***oloboma, ***H***eart disease, Choanal ***A***tresia, growth/mental ***R***etardation with/without CNS anomalies, hypo***G***onadism and ***E***ar anomalies or deafness.

TABLE 12.60: Diagnostic clues for congenital malformations

History
- Family history of malformed parents/sibling
- Parental consanguinity
- Elderly mother or father
- *Teratogens:* Infections, drugs, alcohol
- Maternal diseases, e.g. diabetes
- Oligo-/poly-hydramnios
- Abnormal fetal movements/presentation

Clinical examination
- External appearance
- Patency test/orifice count at birth
- Single umbilical artery
- Stigmata, e.g. spinal hair tuft, auricular tags
- Systemic examination, e.g. CHDs

Diagnosis: Although most congenital malformations are obvious at birth, some may be easily missed in early life. Early diagnosis of major malformations is essential for survival, appropriate management and prevention of late complications. Important clinical clues about presence of a congenital malformation or etiological diagnosis are given in **Table 12.60**, though confirmation may require relevant investigations. Genetic studies are indicated in select cases with intrinsic cause of malformation, to assess the risk of recurrence and prenatal diagnosis. Diagnosis and management of individual congenital malformations has been discussed in related chapters.

CHAPTER 13

Adolescence and Adolescence Disorders

Surbhi Rathi, Mukesh Agrawal

Adolescence is a period of transition from childhood to adulthood with many physical, physiological and psychological changes.

WHO defines *Adolescence* from 10–19 years of age, which may be arbitrarily divided into 3 phases—early adolescence (10–13 years), mid adolescence (14–16 years) and late adolescence (17–19 years). While *Early adolescence* is a period of rapid physical and sexual growth, *mid-adolescence* is characterized by relative slowing of growth spurt but intense emotional changes to develop self-identity. *Late adolescence* marks the completion of physical growth and psychosocial stabilization.

13.1 ADOLESCENT GROWTH AND DEVELOPMENT

Adolescence is a period of: (a) physical growth spurt, (b) sexual maturity (puberty), and (c) marked behavioral or psychological change. A general sequence of important physical and pubertal events during adolescence is illustrated in **Fig. 13.1**, though some important details are as follows:

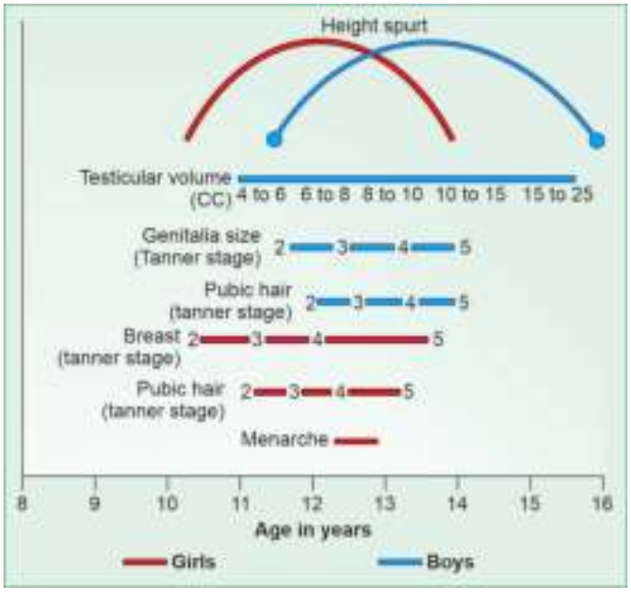

Fig. 13.1: Chronology of pubertal changes.

I. Physical growth: Adolescent growth spurt begins with gradual increase in height velocity, followed by rapid weight gain in both sexes. Important characteristics of physical or somatic growth during adolescence are:

- *Earliest physical change in adolescence is the linear (height) growth spurt*, which begins, peaks and ends earlier in girls than in boys **(Table 13.1)**, as testosterone is a weaker stimulant of growth hormone than estrogens. This spurt is asymmetrical in initial years of puberty, being more prominent in distal parts, e.g. limbs, giving a tall, thin and gawky appearance to adolescents.
- *Peak height velocity* (PHV) in girls is reached earlier than in boys during SMR stage III (discussed later) and *precedes* menarche by 1–1.5 years. In boys, PHV is reached later in SMR stage IV.
- *Rapid weight gain* begins later than the linear growth spurt. An adolescent gains 4–4.5 kg/year, compared to 2–3 kg/year in post-infancy childhood. The distribution of weight gain also differs in two sexes-predominant muscular growth in boys and predominantly fat deposition in girls. Consequently, the lean body mass, which is ~80% in prepubescent children, increases in boys to ~90% and decreases in girls to ~70%.
- *Skeletal growth* is more advanced in girls. In both sexes, bone age correlates better with sexual maturity than chronological age.
- *Other* important physical growth characteristics during adolescence are laryngeal enlargement with voice changes and elongation of optic globe with consequent myopia in some cases.

TABLE 13.1: Linear growth spurt in adolescence

	Males	*Females*
Age of onset	11 years	9 years
Age of PHV	14 years	12 years
Age of completion	18 years	15 years
Total height gain	28 cm	26 cm
Max PHV (per year)	10.5 cm	9 cm

PHV: Peak height velocity. All approximate values

II. Sexual maturity is the hallmark of adolescence, also referred as puberty, i.e. a series of biological changes that lead to development of reproductive capacity and involves development of *primary* (testicular and penile growth in boys and breast and uterine growth in girls) and *secondary* sexual characteristics (pubic and axillary hair, body odor, voice changes, etc.).

While age of the onset and completion of puberty has significant individual variations due to familial, genetic and environmental factors, the sequence of pubertal changes is fairly consistent, usually assessed by ***Tanner's sexual maturity rating*** (SMR) **(Table 13.2)**. Important events in sexual maturity are as follows:

In girls, the first visible sign of puberty is *Thelarche*, i.e. appearance of breast buds at ~11 years (8–13 years), followed by *adrenarche*, i.e. appearance of fine, straight pubic hairs.

Average age of menarche in Indian affluent girls is ~12.5 years (10–16 years), i.e. after ~ 2–2.5 years of thelarche. PHV precedes menarche by 1–1.5 years, i.e. during SMR stage III.

Important genital changes in girls during puberty are: (a) enlargement of external/internal genitals, (b) start of ovulation after 1–1.5 years of menstruation, (c) vaginal mucosal changes, e.g. thickening, glycogen accumulation and increased secretions from Bartholin glands (*physiological leucorrhoea*).

In boys, first visible sign of puberty is the *increase in testicular size* at ~11.5 years (9–14 years), followed by adrenarche and penile enlargement. PHV in boys usually occur late in SMR stage IV.

Important genital changes in boys during puberty are: (a) increase in the testicular volume from ~4 ml in pre-pubertal age to ~20–25 ml by the completion of puberty, (b) effective sperm secretion (*spermarche*) at any time after ~12 years of age, and (c) penile enlargement beginning after ~1 year of starting the testicular growth and continuing till the end of puberty, though final size gain may vary individually.

III. Behavioral changes: Adolescence is a period of intense psychological and emotional turmoil, characterized by identity formation, including development of sexual identity. Important behavioral changes during different phases of adolescence include:

- ***Early adolescence*** is characterized by the preoccupation with body image and pubertal changes along with concrete thinking, i.e. literal perception of concepts and impulsivity with disregard to future implications. Sexual fantasies are common.
- ***Mid adolescence*** is characterised by peer-influence and family/social conflicts to develop self-identity. Risk-taking behavior is common including experiences, e.g. smoking, drinking and sexual actions, to display newly discovered autonomy. Abstract reasoning, to some extent, begins in this phase. This phase is also characterized by formation of sexual orientation and sexual identity.
- ***Late adolescence*** is a phase of stabilization with conflict resolutions with family/society, lessening of impulsivity and peer pressure, development of personal carrier goals and establishment of sexual identity.

Behavioral changes are most prominent during mid-adolescence and gradually culminate into development of stable body image, functional independence, consolidation of sexual identity and stable relationships. Inability to cope with these changes is responsible for behavioral disorders and social maladjustments in youth, discussed later.

13.2 COMMON HEALTH PROBLEMS IN ADOLESCENCE

Adolescence is not only a period of peak physical activity, hormonal changes and emotional stress, but also of heightened concern about body image. Consequently, many health problems present *or* noticed first time in this age group, apart from age-unrelated illnesses **(Table 13.3)**.

TABLE 13.2: Tanner's sexual maturity rating

	(Boys)			*(Girls)*	
Stage	***Testes/Scrotum***	***Penis***	***Pubic hair***	***Breast***	***Pubic hair***
I	Preadolescent	Preadolescent	None	Preadolescent	Preadolescent
II	↑ size, rugosities	↑ size	Scanty, straight, light	Primary mound*	Sparse, light, straight on medial side of labia
III	Larger	Larger	Darker and curlier	↑ areola diameter No separate contour	Darker, curlier
IV	Larger, darker	Thicker, ↑ glans size	Coarse, adult type not on thighs	Secondary mound**	Coarse, curly, not on thighs
V	Adult size	Adult size	On medial thigh	Mature, nipple projects	Adult feminine triangle, spread on medial thighs

*elevated breast/papilla. **areola/papilla with separate contour

TABLE 13.3: Common health problems in adolescence

Developmental disorders
- Delayed/precocious puberty
- Short/tall stature

Physical disorders
- Physiological obesity
- *Nutritional:* Undernutrition, anemia, goiter
- *Skin:* Acne, Hirsutism
- *Orthopedic:* Sports injuries
- *Systemic:* Asthma, hypertension, diabetes
- Accidents

Breast problems
- Physiological asymmetry
- Delayed/premature thelarche
- Gynecomastia
- Breast masses or hypertrophy
- Nipple discharge
- Missed congenital anomalies

Menstrual problems
- Physiological irregularities
- Delayed/premature menarche
- Ammenorrhea/dysmenorrhea
- Abnormal or dysfunctional uterine bleeding

Urogenital problems
- Physiological variations
- Leucorrhoea
- Perineal or peri-genital infections
- Sexually transmitted diseases
- Urinary tract infections
- Missed congenital anomalies

Psychosocial/emotional disorders
- *Adaptive:* Depression, suicide, delinquency
- *Somatic:* Anorexia nervosa, bulimia, hysteria
- *Psychosexual:* Masturbation
- *Social:* Substance abuse, teen pregnancy

A. Developmental disorders: Achievement of *puberty* is the essence of development in adolescence, due to sequence of hormonal changes over time (Ch 22.6.2, **Fig. 22.6)**.

Delayed or precocious onset of pubertal changes is a common cause of medical consultations during adolescence. As most of these variations are familial, detailed parental history, specially regarding their pubertal events, is essential to differentiate normal variants from potentially disease states.

Precocious puberty (PP) is defined as:
- Appearance of secondary sexual characteristics before 8 years in girls and 9 years in boys; or
- Onset of menarche before 10 years, in girls.

Precocious puberty may be *central* in origin-due to premature activation of hypothalamic-pituitary-gonadal (HPG) axis or due to *peripheral* causes, e.g. exogenous administration/endogenous overproduction of gonadal steroids. Peripheral puberty is usually limited to premature development of one or more secondary sexual characteristics, e.g. thelarche or adrenarche, *without* actual reproductive maturation (Ch 22.6.2).

Delayed puberty denotes maturational lag in HPG axis, as indicated by:
- Absence of first pubertal indicator by 13 years in girls (primary breast mound) and 14 years in boys (testicular enlargement),
- A Gap of > 5 years between first sign of puberty and completion of genital growth/menarche, or
- Absence of menarche by 15 years in females.

Delayed puberty is usually *constitutional*, with similar family history and simultaneous delay in height and bone age. *Pathological* delay may be due to central gonadotropin deficiency or peripheral non-responsiveness to these hormones (Ch 22.6.2).

B. Physical problems: Adolescents are susceptible to broad range of physical problems due to growth spurt, increased physical activity, hormonal changes and environmental influences.

Nutritional problems: Common nutritional problems in adolescents include: (a) *iron deficiency* anemia, more likely in girls due to menstrual losses, (b) *calcium deficiency*, due to rapid skeletal growth with less sun exposure, (c) *iodine deficiency* due to increased requirement, i.e. pubertal goiter, (d) undernutrition or obesity due to faulty food habits and changing life style. Adolescents are also prone to psychogenic eating disorders, e.g. anorexia nervosa, discussed later.

Obesity is emerging as a major cause of concern in Indian adolescents due to inappropriate dietary habits and sedentary life style, with immediate risk of developing of low self-esteem due to poor body image and later risk of serious diseases, e.g. diabetes, hypertension, coronary heart disease, strokes and malignancies.

Skin problems, specific during adolescence, usually relate to hormonal changes and imbalance, e.g. *acne* and *hirsutism*. Hirsutism, i.e. androgenic male hair pattern in females, is frequently familial or iatrogenic in origin (steroids, minoxidil, dilantin) and should be distinguished from pathological *virilization*, which is associated with early appearance of secondary sexual characteristics as well.

Orthopedic problems in adolescents originate due to rapid growth of long bones, consequent hypertraction over muscle/tendon insertions and increased sports activity. Important orthopedic problems, specially pertaining to adolescents include—*idiopathic adolescent scoliosis*, *slipped capital femoral epiphysis*, *rheumatoid disorders* and *sports injuries*, etc.

Systemic illnesses: Many physical illnesses, e.g. hypertension, diabetes and rheumatic disorders precipitate or exacerbate during adolescence, due to increased metabolic demands and activity.

TABLE 13.4: Causes of gynecomastia

- Benign gynecomastia in adolescents
- *Drugs:* NSAIDs, digoxin, INH, hormones
- Chronic liver or renal disease
- *Tumors:* Adrenal, gonadal, etc.
- *Endocrinal:* Hypogonadism, hyperthyroidism

At the same time, many childhood illnesses tend to improve, disappear or enter into long remissions at puberty, e.g. asthma, nephrotic syndrome, rheumatic fever, sino-pulmonary infections, etc., due to hormonal changes or reduced risk of environmental exposure.

C. Breast problems: *Physiological variations*, e.g. asymmetric breast size, marginally delayed thelarche or transient nipple discharge in girls and transient gynecomastia in boys are common causes of concern during adolescence, though most of these are normal variations and do not require any intervention except reassurance.

Gynecomastia, i.e. *breast enlargement in boys* is common (~50–60%) during mid-adolescence, which may be unilateral or bilateral and tender or non-tender. Usually, it is a benign process due to hormonal changes that regresses spontaneously within few months and no treatment is required except reassurance. Pharmacotherapy with bromocriptine is indicated only in severe cases with significant physical or psychological discomfort. However, persistent or progressive gynecomastia in adolescents may be pathological **(Table 13.4)** and needs evaluation.

Congenital anomalies, e.g. *amastia* (absent breast), *athelia* (absent nipple), *polymastia* and *polythelia* (supernumerary breasts or nipples), are usually unilateral and frequently missed till adolescence.

Amastia may be associated with *Poland syndrome* (aplasia of pectoralis muscle, rib abnormalities, webbed fingers and radial aplasia). Supernumerary breasts/nipples commonly present along the milk-lines-drawn from shoulder-tip to xiphisternum. Surgical intervention is rarely needed in these cases, except for cosmetic purpose.

Breast hypertrophy or masses may be physiological or pathological **(Table 13.5)**.

Virginal hypertrophy, i.e. massive bilateral breast enlargement in females probably indicates end-organ hypersensitivity to estrogens and may require reduction mammoplasty after late adolescence.

Mastodynia, the painful cyclical breast engorgement, during ovulation/menstruation time is common in late adolescence, which should be treated with analgesics and bra support.

Unilateral breast lumps in adolescence are usually benign, e.g. fibroadenoma (commonest), but rare risk of malignancy must to be excluded by FNAC or biopsy.

TABLE 13.5: Causes of breast masses

- Virginal hypertrophy
- Mastodynia
- Fibroadenoma (commonest mass in adolescence)
- Fibrocystic breast disease
- Mastitis or breast abscess
- *Malignancy:* Rhabdomyosarcoma, lymphoma
- Gynecomastia in boys due to any cause **(Table 13.4)**

TABLE 13.6: Causes of nipple discharge

- *Benign:* Local stimulation
- Pregnancy
- *Drugs:* Contraceptives, methyldopa
- ↑ *prolactin:* Pituitary adenoma, hypothyroidism#
- *Local*:* Ductal ectasia, papilloma, malignancy

* blood-tinged discharge # due to ↑ TRH

Nipple discharge: Transient milky or sticky nipple discharge in adolescent girls is not uncommon due to physical stimulation *or* drugs, e.g. contraceptives. However, persistent *galactorrhea* or blood-tinged discharge needs to be investigated for pathological causes **(Table 13.6)**.

D. Menstrual problems: Mean age of menarche in Indian girls is ~12.5 years (10–16 years) and initial cycles for first 12–18 months are often irregular and anovulatory. Menstrual onset, frequency and duration pattern usually correlates well with maternal pattern

Amenorrhea may be *primary*, i.e. absent menstruation till 16 years of age, despite breast development or *secondary*, i.e. cessation of menstruation for >3 months, after previous regular periods; due to various causes **(Table 13.7)**. Teenage pregnancy is increasingly common and needs to be excluded in cases of secondary amenorrhea.

Dysmenorrhea, i.e. lower abdominal pain or cramps during menstruation occurs in ~60% of teen-girls, frequently leading to school absenteeism. Most cases

TABLE 13.7: Causes of amenorrhea

Primary amenorrhea

- Physiological delay
- Undernutrition
- *Hypothalamic:* GnRH deficiency
- Hypopituitarism
- Gonadal dysgnenesis, e.g. Turner syndrome
- Utero-vaginal anomalies, e.g. imperforate hymen
- *Others:* Hypothyroidism, cortisol excess, etc.

Secondary amenorrhea

- Pregnancy
- *Transient:* Dieting, heavy exercise, stress
- Chronic medical illnesses
- *Endocrinal:* Hypopituitarism, hypothyroidism
- *Gonadal:* Polycystic ovary, pelvic radiation/surgery
- Utero-vaginal synechiae
- *Drugs:* Oral contraceptives, phenothiazines

TABLE 13.8: Causes of abnormal uterine bleeding

- Dysfunctional uterine bleeding (DUB)
- Threatened abortion/ectopic pregnancy
- Vaginal infections, trauma or foreign body
- *Uterine:* Endometriosis, congenital anomalies
- *Ovarian:* Polycystic ovary, tumors
- Pelvic inflammatory disease
- Systemic bleeding disorders
- *Endocrinal:* Thyroid or adrenal disorders
- *Drugs:* Oral contraceptives, aspirin

may be treated with rest and anti-inflammatory agents. Severe or secondary dysmenorrhea after initial painless cycles must be investigated for—(a) pelvic inflammatory disease, (b) endometriosis, (c) intrauterine devices, (d) utero-vaginal anomalies/tumors, and (e) ectopic pregnancy.

Abnormal uterine bleeding may be *dysfunctional* (no underlying pathology) or *secondary* **(Table 13.8)**.

Dysfunctional uterine bleeding (DUB) is a diagnosis of exclusion, usually associated with anovulatory cycles without progesterone production and unopposed estrogen excess. Treatment of severe DUB includes cyclic estrogen-progesterone therapy and iron supplementation.

E. Urogenital problems: Urogenital problems are common in adolescence due to increasing genital concerns, local mucosal susceptibility due to hormonal changes and precocious sexual activity.

Physiological leucorrhoea, i.e. thin, mucoid, acidic and non-foul smelling discharge, usually before menstruation, is common in adolescent girls due to high estrogen levels and needs no treatment except reassurance. However, any purulent, bloody or foul smelling discharge or that associated with pruritis or urinary complaints needs evaluation **(Table 13.9)**.

Non-specific vaginosis (NSV) is the commonest cause of pathological vaginal discharge in adolescent girls, due to: (a) inadequate external protection due to lack of labial pad of fat and pubic hair, (b) thin, atrophic, less acidic vaginal epithelium, (c) close proximity with anal orifice, and (d) experimental sexual activity, e.g. masturbation.

TABLE 13.9: Causes of vaginal discharge

- Physiological leucorrhoea
- Non-specific vulvovaginitis
- Vulvo-vaginal candidiasis
- Sexually transmitted diseases
- Genital trauma or foreign body
- Urethral prolapse
- Genital tumors

Common microbial etiology of NSV includes fecal pathogens, e.g. enterococci, *Staph. aureus*, anaerobic pathogens, candida, etc.

Management of these cases include: (a) good perineal hygiene, (b) symptomatic treatment, (c) topical antifungal/antibiotic agents, and (d) systemic antibiotics in selected cases. NSV need to be differentiated from more serious STDs with vaginal discharge.

Superficial perineal infections, e.g. intertrigo, fungal infections or pediculosis, etc. are common **in** both sexes due to poor perineal hygiene, use of tight underwears and sweat-induced moisture. Presence of fungal infection may be confirmed with wet KOH preparation and treated with topical antifungals, e.g. clotrimazole.

Sexually transmitted diseases (STDs) are often underdiagnosed in adolescence and may be acquired by casual contact or genital handling with contaminated fingers. According to the syndromic approach, clinical presentation of STDs may be broadly divided into *four* groups—*(a) vaginal or urethral discharge, (b) ulcerative genital lesion, (c) inguinal lymphadenopathy, and (d) pelvic inflammatory disease (PID).*

Although detailed discussion of STDs is beyond the scope of this book, a short summary of common STDs is presented in **Table 13.10**.

Congenital urogenital tract anomalies, though present since birth, are frequently noticed first time during adolescence due to menstrual problems (imperforate hymen, vaginal septa/atresia and uterine anomalies) and increased genital concerns (epispadias, hypospadias or undescended testes).

TABLE 13.10: Common sexually transmitted diseases in adolescents

	Pathogen	*Clinical feature*	*Diagnosis*	*Management**
Gonorrhea	*N. gonorrhoeae*	Discharge/PID	Gram stain	Cefixime
Chlamydia	*C. trachomatis*	Discharge/PID	Serology	Azithromycin
Trichomonas	*T. vaginitis*	Discharge	Microscopy	Metronidazole
Syphilis	*T. pallidum*	Painless ulcer	Serology	Benzathine Penicillin
Chancroid	*H. ducreyi*	Painful ulcer	Microscopy	Erythromycin
Genital herpes	*H. simplex II*	Multiple vesicles	Microscopy	Acyclovir
Genital warts	HPV	Painless warts	Clinical	Cryotherapy

*in uncomplicated disease, **PID:** Pelvic inflammatory disease

13.3 PSYCHOSOCIAL PROBLEMS IN ADOLESCENCE

Adolescents are highly susceptible to behavioral problems due to emotional turmoil and search for the independence, sometimes crossing the social barriers with substantial anti-social dimensions

Prevalence of mental health problems in Indian adolescents is estimated to be about 10–15%, though many of them remain unrecognized due to ignorance and taboo attached to them. Common psychological problems in this age group may be broadly divided into following categories:

- *Adaptive disorders,* e.g. depression, suicide, juvenile delinquency, etc.
- *Psychosomatic disorders*, e.g. anorexia nervosa, bulimia, conversion reactions, etc.
- *Disorders of sexuality*, e.g. masturbation, pregnancy.

Some common mental health issues in adolescents are discussed as follows:

Anorexia nervosa (AN) is an increasing common behavioral problem in adolescent girls, characterized by:

- Intense fear of obesity despite weight loss,
- Denial of weight loss, even if obvious,
- Refusal to maintain weight above minimal limits,
- Secondary amenorrhea for >3 cycles in females.

Epidemiology: AN is estimated to be prevalent in ~1–5% of teen girls, with a female to male ratio of 20:1. Important *risk* factors for AN include-family history, low-self esteem and preoccupation with self-image.

Clinical manifestations usually begin in adolescence with moderate efforts of dieting to improve the self-appearance, which ultimately progress to severe malnutrition. Two type of dieting efforts prevail-*restricted-eating* and *bulimic-type*, i.e. binge-eating with self-induced vomiting. Gradually the patient becomes extremely cachexic with rough and scaly skin, alopecia, constipation and signs of vitamin/mineral deficiency.

More severe cases may also develop complications, e.g. (a) dehydration/dyselectrolytemia, (b) postural hypotension, (c) neuropsychological problems, (d) pancytopenia, and (e) endocrinal problems, e.g. amenorrhea. About 10% of them may even die due to severe dehydration/shock, dyselectrolytemia and anemia.

Management of AN requires a combination of nutritional rehabilitation and psychotherapy, e.g. behavioral modification. Pharmacotherapy with antidepressants are useful only in cases with associated depression.

Bulimia nervosa (BN) is a distinct entity from AN, characterized by recurrent episodes of:

- Binge-eating, e.g. compulsive excessive and frequent eating, followed by;
- Inappropriate efforts to control weight gain, e.g. self-induced vomiting or misuse of laxatives, diuretics, enema, etc.

Unlike AN that is common in girls with low self-esteem, BN is more common in girls with impulsive or anti-social personalities like those with history of drug abuse, sexual promiscuity and suicidal attempts and stealing. Electrolyte abnormalities due to excessive vomiting or laxative use is the predominant morbidity in these cases.

Management includes a combination of nutritional monitoring, psychological support and antidepressants.

Substance abuse: Although experimental substance abuse may be considered as part of normal psychosocial development, habitual or compulsive abuse among adolescents has shown a distinctly upward trend during recent years.

Commonly used substances in India are alcohol, nicotine and volatile substances, e.g. spirit and shoe polish. Drug abuse due to other agents, e.g. hallucinogens (LSD or *ecstasy*), barbiturates, opiates and cocaine is rising; as also the use of anabolic steroids to enhance atheletic performance.

Risk factors for substance abuse include—(a) social and peer pressure, (b) emotional stress, (c) low-self-esteem, (d) family maladjustments, and (e) lack of inhibitory influences. Role of unknown genetic or biological factors has been postulated in cases with severe substance abuse or dependence.

Clinically, substance abuse should always be suspected in any adolescent with unexplained: (a) abnormal behavior, e.g. depression or mood elevation, (b) physical signs, e.g. respiratory depression, coma, papillary abnormalities, and (c) superficial indicators, e.g. unexplained needle marks or breath odor.

Management of these cases includes: (a) treatment of acute episodes with specific antidotes and supportive measures, (b) enrolment in long-term detoxification programs, (c) psychological evaluation and counseling of patient and family, (d) elimination of precipitating factors, and (e) rehabilitation in the school, family or workplace.

Masturbation, i.e. stimulation of one's own genitals to derive pleasure, is not an uncommon behavior even in pre-adolescents but becomes more common in adolescence with an incidence of as high as 90% in boys and 30% in girls. It may also be a manifestation of sexual abuse or exposure to explicit sexual material/events.

However, compulsive, intense masturbation that disturbs other activities, inter-personal relationships or involves use of objects/public display is not normative and needs counseling. Parents must be counselled about normal nature of this act. Moral lectures or punishment only intensifies this behavior. Behavioral therapy is

indicated only in rare selected cases with compulsive acts, leading to development of guilt and anxiety in adolescents and their parents.

Teen pregnancy is estimated to account for ~15% of all pregnancies in India and often get underreported.

Epidemiologically, three important risk factors for teen pregnancy in India are—(a) early marriage as a prevalent social custom in many backward regions, (b) experimental tendencies in adolescents (unwed mothers), and (c) inadequate sexual education or awareness about contraceptive methods.

Consequences of teen pregnancy are disastrous not only to mother but also to family and offspring **(Table 13.11)**. Maternal and infant mortality rates in teen mothers are ~2–3 times higher than in general population.

Prevention: Although legal barriers for early/childhood marriages are already in place in India, important preventive measures against teen-pregnancies include-(a) social reforms and community-awareness campaigns to discourage child marriages, (b) adolescent counseling at every contact level, regarding hazards and protection methods, (c) changes in adolescent-parent communication ties, (d) promotion of female literacy, and (e) easy and confidential availability of birth control education, devices and obstetrical care.

Teen-suicide: Suicide is the third leading cause of adolescent mortality in India and the fifth leading cause, globally.

Adolescents are at risk for suicide or attempted suicide due to cognitive immaturity and impulsivity. Successful attempts are more common in boys while failed attempts are more common in girls.

Adjustment disorders, anxiety and depression, substance abuse, physical/sexual abuse and parent-child conflict are common causes of suicide in adolescents.

Family history of suicide and non-suicidal self-injury behavior, i.e. deliberate destruction or alteration of body tissue without suicidal intent to cope with mental distress or secure attention are important risk factors for suicide in teens.

Many scoring systems have been developed to assess the risk of self-inflicted injury or suicides in teens, which can be used to identify high-risk cases and refer them for mental health support. HEEADSSS screening, a useful tool to assess psychosocial history in adolescents may also be used to identify high-risk cases (Ch 13.4).

TABLE 13.11: Consequences of teen-pregnancy

Maternal *(high maternal mortality)*
- *General:* Undernutrition, anemia, osteoporosis
- *Local:* Vaginal infections and STDs
- *Psychological:* Distress, depression and suicides

Obstetrical
- Cephalopelvic disproportion
- Peurperal sepsis
- Birth-canal trauma

Neonatal *(high perinatal/infant mortality)*
- Abortions and stillbirths
- Prematurity and low birth weight
- Neonatal sepsis

Socioeconomic
- Social ostracization
- Economic drawbacks
- Increased cost of health care

13.4 ADOLESCENT HEALTH CHECK-UP

Assessment of an adolescent in terms of medical issues must follow the same process as for others, though some issues are important and needs to be considered:

- **Privacy and confidentiality:** Most adolescents prefer to discuss their health issues or concerns on one-to-one basis and may be hesitant to open-up even in presence of parents or friends. Due regard for privacy is necessary during health assessment of an adolescent to permit him to discuss his/her concerns in a frank and friendly manner, without any disturbance or inhibition.

  Confidentiality is an assurance between adolescent and health-provider not to share the information exchanged between them during the assessment process, unless contravening the law or exposing him/her to harm, e.g. suicide, abuse, etc.
- **Communication and rapport building:** Health-care provider must be empathetic and non-judgement towards the adolescent to ensure good communication. Use of simple ice-breaker questions before sensitive questions, showing interest in their concerns and permitting them to express freely without arguments will allow building of a rapport between HCW and adolescent.
- **History-taking:** History must be first obtained by the adolescent himself/herself before inving the parent to collaborate, if required. It is also advisable to go beyond the presenting complaints and enquire about other issues as well as family/school environment.

  HEEADSSS is an acronym of a very useful tool to assess psychosocial history in almost all domains in adolescents. It includes eight components representing assessment of **H**ome environment**, E**ducation/employment status, performance and expectations, **E**ating/Exercise behavior including recent changes, **A**ctivities, hobbies and peer-relationships, **D**rug abuse/experimentation, **S**exual activity/behavior, **S**uicide and mood/mental health status and **S**afety/spirituality behavior including risk-taking.
- **Consent** is necessary from all adolescents 18 years of age for any examination/procedure, irrespective of the parental consent or refusal to consent and must be recorded in writing after due explanation.

In adolescents 12–18 years of age, both, an assent from them and a consent from parent is required. Parental consent is enough for children <12 years, though they must be explained the need and process of examination/procedure irrespective of the age.

- **Physical examination** must include assessment of physical growth by anthropometry vis a vis reference norms, sexual maturity using Tanner's SMR staging and detailed general and systemic examination. However, adolescents are often quite sensitive and vulnerable and following precautions are must during physical examination:
  - Record the consent before examination, as discussed earlier.
  - Ensure that a chaperone (Nurse/relative) of same sex as adolescent is present, if gender of the doctor differs from the patient.
  - Ensure complete privacy in the examination room by closing the door or using heavy curtains
  - Explain the adolescent steps and scope of examination, including the need for it, specially when assessing SMR.
  - Watch for any discomfort or change in the behavior of adolescent and abort the examination if required.
- **Disclosure:** Explain the assessment findings at the end as well as interpretation and the need for further assessment, referral, follow-up or investigations.
- **Information, education and counseling:** All opportunities to interact with adolescents should be used to provide them necessary information about nutrition, sexual changes, life-style and mental health issues, other than addressing their specific health concerns.

  Anticipatory guidance is defined as proactive counseling about expected physical, motional, psychological, and developmental changes in adolescents till next health visit to prepares them and their families for what to expect next in their child's development.
- **Referral**, if necessary for speciality services or other service delivery points, e.g. integrated counseling testing centre, de-addiction centres, social workers, mental health professionals, etc., after explaining the need for such referral.

Under the *Protection of Child Rights Act, 2005* and *Protection of Child from Sexual Offenses Act (POCSO) 2012*, it is mandatory to inform regulatory authorities, if a heath care worker comes across any suspicion act of physical or sexual abuse during the assessment process in a child or adolescent < 18 years of age.

13.5 ADOLESCENT FRIENDLY HEALTH SERVICES (AFHS)

Adolescents, generally considered as healthy, are actually at higher risk for many nutritional, life-style, sexual and mental health as well as violence and injuries. Unfortunately, existing health facilities are neither adequate nor appropriate to provide adolescent-friendly services, who are also hesitant to utilize them due to concerns, e.g. privacy, confidentiality, judgmental attitudes of staff as well as myths, misconceptions and lack of awareness.

Concept of Adolescent Friendly Health Services (AFHS) was first coined by WHO (2000), to provide broad range of preventive, promotive and curative services, specially dedicated to this age group under one roof to improve availability, accessibility and utilization.

India adopted a two-pronged strategy to provide adolescent-specific services at public health facilities during routine hours as well as n dedicated days/times since 2006 as *Adolescent Reproductive Sexual Health* (ARSH) Clinics, later expanded as AFHS clinics under *Rashtriya Kishor Swasthya Karyakram* (RKSK).

These services are delivered through trained service providers including health staff and counsellors at existing health centers, out-reach centers, e.g. schools/colleges or through telemedicine or social media. Now, many governmental, private and voluntary health agencies run dedicated AFHCs, sometimes with different names, e.g. youth clinics, youth friendly center, Jagruti, Jigyasa, etc.

Objectives: AFHCs aims to provide whole gamut of clinical and counseling services on diverse adolescent health issues including: (a) sexual and reproductive health, (b) nutrition, (c) substance abuse, (d) injuries and violence, (e) non-communicable diseases, and (f) mental health.

Functions: AFHCs aim to provide following services:

- ***Promotion of healthy life-style*** by appropriate counseling regarding nutrition, sleep and avoidance of substance abuse.
- ***Information, education and communication/counseling (IEC)*** for reproductive/sexual health issues, health concerns and life-style diseases as well as the availability of support system.
- ***Preventive services,*** e.g. growth assessment, immunization and identification of risky behavior for life-style diseases, mental health problems or social adjustment issues.
- ***Establishing a rapport*** to provide them a channel to discuss their concerns, including setting up of 24-hour help-lines.
- ***Curative services*** to diagnosis and management of health problems issues including age-specific problems,
- **Referral** to appropriate health facilities or other service delivery points, e.g. Integrated Counselling Testing Centre (for HIV), de-addiction centres, etc.

- ***Sensitize the caregivers and influencers*** on various adolescent health issues and apprise them of various available adolescent friendly health services.

Attributes: The concept "***Friendly***" in AFHCs denotes that these services should be *accessible, equitable, acceptable, appropriate, comprehensive and efficient.* These clinics should also have further referral linkages with the higher facilities and specialty clinics.

AFHC staff is specially trained to: (a) show respect for adolescents with a non-critical approach towards issues, specially related to reproductive/sexual health, (b) ensure privacy and confidentiality without sharing information provided by them with others, including parents, (c) spend adequate time and have patience to make the adolescent feel comfortable to discuss all issues related to puberty such as body image, relationships and sexuality.

CHAPTER

14

Gastrointestinal Disorders

Prachi S Karnik, Aditi Dharap, Mukesh Agrawal

Gastrointestinal tract (GIT) disorders are the second commonest cause of morbidity and mortality in Indian children, after respiratory disorders.

14.1 BASIC CONSIDERATIONS

Embryologically, GIT is largely derived from primitive *endodermal* gut tube **(Fig. 14.1)**, except the oral cavity and anus, which develop from ectodermal invaginations on two ends of this tube. In early fetal life, two membranes-buccopharyngeal and cloacal membranes, separate primitive gut tube from oral cavity and anus, respectively.

During 4–5th week, this tube elongates and divides into three segments—foregut, midgut and hindgut. The *primitive foregut* develops into pharynx, esophagus, stomach and proximal duodenum, while ancillary structures, e.g. liver, gallbladder and pancreas are derived from its ventral and dorsal outpouches, distal to the stomach. Another ventral outpouching of gut, proximal to primitive stomach, develops into respiratory tract and lungs.

The *primitive midgut* is connected to the yolk sac via *vitelline or omphalomesentric* duct till 6–8 weeks, though its proximal part may remain patent in 1–2% population as *Meckel's diverticulum*. Distal half of duodenum, small intestine, ascending colon and right 2/3rd of transverse colon develop from midgut.

The *primitive hindgut* develops into left 1/3rd of transverse colon, descending colon and rectum till the cloacal membrane, to join ectodermal anus. Lower part of this hindgut is vertically divided into two parts-anterior urogenital sinus to form urogenital system and posterior cloacal sinus to form upper part of anal canal. *Vascular and muscular layers* of gut are derived from mesoderm, while neural elements migrate from the neural crest to differentiate into intrinsic autonomic plexus. GIT also receives extrinsic nerve supply form vagus and splanchnic nerves.

Anatomically, Basic architecture of all parts of GIT is similar, composed of four layers from in-outwards—(a) *mucosal layer* with its three parts—epithelium, lamina propria and muscularis mucosae, (b) *submucosal layer*, (c) *muscularis propria* with inner circular and outer longitudinal smooth muscles and intervening myenteric plexus, and (d) *serosal or adventitious layer*. However, variations in mucosal and muscular structure as well as presence of exocrine glands and enzymes, determine specific functions of each part.

Physiologically, apart from the primary function of food assimilation, GIT also acts as physical and *immunological*

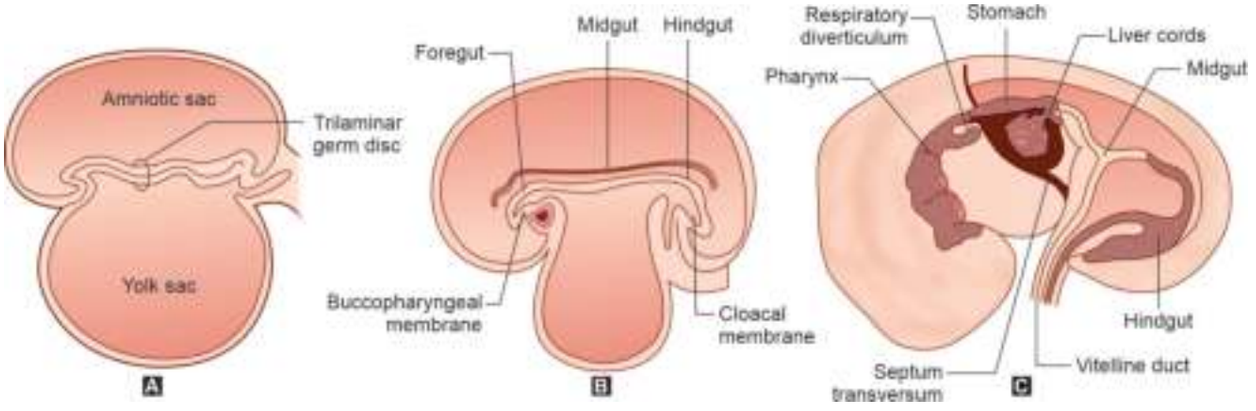

Fig. 14.1: **Development of gastrointestinal tract.**

barrier between external and internal environment, as well as an *endocrinal organ* to produce various hormones.

PHYSIOLOGY OF DIGESTION

Digestion and absorption of nutrients is a complex process, involving various digestive enzymes and transporter mechanisms, as follows:

- **Carbohydrates,** which contribute to ~60–70% of diet, are consumed as polysaccharides (starch, dextrin), disaccharides (sucrose, maltose, lactose) or monosaccharides (glucose, fructose and galactose).

  Digestion of carbohydrates involves conversion of all polysaccharides and disaccharides into monosaccharides by salivary and pancreatic amylase, and then by intestinal disaccharidase enzymes, e.g. lactase, sucrase, maltase, isomaltase, etc. Lactose splits into glucose and galactose, sucrose into glucose and fructose and maltose into two molecules of glucose. Disaccharidase enzymes are mainly present on brush borders and easily lost in diarrhea or severe malnutrition to cause carbohydrate intolerance.

  Absorption of monosaccharides across the intestinal mucosa is an active, energy-consuming process involving specific carrier substances. Glucose, sodium and certain amino acids share some of these carrier substances (basis for oral rehydration therapy).
- **Proteins,** constituting ~15–20% of diet, are consumed as complex organic compounds, which need to be split into smaller peptides or constituent amino acids before absorption. However in newborns, even intact protein molecules may be transported across the mucosal cells via *pinocytosis,* leading to sensitization of immune cells in lamina propria (basis for atopic disorders after early top-feeding).

  Digestion of complex proteins into smaller peptides/amino acids requires many enzymes, including (a) *pepsin* from pyloric and duodenal glands, (b) *trypsin* from pancreas, (c) *enterokinase* from brush borders and (d) *peptidase enzymes* in intestinal mucosal cells. In addition, gastric acid denatures proteins for easier digestion as well as activates Pepsinogen to Pepsin.

  Absorption of amino acids is also an active process, requiring many transport systems. Many amino acids share common transport mechanism, and compete with each other for absorption (basis for Pellagra in *maize-eaters*, in whom high leucine content of maize interferes with absorption of tryptophan-a niacin precursor).
- **Fats,** which form ~15–20% of diet, are consumed as visible fats (ghee, oils) or invisible fats (cereals, pulses). Biochemically, fats may be classified as *simple fats*, e.g. triglycerides (most abundant, ~98%), *derived lipids*, e.g. cholesterol and *compound lipids*, e.g. phospholipids.

  Digestion of fats requires hydrolysis of triglycerides by pancreatic *lipase* to convert into diglycerides, then monoglycerides and ultimately, into fatty acids and glycerol. *Bile salts* from the liver activate lipase and emulsify fats to convert fat-soluble monoglycerides and fatty acids into water-soluble *micelles*. *Lipase,* which is also present in salivary and gastric secretion, contributes in pre-pyloric partial fat digestion.

  Absorption of fats is a complex process. When micelles come in contact of intestinal epithelium, monoglycerides and fatty acids diffuse into mucosal cells and remaining part of the micelle, i.e. bile acids, move back into lumen for re-utilization. Inside the mucosal cell, monoglycerides are further hydrolyzed by intracellular *lipase* into fatty acids and glycerol. While water-soluble glycerol quickly enters into portal circulation, long-chain fatty acids are re-esterified into triglycerides. These triglycerides, along with cholesterol and phospholipids form a globular mass, i.e. *chylomicrons* which are extruded into the intercellular space to pass through lacteals to thoracic duct and finally reach to circulation.

Unlike long-chain fatty acids, medium-chain fatty acids do not require re-esterification and absorbed directly into the portal circulation (basis for the use of medium chain triglycerides as predominant fat in liver diseases).

Physiology of digestion and absorption for micronutrients has been discussed in respective chapters.

14.2 CLINICAL EVALUATION OF GIT DISEASE

Evaluation of GIT disease depends on presenting symptoms though general aspects are as follows:

I. History in GIT disease should include *onset*, *duration* and *progression* of presenting complaints, apart from review of general GIT functions, e.g. dietary intake, feeding habits and appetite as well as frequency and nature of stools,. Past history of worm infestations or recent travel and environmental history regarding water supply and sanitation should also be recorded.

II. General examination specially relates to anthropometric parameters, local examination of oral cavity and signs of dehydration, micronutrient deficiencies or hepatic dysfunction. Search for extra-intestinal septic focus as well as cardiovascular and respiratory examination is equally important to assess the cause/effect of GIT disorders.

III. Abdominal examination is the most important and specific component of GIT evaluation, which includes: *inspection, palpation, percussion* and *auscultation* of abdomen as well as *examination for genitals, hernia sites and spine.*

- **Inspection** involves visual examination for—(a) abdominal shape and appearance of skin, (b) movements

with respiration, (c) umbilical site, (d) superficial abnormalities, e.g. scars, sinuses and dilated veins, (e) hernia sites, (f) genitals, and (g) perineum.

Abnormal shapes include scaphoid (diaphragmatic hernia) or distended abdomen. Asymmetrical abdomen may be either due to phantom hernia or underlying mass.

Restriction of abdominal movements during breathing indicates peritonitis, while visible peristalsis may be due to underlying dynamic intestinal obstruction. Paradoxical abdominal movements suggest diaphragmatic paralysis.

Umbilicus is transversely stretched (*smiling umbilicus)* in abdominal distension. Cherry-red swelling of umbilicus in para-neonates indicates umbilical granuloma, while bluish periumbilical pigmentation suggests intra-peritoneal bleeding (*Cullen sign).*

Abdominal veins are normally visible in early infancy or in thin, fair-complexion children. Dilated veins indicate portal hypertension or inferior vena cava (IVC) obstruction, further differentiated by their location and direction of blood flow on *milking-refilling method*—(a) dilated flank and back veins with upward flow indicate IVC obstruction, e.g. Budd-Chiari syndrome, while (b) dilated and radiating periumbilical veins, flowing away from umbilicus (*Caput medusae*) indicate portal hypertension.

Genitals should be examined for descent of testes and urethral opening in males vaginal discharge in females and abnormal fecal passage for anorectal malformations. Inguinal hernia must be specially looked for, in cases of undescended testis.

Perineal inspection for anal patency, fissures or excoriation is essential in all, though per-rectal examination should be avoided and advised only in select cases, e.g. suspected Hirschsprung disease.

- **Palpation** should be done in supine position with semi-*flexed* lower limbs, to confirm inspection findings and assess for: (a) abdominal tenderness, guarding or rigidity, and (b) organomegaly.

  Abdominal tenderness, voluntary guarding or involuntary rigidity may be local or generalized and suggests underlying peritoneal or visceral inflammation. Persistent generalized abdominal rigidity also indicates muscle spasms, e.g. in tetanus. Abdominal girth should always be recorded in cases with distended abdomen, for monitoring.

  Liver must be palpated from right iliac fossa upwards, to record its—(i) size, (ii) span, (iii) surface, (iv) margins, (v) consistency, (vi) tenderness and (vii) pulsations (Ch 15.2). Liver is normally palpable till two years of age.

  Spleen is palpated from right iliac fossa by moving obliquely towards left costal margin. It may be normally palpable in first 3 months. Enlarged spleen must be assessed for size and need to be differentiated from renal mass (Ch 19.16).

  Kidneys are palpated bimanually in supine and standing position. Lower pole of the left kidney may be normally palpable in infants.
- **Percussion** mainly aims to detect presence of fluid in peritoneum by—(a) *fluid thrill* for large ascites, (b) Horse-shoe dullness for moderate ascites, (c) *shifting dullness* for mild fluid collection, and (d) *Puddle sign* in knee-chest position for minimal fluid collection of <50 ml. Percussion is also used to determine liver span and bladder fullness.
- **Auscultation** includes search for abnormal peristaltic activity, renal arterial bruit in renal artery stenosis and periumbilical venous hum suggestive of portal hypertension. Intestinal peristalsis are best heard in left lumbar region with a rate of ~1–3/minute; increased in intestinal obstruction and decreased in paralytic ileus or peritonitis.

14.3 LABORATORY EVALUATION OF GIT DISEASE

Laboratory evaluation in GIT disorders depend on the suspected etiology, though some important investigations are as follows:

I. Stool examination is the baseline investigation for suspected GIT disease. A freshly collected sample should be examined for:

- **Gross characteristics,** which vary according to the age and dietary pattern. Older children on home diet usually pass well-formed stools, which are brownish due to bile pigment and slightly foul smelling due to presence of indole and *skatole* – degradation products of organic matter.

  Gross stool examination includes evaluation of its: (a) bulk, (b) consistency, (c) color, (d) odor, and (e) presence of unusual substances, e.g. blood, mucus or worms.

  Some important diagnostic clues are as follows:
  - Clay-colored stools indicate obstructive jaundice, while black-tarry stools may be due to melena or after iron administration.
  - Rice-water stools indicate cholera or ETEC diarrhea.
  - Hard stools with pellet or ribbon-like appearance indicate Hirschsprung disease.
  - Bulky, pale, extremely foul-smelling stools with fat-globules indicate fat malabsorption (*steatorrhea*).
  - Frothy, explosive and watery stools indicate lactose intolerance.
  - Presence of blood indicates dysentery or GIT bleeding.
- **Biochemical examination** commonly includes: (a) *pH* estimation, (b) Benedict test and (c) Benzidine test.

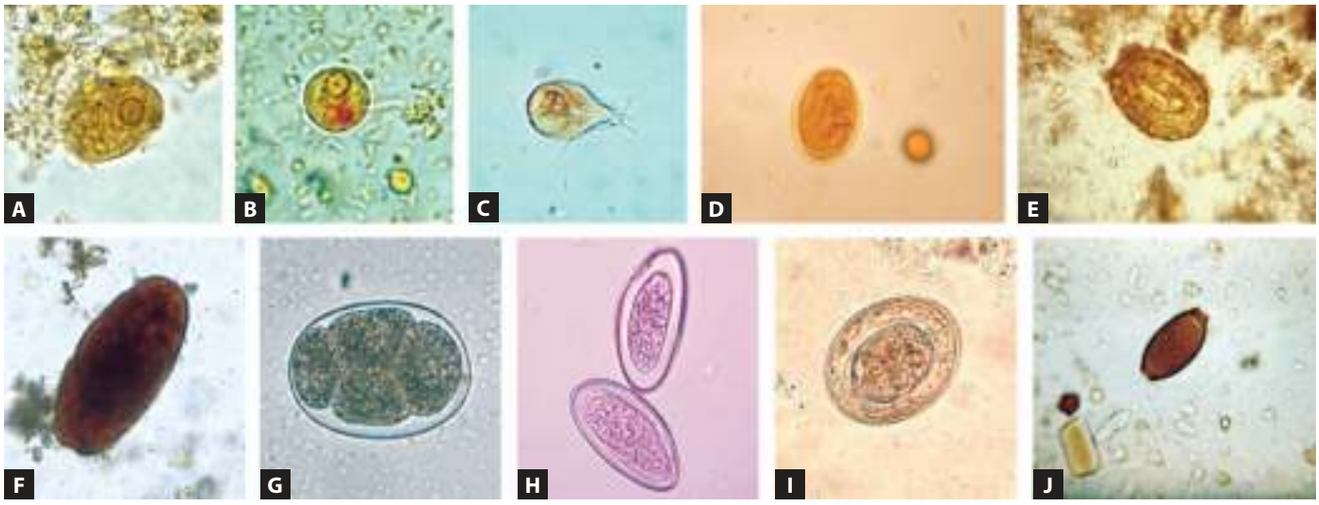

Fig. 14.2: Common ova and cysts on stool microscopy.
(A) *E. histolytica* (trophozoites); (B) *E. histolytica* (cysts); (C) *G. lamblia* (trophozoites); (D) *G. lamblia* (cysts); (E) *Ascaris lumbricoidis* (fertilized egg); (F) *Ascaris lumbricoidis* (unfertilized egg); (G) *Ankylostoma duodenale* (egg); (H) *Enterobius vermicularis* (egg); (I) *H. nana* (egg); (J) *T. trichuria* (egg).

  - Normal stool pH is alkaline, estimated by dipping a pH paper in stool suspension (red turns blue). Acidic stools (blue turns red) indicate lactose intolerance.
  - *Benedict test* detects presence of reducing sugar in stools, e.g. in disaccharide intolerance, performed in similar manner as for urine, except the use of a stool-saline suspension instead of urine sample (Ch 21.2).
  - *Benzidine test* detects presence of occult blood in stools, e.g. in hookworm infestations, performed in similar manner as for urine, except the use of a stool-saline suspension (Ch 21.2).
- **Microscopic examination:** An unstained slide of saline stool suspension should be examined for-(a) cellular elements, e.g. RBCs or pus cells, (b) ova/cysts of protozoa and parasites **(Fig. 14.2)**. Iodine staining for nuclear structures is commonly used to differentiate organic from inorganic matter.

  Hanging-drop preparation is essential in rice-water diarrhoea to exclude cholera. A drop of fresh stool sample is placed on cover-slip, which is then inverted on a slide to *see darting motility* of *V. cholerae* on microscopy.

II. Radioimaging studies: The choice of radioimaging depends on the suspected etiology, though common methods include:

- **Plain X-rays** are of limited use in GIT evaluation due to presence of gases and limited air-tissue contrast. However, an erect X-ray is essential in *acute abdomen* and must be evaluated for: (a) multiple air-fluid levels* in intestinal obstruction, (b) gas under diaphragm in intestinal perforation, extra-abdominal soft tissue, (c) lower lung abnormalities in basal pneumonitis/pleuritis, (d) foreign bodies and other obvious lesions, e.g. musculoskeletal deformities.

  *Up to three air-fluid levels are normal in standing X-ray abdomen, denoting interface at stomach, ileocaecal region and sigmoid colon. More than >3 levels indicates paralytic ileus or mechanical intestinal obstruction.
- **Barium studies** are more useful to delineate structural abnormalities and include: (a) *barium swallow* for suspected esophageal pathology, (b) *barium meal* for suspected gastric pathology, (c) *barium meal with follow-through* for small intestinal lesions, and (d) *barium enema* for colonic lesions.
- **Ultrasonography** is the preferred base-line investigation for evaluation of almost all abdominal pathologies including visceral masses, ascites and even unexplained presentations. CT/MRI is indicated only in selected cases to supplement USG findings.

III. Endoscopy is being increasing used for various diagnostic and therapeutic procedures in children with suspected GIT disorders **(Table 14.1)**. While *upper GI endoscopy* provides an opportunity to visualize from esophagus till duodenum and proximal jejunum, *colonoscopy* is used to reach pathologies from anal canal till distal ileum through ileocaecal valve.

14.4 COMMON PRESENTATIONS IN GIT DISEASE

Clinical manifestations in GIT disorders depend on the site of pathology. While *upper GIT lesions* usually present with dysphagia, vomiting, epigastric/retrosternal pain or hematemesis; *lower gut disorders* manifest with diarrhea, abdominal pain, distension, mass, constipation or hematochazia. However, such distinction is usually

TABLE 14.1: Common indications for GIT endoscopy

Diagnostic visualization
- Unexplained dysphagia
- Unexplained hematemesis
- Suspected foreign body
- Suspected GER, esophageal varices, gastric ulcers
- Chronic diarrhea or malabsorption syndrome

Diagnostic procedures
- GIT biopsy
- Collection of GIT secretions
- ERCP studies*

Therapeutic interventions
- Sclerotherapy
- Foreign body removal
- Dilatation of anorectal malformations
- Colonic surgery, e.g. polyp removal

GER: Gastroesophageal reflux; **ERCP:** Endoscopic retrograde cholangio-pancreatography.

TABLE 14.2: Causes of dysphagia

- **Oropharyngeal lesions**
  - *Congenital:* Cleft-palate, macroglossia
  - *Inflammatory:* Stomatitis, tonsilopharyngitis, diphtheria
  - *Extrinsic:* Retropharyngeal abscess, tumors
- **Esophageal lesions**
  - Strictures—congenital, GER, corrosive poisoning
  - Foreign body
  - *Inflammatory:* Reflux esophagitis, candidiasis*
  - *Extrinsic:* Aortic ring, mediastinal tumors
- **Neuromuscular un-coordination**
  - Physiological in preterms
  - Bulbar/pseudobulbar palsy (transfer dysphagia)
  - Achalasia/Hiatus hernia
  - *Motility disorders:* Riley-Day syndrome, myasthenia

*important in immunocompromised host.

obscured in later stages and hence, the onset, duration and progression of complaints are highly informative in clinical diagnosis. This chapter deals with common clinical presentations of GIT disorders, excluding diarrhea discussed later in Ch 14.10.

14.4.1 DYSPHAGIA

Swallowing is a voluntary as well as reflex activity, initiated by the presence of food or saliva in oral cavity and requires close coordination between—(a) closure of nasopharynx by soft palate to prevent nasal regurgitation, (b) closure of glottis to prevent aspiration and (c) relaxation of upper esopharyngeal sphincter to transfer food bolus into esophagus. Further esophageal passage is facilitated by peristaltic waves, culminating into relaxation of lower esophageal sphincter and transfer of food into stomach.

Dysphagia, i.e. difficulty during deglutition indicates either obstruction in food passage *(Mechanical dysphagia) or* neuromuscular incoordination in swallowing mechanisms *(Transfer dysphagia).*

Etiology: Foreign body ingestion is the commonest cause of acute dysphagia in childhood, while chronic dysphagia may be due to impacted foreign bodies or bulbar/pseudobulbar palsy **(Table 14.2)**.

Diagnostic evaluation in dysphagia includes:
- ***Detailed history,*** specially for foreign body ingestion, and relationship of dysphagia with type of foods. Neuromuscular dysphagia is more marked with ingestion of liquids, while difficulty in swallowing solids indicates mechanical obstruction.
- ***Throat examination*** to exclude local pathology, and detailed ***neurological evaluation*** for neuromuscular disorders.
- ***Relevant investigations,*** e.g. (a) X-rays for foreign body, (b) barium swallow for strictures, foreign body and achalasia, (c) esophagoscopy – preferred if possible, and (d) 24 hr pH-impedance with manometry in select cases to exclude gastroesophageal reflux disease (GERD).

14.4.2 VOMITING

Vomiting, i.e. *forceful expulsion of gastric contents with nausea or retching*, is a protective reflex, controlled by central emesis centers, which should be differentiated from regurgitation-an effortless involuntary event without nausea or retching.

Emesis *centres* are located in medulla and stimulated either directly by neurogenic afferents from GIT or indirectly by chemical stimuli from nearby chemoreceptor trigger zone (CTZ). Efferent response involves sudden violent descent of diaphragm and contraction of abdominal muscles to increase intra-abdominal pressure, with relaxation of cardiac sphincter to expel gastric contents.

Etiology: Occasional episodes of self-limiting vomiting are common in infancy due to *possetting*, *overfeeding* or *aerophagia*. A vomiting is likely to be pathological in presence of following *Red-flag signs*-(a) persistent or recurrent vomiting, (b) associated diarrhea, constipation or abdominal pain/distension, (c) associated fever, respiratory distress, altered sensorium or seizures, or (d) presence of bile or blood in vomitus **(Table 14.3)**.

Diagnostic evaluation aims to identify the etiology as well as consequences of vomiting, e.g. dehydration, dyselectrolytemia and growth failure in persistent/recurrent cases. *Metabolic alkalosis with hypochloremia* is commonest electrolyte abnormality due to loss of acidic gastric juices in vomiting. Important diagnostic clues include:
- *Age of onset:* Vomiting in *newborns* is a warning for congenital gut anomalies or neonatal sepsis after excluding benign causes, e.g. possetting, aerophagia or overfeeding. *Infants* with recurrent vomiting must be investigated for GERD, pyloric stenosis and inborn

TABLE 14.3: Causes of acute *or* persistent vomiting

	Acute vomiting	*Persistent vomiting*
Intestinal		
Esophageal	Foreign body, erosive esophagitis	GERD, foreign body, achalasia
Diaphragmatic	–	Eventration, hiatus hernia
Gastric	Acute gastritis—viral/drug induced	Peptic disease, IHPN, bezoars
Intestinal	Acute intestinal obstruction, NEC	Chronic obstruction, malrotation, worms
Visceral	Acute appendicitis, pancreatitis	Chronic pancreatitis, CIBD
Peritoneal	Acute peritonitis	Chronic peritonitis
Hepatic	Viral hepatitis, acute cholecystitis	Chronic liver disease, choledochal cysts
Extraintestinal		
Neurological	CNS infections, cerebral edema	ICSOL, hydrocephalus, migraine
Genitourinary	UTI, acute nephritis	Uremia, RTA, chronic UTI
Metabolic	Reye syndrome	IEMs, e.g. galactosemia
Endocrinal	Diabetic ketoacidosis	Adrenal insufficiency (CAH)
Drugs	Aspirin, quinines, digoxin, steroids	Anti-cancer drugs, radiotherapy
Poisoning	Food poisoning	Heavy metal poisoning
Others	Post-nasal drip, motion sickness	Whooping cough, food allergy

GER: Gastroesophageal reflux; **IHPN:** Infantile hypertrophic pyloric stenosis; **NEC:** Necrotizing enterocolitis; **CIBD:** Chronic inflammatory bowel diseases; **ICSOL:** Intracranial space occupying lesion; **RDS:** Riley-Day syndrome; **CAH:** Congenital adrenal hyperplasia; **IEM:** Inborn errors of metabolism

errors of metabolism. In *older children*, viral or drug-induced gastritis is the leading cause of vomiting apart from surgical abdominal emergencies, viral hepatitis, CNS infections, urinary tract infections, etc.

- *Onset and course:* Sudden onset of vomiting is usually due to local causes, e.g. viral or drug-induced gastritis or intestinal obstruction; while recurrent/persistent episodes indicates systemic pathology, e.g. raised intracranial pressure (ICP), hepatorenal disease or metabolic disorders. Recurrent vomiting with normal intervening period may also suggest cyclical vomiting syndrome or abdominal migraine.
- *Force, e.g.* forceful projectile vomiting indicates raised ICP or pyloric stenosis.
- *Diurnal/postural variations,* e.g. early morning vomiting episodes may be due to raised ICP, while tendency to vomit in recumbent position indicates possible GERD.
- *Relation with feeds:* Vomiting during or immediately after feeds indicates esophageal obstruction, while a delay of 15–20 minutes is common in pyloric stenosis. Vomiting due to extra-intestinal causes is not related to feeds.
- *Contents:* Presence of undigested food or fresh blood indicates upper GIT pathology, while bile indicates post-duodenal obstruction. Vomitus is highly foul-smelling in colonic obstruction and may contain fecal matter. Persistent, large, watery vomiting may also be due to rare *Zollinger-Ellison syndrome*.
- *Preceding/comorbid events*, e.g. headache, infection, drug ingestion, dietary intake, worm infestation, diarrhoea/constipation, foreign body and similar family history (food poisoning, migraine, metabolic defects) provide vital diagnostic information.
- *Physical examination* helps in etiological diagnosis, with presence of *icterus* in viral hepatitis, *abdominal tenderness* in surgical causes, *neurological signs* or papilledema in raised ICP; as well as to assess complications, e.g. dehydration, electrolyte disturbances, failure to thrive. Failure to thrive indicates chronic cause, e.g. infections, subacute obstruction and metabolic disorders.

Relevant investigations are necessary for etiological diagnosis as well as to assess fluid and electrolyte status. Important investigations in persistent vomiting include-urine analysis, liver/renal functions tests and abdominal ultrasonography, followed by CSF examination, esophagoscopy and metabolic screening in selected cases.

Differential diagnosis of common causes of vomiting in childhood include:

- **Possetting,** i.e. effortless recurrent regurgitation of gastric contents, reflects developmental immaturity of cardiac sphincter in early infancy to prevent backflow of gastric contents. Babies often outgrow it by 7–8 months and no intervention is required except burping after each feed.
- **Esophageal obstruction** (foreign body or strictures) presents with vomiting soon after feeding and contains recently ingested undigested food. Liquid are better tolerated than semi-solids.

- **GERD:** Vomiting is more common in lying down position and semisolids are better tolerated than liquids (Ch 14.6.2).
- **Food poisoning** often involves other members of family/group and diarrhea is common.
- **Infantile hypertrophic pyloric stenosis (IHPS)** is associated with typically projectile and non-bilious vomiting after 15–20 minutes of feeds, along with a mass, which is visible after feeds and disappears after vomiting (Ch 14.8.1).
- **Cyclic vomiting** refers to stereotypic episodes of intense nausea and vomiting with normal intervening period (see below).
- **Intestinal obstruction:** Vomiting is usually bilious, associated with abdominal distension and constipation. (Ch 14.13)
- **Raised ICP** in neurological disorders leads to early morning projectile vomiting, associated with headache, which is relieved after vomiting. Paroxysmal vomiting with preceding headache indicates migraine.
- **Rumination** denotes recurrent regurgitation of recently ingested food with subsequent spitting/remastication and swallowing. Self-induced vomiting is seen in adolescent girls with anorexia nervosa or bulimia.

Management of vomiting includes:

- *Symptomatic antiemetic therapy,* preferably with Domperidone (PO 0.3 mg/kg/dose) or Ondansetron (PO/IV 0.15–0.3 mg/kg/dose).

  Antiemetic drugs act by suppression of CTZ or facilitation of gastric emptying and include- (a) Dopamine antagonists, e.g. metoclopramide or domperidone; or (b) Serotonin-3 antagonists, e.g. ondansetron or granisetron. Other antiemetics, e.g. CTZ suppressors (prochlorperazine) or Antihistamines, (promethazine) are not used in children due to high risk of extrapyramidal reactions and sedation respectively.
- Correction of fluid and electrolyte imbalance.
- Evaluation of primary cause and its treatment.

Cyclic vomiting: Most cases have onset in pre-school or school age (> 2 years of age) and family history is present in 30–40%. Exact cause is unknown but each episode usually begins with autonomic features, e.g. lethargy, tachycardia, hypertension and abdominal pain.

Diagnostic criteria includes: (a) minimum total 5 episodes or 3 episodes in 6 months, (b) each episode lasting from 1 hour to 10 days with at least one week normal interval, (c) > 4 vomiting/hour for at least one hour, and (d) no identifiable cause.

Management includes antiemetics and supportive therapy during the episode, which can be prevented with Cyproheptadine (PO.25–0.5 mg/kg/d q8–12hr) or Propranolol (PO 0.25–1 mg/kg/d at bed time.

14.4.3 ABDOMINAL PAIN

Abdominal pain is a very common complaint in childhood, though may not be recognized in infants. Sudden coiling-up of body with abdominal rigidity, excessive crying and anxious, restless appearance may be a sign of abdominal pain in young children.

Abdominal pain may arise from somatic tissues or internal viscera. Visceral pain indicates spasm, distension, inflammation or ischemia of these organs and may be referred from or to other sites, e.g. abdominal pain due to basal pneumonia or right shoulder pain from the gallbladder.

Etiology: Abdominal pain may be acute *or* recurrent and idiopathic *or* secondary to identifiable cause **(Table 14.4)**.

Acute abdominal pain is usually organic in origin and needs exclusion of surgical/medical emergencies, specially if—(a) lasts for >3 hours, (b) well-localized or (c) associated with abdominal tenderness, distension, vomiting, fever or sick appearance. However, mild, short-duration, colicky pain is common in children and tends to be benign.

Recurrent abdominal pain (RAP), defined as *at least one episode per month for minimum three consecutive months*, is complained by 10–20% of children, of which ~70–80% are functional or psychological. It is often, but not always, possible to differentiate functional RAP from organic causes **(Table 14.5)** to avoid unnecessary investigations.

Functional RAP is uncommon below 5 years of age and tends to be more common in females, first-born children and those with timid or anxious personality. These children often find it difficult to describe or localize the pain and are usually normal in between attacks. Any stress in family or school may precipitate these attacks. Many functional disorders associated with abdominal pain have been described, as follows:

- *Irritable bowel syndrome (IBS),* defined as abdominal pain for at least one day per week in last 3 months, with any one of the following features during the episode: (a) pain related to defecation, (b) change in frequency of stools, and (c) change in consistency of stools (*Rome IV criteria*). Onset of symptoms must be at least 6 months before diagnosis.
- *Abdominal migraine* presents with paroxysmal episodes of intense abdominal pain, lasting for at least one hour with normal intervening periods of weeks/months *and* presence of any two of the following associated features – nausea, vomiting, anorexia, headache, photophobia and pallor.
- *Functional dyspepsia* denotes any one of the following for at least four times in a month for 2 months with- (a) post-prandial fullness, (b) early satiety, (c) epigastric pain.
- *Functional abdominal pain-not otherwise specified* (FAP-NOS), refers to episodic or continuous periumbilical

TABLE 14.4: Causes of abdominal pain

		Acute abdominal pain	*Recurrent abdominal pain (>3 months)*
a.	**Non-organic**	Dietary indiscretion, aerophagia	Infantile colic, psychological
b.	**Intra-abdominal**		
	• Esophagus	Acute esophagitis	Reflux esophagitis (GER, hiatus hernia)
	• Stomach	Acute gastritis (drug or viral)	Peptic ulcer (*H. pylori* infection), bezoars
	• Intestines	AGE, AIO, strangulated hernia	Constipation, worms, MAS
	• Liver	Hepatic abscess, cholecystitis	Gallstones, choledochal cysts
	• Pancreas	Acute pancreatitis	Chronic pancreatitis, pseudocyst
	• Peritoneum	Acute peritonitis, ischemia (SCD)	Koch's abdomen, gross ascites
	• Kidney	UTI, Dietel's crisis	Wilms' tumor, stones, chronic UTI
	• Spleen	Traumatic rupture	Gross splenomegaly
	• Pelvic disease	Testicular torsion	PID, Ovarian cyst
c.	**Somatic**	Trauma, infections	Non-specific myalgia
d.	**Extra-abdominal**	Non-specific myalgia	
	• Respiratory	Basal pneumonia, pleurisy	–
	• Cardiac	Rheumatic fever, pericarditis	–
	• Neurological	–	Abdominal epilepsy, migraine
	• Metabolic	Hypoglycemia	Porphyria
	• Spinal	Trauma	Tumor, Pott's spine
	• Endocrinal	Diabetic ketoacidosis	Hyperthyroidism, Addison disease
	• Poisoning	Ac. drug/chemical ingestion	Lead poisoning
	• Hematological	Sickle cell disease, porphyria	Tumors and lymphomas
	• Collagen disorders	Henoch-Schonlein purpura	–

AGE: Acute gastroenteritis; **AIO:** Acute intestinal obstruction; **GER:** Gastroesophageal reflux; **MAS:** Malabsorption syndrome; **PID:** Pelvic inflammatory diseases; **UTI:** Urinary tract infection.

TABLE 14.5: D/D functional vs organic RAP

	Functional	*Organic*
Age of onset	>5 years	<5 years
Location	Diffuse/Periumbilical	Localized
Character	Non-specific	Specific
Duration	>2 months	–
Symptoms at rest	Absent	Present
Effect on activity	None	Present
Assoc. findings	None	Present

pain at least four times in a month for >2 months, which does not fulfil criteria for IBS, Abdominal migraine or functional dyspepsia. Treatment includes reassurance, high-fiber diet, avoidance of carbonate drinks/refined food and psychotherapy.

Diagnostic evaluation of abdominal pain includes:

- ***Detailed history*** about its—(a) *onset, duration and progression*, (b) *character* (colicky, dull, burning, sharp shooting), (c) *localization** (epigastric, supraumbilical or infra-umbilical), (d) any *migration or change* in its character and severity, (e) *relationship with feeding, respiration and movements* and (f) *associated complaints*, e.g. vomiting, diarrhea/constipation, worm infestation, pica, urinary complaints and abdominal trauma, etc. Menstrual history is important in pubertal girls.

  **Pain arising from stomach, upper bowel, hepatobiliary system and pancreas is often localized in epigastrium. Periumbilical pain, common characteristic in appendicitis, also indicates distal bowel, cecal or proximal colon disease. Distal colonic, pelvic and bladder pain is usually suprapubic in location.*

- ***Clinical examination*** for abdominal distension, tenderness, rigidity or guarding, ascites, organomegaly, lump, bowel sounds, etc., along with examination of hernial sites, genitals and spine. Examination of lungs (basal pneumonia), heart (CCF/pericardial effusion) and rectal examination for pelvic inflammatory disease (in adolescents) is necessary to exclude extra-intestinal causes.
- ***Baseline investigations*** are necessary even in apparently functional cases to exclude organic pathologies and include:
  - Complete hemogram
  - Stool exam, specially for parasites and occult blood

  - Urine exam, specially for pus cells and crystals
  - Chest skiagram for basal pneumonia, TB, etc.
  - Tuberculin test
  - X-ray abdomen for obstruction, stones, etc.
- ***Relevant investigations:*** Ultrasonography is highly informative and essential investigation in all cases of unexplained/recurrent abdominal pain. Other investigations, e.g. contrast studies, CT/MRI or endoscopies are necessary only in selected cases.

Differential diagnosis of some important causes of organic abdominal pain is as follows:

- **Esophagitis or gastritis** presents with retrosternal pain with burning character, frequently associated with history of drug intake or viral infection.
- **Intestinal obstruction** may be acute or subacute and associated with vomiting, constipation and distension.
- **Acute appendicitis** begins in periumbilical pain, which slowly migrates to right ileac fossa after 4–6 hours. Rebound tenderness at *McBurney's point* is characteristic.
- **Biliary colic** is rare in children and generally presents with pain referred to right scapula or back. Intermittent colic with jaundice is a strong indicator of gallstones, specially in hemolytic anemia.
- **Ureteric or renal colic** typically begins in lumbar region and descends from loin to groin. Urinary retention for variable period during these episodes is common.
- **Dietel's crisis** presents with severe intermittent pain and oliguria, followed by polyuria after torsion of ectopic kidney is relieved.
- **Pelvic inflammatory diseases** are common in sexually active adolescents, best diagnosed on rectal examination.

14.4.4 CONSTIPATION

Constipation is a relative term as frequency of defecation varies significantly in different children. For practical purpose, *passage of hard stools every third day or even at lesser frequency* may be termed constipation. Constipation lasting for more than 4 weeks is considered as *chronic constipation*.

Defecation is largely a reflex activity in infants, before gradual development of voluntary control. Reflex is initiated by the distension of rectum by faeces sending afferent stimuli to spinal defecation centers at S_{2-4} followed by efferent parasympathetic impulses to relax anal sphincter.

Voluntary control by higher centres generally develops by 18 months, when defecation may be initiated or inhibited using abdominal and diaphragmatic musculature to alter abdominal pressure and anal tone.

Etiology: Constipation may be functional or organic **(Table 14.6)**. Organic constipation may arise from: (a) filling, (e.g. starvation, ileus) or evacuation, (e.g. anal fissures) defects in rectum, (b) impaired defecation reflex (Hirschsprung disease, spinal lesions), or (c) lack of effective contraction due to hypotonia of voluntary muscles.

TABLE 14.6: Causes of constipation

Non-organic
- *Habitual (functional):* Faulty toilet training
- *Low fecal load:* Under-feeding, low fiber diet
- *Dehydration:* Top feeding, poor water intake

Organic
- Dehydration: Fever, polyuria (Diabetes mellitus/insipidus)
- Mechanical: IHPS, AIO, anorectal anomalies
- Poor evacuation reflex: Hirschsprung disease
- Painful defecation: Anal fissure, hemorrhoids
- Hypotonia
  - General—hypothyroidism, floppy child, C. palsy
  - Local—spinal lesions, paralytic ileus, hypokalemia
- *Drugs:* Iron, laxative abuse, antihistaminics

IHPS: Infantile hypertrophic pyloric stenosis, **AIO:** Acute intestinal obstruction.

Anal fissures, Hirschsprung disease and hypothyroidism are three most common causes of organic constipation, except in early infancy when mild anorectal malformations have to be excluded.

Constipation tends to be *self-perpetuating*, with hardening of stools due to excessive retention in colon, making act of defecation further painful with voluntary retention. Eventually, watery colonic contents may percolate around hard-retained stools (*fecoliths*) and leak through anal sphincter, leading to *encopresis*.

Functional constipation is defined as persistence of constipation for >4 weeks with any two or more of following features: (a) stool frequency ≤2 per week, (b) hard, painful bowel movements, (c) excessive retention of stools, (d) large diameter stool obstructing the Indian pots, (e) faecal incontinence, (f) faecal mass or fecoliths on abdomen/rectum examination (*IAP 2018*).

Faulty and coercive toilet training, changes in the diet, acute illness or lack of clean toilet are important causes of functional constipation in children.

Diagnostic evaluation of constipation involves:

- *Age of onset:* Functional constipation often begins after 2 years of life
- *Clinical evaluation* for possible organic cause, as indicated by presence of intermittent diarrhea, significant abdominal distension and failure to thrive.
- *Stool examination:* Hard pellet or ribbon-like stools indicate Hirschsprung disease.
- *Per-rectal examination* to assess for anal position (anorectal malformations), fissures, anal tone (lax in spinal lesions), rectal findings (empty in Hirschsprung disease, fecoliths in functional constipation) and gush of fecal matter after withdrawal of finger (Hirschsprung disease).

- *Exclusion of hypothyroidism* by bone age estimation and serum TSH levels.
- Anorectal manometry for suspected Hirschsprung disease.

Treatment of organic constipation depends on the cause, while functional cases are treated with: (a) Regular *toilet training*, (b) *high-fiber diet* (0.5 g/kg/day) with adequate water intake, (c) *faecal disimpaction, and* (d) *oral laxatives.* Anal fissures, if there, must be treated.

Faecal disimpaction is indicated in acute severe cases with PO polyethylene glycol (25 ml/kg/hr for 4–6 hours) or per-rectal enema (sodium phosphate enema 2.5 ml/kg > 2 years). Saline enema is used in young infants.

Oral laxatives are indicated in sub-acute or chronic cases after excluding an obstructive pathology. Polyethylene glycol (0.5–1 gm/kg/day q12–24hr) is the preferred laxative of choice in children, though other osmotic laxatives, e.g. lactulose (1–3 ml/kg/day q12–24 hr) or Lactilol (200–400 mg/kg/day q12–24 hr) may also be used. Laxative therapy should be continued for many weeks before slow tapering.

Oral stimulant laxatives, e.g. Sodium picosulfate (10–20 mg/day q24 hr) or Bisacodyl (5 mg/day > 3 yr of age) may be used as *rescue therapy* for 2–3 days in patients on osmotic laxatives with intermittent exacerbations.

14.4.5 GIT BLEEDING

GIT bleeding may be broadly divided into three categories:

a. *Hematemesis*, i.e. blood-mixed vomitus containing either *fresh blood* suggestive of oropharyngeal, esophageal or gastric bleeding, or *altered blood* due to acid hematin formation in gastric bleeding.
b. *Melena*, i.e. dark tarry stools containing altered blood suggestive of upper GIT bleeds after a few hours, due to downward passage of blood.
c. *Hematochezia*, i.e. passage of fresh blood in stools, suggestive of colorectal or anal bleed.

Etiology: GIT bleeding indicates either a local pathology or a systemic bleeding diathesis **(Table 14.7)**. Esophageal varices or drug-induced gastritis are predominant causes of hematemesis and melena, while hematochezia usually indicates local pathology, e.g. anal fissures.

Diagnostic evaluation of GIT bleeding depends on the clinical presentation—hematemesis, melena or hematochezia. Other important etiological clues include:

- ***Detailed history,*** specially regarding-age of onset, coexisting abdominal pain, diarrhea, constipation or painful defecation, recent drug ingestion or worm infestation and past history of similar attacks.
- ***Physical examination*** specially for signs of nasal/dental bleed, portal hypertension, abdominal tenderness, anal fissure as well as sepsis or bleeding diathesis, e.g. purpura. In cases of massive bleeds, it is important to assess the severity of anemia (pallor) and circulatory insufficiency (hypotension/shock).
- ***Relevant investigations*** depending on probable site of bleed and include:
  - Endoscopy, i.e. esophagoscopy (for hematemesis) and proctoscopy/colonoscopy (for hematochezia) in severe or persistent unexplained bleeding.
  - Stool exam for occult blood and ova/cysts.
  - Plain/contrast radioimaging studies, specially to identify small intestinal causes – a region not easily accessible through endoscopes.
  - Screening for bleeding disorders, e.g. BT/CT, platelet count, coagulation profile, etc.
  - Sepsis screening, including blood cultures in suspected septic cases.

Table 14.7: Causes of GIT bleeding

A. Swallowed blood: Maternal*, epistaxis, caries	
B. Upper GIT bleed: (Hematemesis/ Melena)	
– *Esophageal*	: Varices, esophagitis, foreign body
– *Gastric*	: Acute gastritis, stress/peptic ulcer Mallory-Weiss syndrome
C. Lower GIT bleed (Hematochezia)	
– *Intestinal*	: Dysentery, IBD, NEC*, intussusception Meckel's diverticulum#, milk allergy#, Hookworm infestation#
– *Anorectal*	: Fissures, hemorrhoids, polyps, trauma
D. Systemic	: HDN*, septicemia, DIC, ITP, HSP.

IBD: Inflammatory bowel diseases, **HSP:** Henoch-Schönlein purpura
HDN: Hemorrhagic disease of newborn, **ITP:** Idiopathic thrombocytopenic purpura
*common causes in newborns, #occult bleeding.

Differential diagnosis of common causes of GIT bleeding are as follows:

- *Swallowed blood* is usually miniscule in amount, with prior history of epistaxis or gingival bleeding.
- *Esophageal bleeding* usually presents with sudden, large vomiting of fresh blood without gastric contents. Esophageal varices due to portal hypertension are the commonest cause of recurrent hematemesis. Retrosternal burning pain may be present in early cases.
- *Gastric bleeding* is common after ingestion of drugs, e.g. chloroquine or NSAIDs, and contains undigested food. *Mallory-Weiss syndrome* denotes hematemesis due to longitudinal mucosal tear at gastroesophageal junction or gastric cardia, following forceful vomiting/retching, irrespective of cause.
- *Meckel's diverticulum* is the commonest cause of recurrent painless hematochezia/melena, though abdominal pain may be present.

TABLE 14.8: Causes of abdominal distension

- ***Physiological:*** Obesity, constipation
- ***Hypotonia:*** PEM, rickets, hypothyroidism
- ***Fluid:*** Ascites, peritonitis
- ***Gaseous distension:***
  - Aerophagia (swallowed air)
  - *Malabsorption:* Lactose intolerance, gastroenteritis
  - Stasis, e.g. intestinal obstruction, paralytic ileus
- ***Intra-abdominal solids:***
  - Intestinal, e.g. fecoliths, Hirschsprung disease
  - Hepatosplenomegaly
  - Tumors

- *Hookworm infestation* is the commonest cause of occult bleeding in Indian children, while cow-milk allergy is common in infants.
- *Intestinal polyps* lead to painless bleeding which is rarely severe. *Peutz-Jeghers syndrome* is an autosomal disorder, characterized by intestinal polyposis and perioral pigmentation.
- *Anal fissures* are the commonest cause of painful hematochezia, associated with constipation.

14.4.6 ABDOMINAL DISTENSION

Abdominal distension indicates either hypotonia of abdominal musculature (Pot belly) *or* increased intra-abdominal pressure due to fluid, gas or organomegaly- often referred as 4 Fs, i.e. *f*at, *f*luid, *f*latus and *f*eces **(Table 14.8)**. A 5th F, i.e. *f*etus may be considered in adolescent females.

Acute intestinal obstruction is the most important cause of sudden abdomen distension in childhood, while gradually progressive distension usually indicates ascites.

Pot belly is a common cause of distended abdomen in Indian toddlers due to malnutrition or rickets, which needs to be distinguished from serious pathologies.

14.4.7 ABDOMINAL MASS/LUMP

Abdominal masses in children may arise from any visceral organ; best identified according to their location **(Table 14.9)** as well as associated complaints.

Local examination of mass for location, size, surface, consistency, tenderness, ballotability (renal masses) along with per rectal examination in pelvic masses, often limits the diagnostic possibilities. Presence of *hypertension* is an important clue towards renal mass.

Although the choice of investigations depends on probable cause, ultrasonography is a baseline investigations in most cases, apart from urine and stool examination. CT/MRI and radionucleotide scan may be required in selected cases.

TABLE 14.9: Causes of abdominal mass/lump

Right hypochondrium (hepatobiliary)
- Hepatomegaly
- Liver abscesses and cysts
- Liver tumors (primary/secondaries)
- Choledochal cysts, hydrops

Left hypochondrium (splenic)
- Splenomegaly/cysts
- Renal masses (see below- Lumbar mass)

Mid-abdominal (peri-umbilical)
- Infantile hypertrophic pyloric stenosis
- Intestinal—volvulus, intussusception, duplication
- Mesenteric—cysts, lymphadenoapthy
- Pancreatic—pseudopancreatic cysts

Lumbar (renal)
- Congenital anomalies, e.g. polycystic kidney
- Hydronephrosis
- Renal vein thrombosis
- Wilms' tumor

Suprapubic
- Full bladder
- Uterine mass, e.g. hydrometrocolposis
- Sacroccygeal teratoma

Iliac region
- Fecoliths
- Appendicular abscess (Rt side)
- Ovarian tumors or cyst
- Pelvic inflammatory diseases

14.5 DISORDERS OF ORAL CAVITY

Various structures of oral cavity participate in sucking, biting, chewing, lubrication and swallowing of ingested food, which is also primed for digestion by various salivary enzymes, e.g. amylase or lingual lipase. While sucking mechanisms are well developed at birth in term newborns, swallowing matures slowly over 1–2 months leading to higher risk of aspiration in newborns. Chewing mechanisms usually matures by 6–8 months, by the time to start weaning.

14.5.1 CLEFT LIP AND CLEFT PALATE

Cleft lip and cleft palate (CLP) are two distinct but closely related developmental malformations of oral cavity with impaired development or fusion of facial processes.

Embryology: Normally, the lip and alveolus develop by fusion of maxillary and medial nasal processes, while palate develops by fusion of two palatal halves in midline. Thus, *Cleft lip* represents absence of fusion between medial nasal process with maxillary process, while *cleft palate* indicates failure of two palatal shelves to approximate or fuse.

Incidence of cleft lip with/without palate and cleft palate alone is ~ 1:1000 and ~1:2000 children respectively, former being more common in males. Isolated cleft palate is more common than isolated cleft lip (40% *vs* 15%), while ~45% cases have combined defect.

Fig. 14.3: **Cleft lip (A) and cleft palate (B).**

Cleft lip is usually an isolated defect, while cleft palate may be either alone or with other congenital malformations, e.g. first branchial arch defects or chromosomal abnormalities.

Etiology of CLP is multifactorial with a genetic basis and environmental factors, e.g. maternal smoking or alcohol/drug consumption. Familial tendencies are known, with recurrence risk of ~3–4% and ~10–15% in siblings and offsprings of the index case, respectively. Many genetic mutations have been identified associated with CLP, e.g. TGFA, TGF-133, etc.

Clinically, cleft lip may be unilateral or bilateral, varying from being a small notch in vermillion border to complete separation extending up to nasal floor. Cleft palate may involve uvula, soft and hard palate or even combine with cleft lip to expose one or both nasal cavities **(Fig. 14.3)**.

Functionally, cleft lip alone is a cosmetic abnormality, while cleft palate can adversely affect various facial functions e.g,

- Feeding difficulties, due to inability to create sufficient negative pressure for sucking.
- Recurrent aspiration and respiratory infections
- Deafness, due to eustachian tube dysfunction and recurrent otitis media.
- Dental malocclusion and caries.
- Speech defects, due to misarticulation, hyper/hyponasality and nasal escape.

Management of CLP is a team-work involving surgeon, dentist, pediatrician and speech therapist. Treatment of cleft lip is mainly surgical, while cleft palate requires special medical care till repaired.

Medical management of cleft palate includes:

- *Feeding:* While many babies with cleft palate can suck effectively, it is preferable to feed them expressed breast milk via a bondla or spoon to obviate the need of sucking and in propped-up position to prevent aspiration. *Obturators* may be useful to allow direct breastfeeding in smaller clefts.
- *Speech* often remains impaired till surgery, but subsequently normal speech may be attained after surgery by speech therapy.
- *Dental malocclusion* requires post-operative orthodontic correction. Normal jaw growth and dental occlusion may remain subnormal even after surgery, due to abnormal compression of the repaired lip, inherent bony deficiency and scar contracture.
- *Hearing* is commonly impaired due to recurrent otitis media and hence, early treatment of these cases is critical to retain hearing and later speech.

Surgical management aims to aesthetically reconstruct the defect, to obtain adequate speech and feeding functions, and to encourage adequate growth of facial skeleton. Just after birth, pre-surgical orthodontics/nasoalveolar molding may be given to reduce the width of the cleft, correct the depression of the alar base and improve alveolar alignment.

- ***Cleft lip*** is usually operated at 3–6 months (Rule of 10-age: 10 weeks; Weight: 10 lb; Hb: 10 gm) with *Z-plasty*, though revision surgery may be needed at 5–6 years and rhinoplasty during adolescence.
- ***Cleft palate*** is usually operated at 9–12 months to allow normal speech development, though timing has to be individualized according to the size of defect. Good post-operative care is critical for surgical success, as wound infection with re-opening of defect and aspiration are common post-operative complications.

Some other important orofacial malformations are as follows:

Pierre-Robin syndrome is an important orofacial malformation with mandibular hypoplasia, characterized by a triad of—(a) micrognathia/retrognathia, (b) macroglossia, and (c) glossoptosis. These cases must be managed in prone position to prevent posterior displacement of the tongue that may obstruct airways. Severe cases may require suturing of the tongue with alveolar margins and/or tracheostomy, till mandibular growth is adequate.

Treacher Collins syndrome (Mandibulo-facial dysostosis) is a rare facial dysmorphism, with triangular face, receding chin, blind fistulas between ears and angle of mouth, downward slant of eyes, coloboma of eyelids and ear abnormalities with/without deafness.

14.5.2 DENTAL CARIES

Dental caries (*tooth decay*), is a very common problem in Indian children, involving mainly deciduous teeth.

Etiologically, caries may be divided into three steps:

a. Collection of residual carbohydrates over dental pits and between teeth, forming a *plaque.*
b. Fermentation of these plaques by acid-forming oral flora, e.g. *Strept. mutans,* lactobacilli, etc.
c. Demineralization and destruction of enamel by these acids.

Fig. 14.4: **Dental caries.**
(*Courtesy:* Dr Adesh Kakade)

Risk factors: Bottle-feeding, sticky candies, and enamel hypoplasia due to malnutrition or fluorine deficiency are three most important risk factors for caries, apart from others, e.g., poor oral hygiene, salivation disorders, GERD and family history.

Clinically, dental caries generally begins in *difficult to see* areas, e.g. pits,fissures or contact surfaces of two adjoining teeth, as an opaque white plaque that enlarges and deepens gradually to produce visible cavities. Presence of pain indicates spread of caries to the pulp.

Untreated caries may progress to develop more severe complications, e.g. (a) pulpitis, (b) dental abscess, and (d) neighbouring infections, e.g. gingivitis, facial cellulitis, Ludwig angina and osteomyelitis **(Fig. 14.4)**.

Treatment: Role of pediatrician in dental caries primarily involves: (a) early detection of lesions and timely referral to dentist, (b) control of pain/inflammation with analgesics and antibiotics, and (c) management of complications, apart from preventive guidance.

Prevention depends on: (a) maintenance of oral hygiene, (b) improvement of nutrition and avoidance of sweetened foods, (c) adequate fluoride content of water (minimum 1 ppm) and monitoring of high-risk cases. Use of topical fluoride agents or dental sealants is beneficial in some cases.

14.5.3 ORAL CAVITY INFLAMMATIONS

Oropharyngeal inflammations may be infectious *or* non-infectious in origin. Some common inflammatory disorders of oropharynx include:

Cheilitis, i.e. *inflammation of lips and angle of mouth* (angular cheilitis) is commonly caused by dryness in winter or windy weather, which may be treated with frequent application of petroleum jelly. However, severe/refractory cases may be due to—(a) zinc deficiency, (b) contact/atopic dermatitis, and (c) extension of oral thrush.

Aphthous ulcers *or* stomatitis present as solitary or multiple, well-circumscribed lesions of variable sizes, with gray fibrinous exudates and erythematous halo on gingival, lingual or palatal mucosa.

Etiology is probably multifactorial, thought may be associated with local trauma, vitamin B_{12} deficiency, emotional stress, malabsorption syndrome or allergy. Most cases improve spontaneously within 7–10 days and treatment is palliative with topical application of viscous xylocaine or steroids before feeding.

Severe/recurrent/persistent ulcers are seen in-(a) entero-viral infections, e.g. herpangina, hand-foot-mouth disease, (b) chemical/thermal burns, (c) gingivostomatitis due to anaerobic infections, and (d) systemic diseases, e.g. Crohn disease, Behçet's syndrome, SLE, etc.

Vincent angina (Trench mouth) is an acute, fulminant, necrotizing infection of oral cavity due to *anerobic* flora, e.g. fusobacteria and spirochetes. Mostly seen in severely malnourished children, these cases present with-(a) painful gingival ulceration and swelling, (b) adherent grayish pseudomembrane over affected gingival and (c) foul-smelling breath with/without signs of systemic infection. Treatment includes antibiotics (penicillin/erythromycin), local debridement and analgesics.

Oral thrush is very common in normal newborns or young infants <3 months. In older children, it may be seen in cases with—(a) prolonged antibiotic therapy, (b) chronic debility or immunodeficiency states.

Clinically, thrush appears as whitish patches over oral mucosa **(Fig. 14.5)**, with inflamed base that leaves pin-point hemorrhages on removal (*d/d* milk patch).

Topical nystatin or clotrimazole application is often enough, though severe/persistent thrush requires exclusion of immunodeficiency disorders and systemic

Fig. 14.5: **Oral thrush.**

antifungal therapy. Oral rinses with 0.2% chlorhexidine may be useful to prevent recurrence, specially in immunocompromized cases.

14.5.4 TONGUE DISORDERS

Common tongue disorders include abnormalities of its size or appearance, which may/may not be of clinical consequence.

Macroglossia is seen in hypothyroidism, Down syndrome, Beckwith syndrome, Pierre Robin syndrome and tongue hemangioma.

Abnormal appearance, e.g. *geographic tongue* (single/multiple, well-demarcated, smooth red plaques due to transient papillary atrophy), *scrotal tongue* (deep fissured tongue with wrinkled appearance), *black hairy tongue* (dark-coated tongue with papillary hyperplasia) may be idiopathic or secondary to infection, malnutrition, atopy or trauma. No treatment is needed in these cases, except to ensure adequate oral hygiene, nutrition and control of infection, if present.

14.5.5 SALIVARY GLAND DISORDERS

Salivary gland abnormalities may involve one or more of three salivary glands—parotids, submandibular or submental glands.

Acute parotitis is almost always caused by mumps (usually bilateral), though needs to be differentiated from rare case of *acute suppurative parotitis* in staphylococcal infections (unilateral), or other causes of *parotid enlargement*, e.g. malnutrition, HIV infection, cystic fibrosis and benign salivary gland hypertrophy.

Xerostomia *(dry mouth)*, seen in any fever, dehydration, anticholinergic therapy and Sjögren's syndrome, may also precipitate parotid swelling/parotitis due to desiccation of salivary secretions in their ducts.

Ranula is a common cyst of major salivary gland (usually sublingual), presenting as a large, soft, mucus containing swelling over floor of the mouth at any age, which needs to be excised.

14.6 ESOPHAGEAL DISORDERS

Esophagus propels the swallowed food from oropharynx to stomach by peristaltic activity, as well as prevents regurgitation of gastric contents by tight closure of lower esophageal sphincter at rest. A sharp angulation between lower esophagus and gastric fundus also prevents regurgitation.

In newborns, developmental incompetence of lower esophageal sphincter and relative straightening of gastroesophageal junction may lead to transient gastroesophageal reflux, which improves with age.

Dysphagia, odynophagia and vomiting or regurgitation of gastric contents are common presentations in esophageal disorders.

14.6.1 TRACHEOESOPHAGEAL FISTULA (TEF)

Esophageal atresia (EA) with or without tracheoesophageal fistula (TEF) is a life-threatening surgical emergency in newborns, seen in ~1:3000–5000 live births and carries high mortality, unless operated within 24 hours of birth.

Embryogenesis: Esophagus and trachea develop from a common primitive foregut, separated by a tracheoesophageal septum. EA usually results from posterior deviation of this septum, while its incomplete development results in concurrent TEF. EA without TEF may also result from incomplete canalization of the primitive esophagus.

Other congenital anomalies are present in ~50% cases, including VACTERL association, i.e. ***V***ertebral, ***A***norectal, ***C***ardiac, ***T***racheo***e***sophageal fistula, ***R***enal/***R***adial and ***L***imb defects.

Pathogenesis: Due to blocked esophageal passage and fistulous communication, these babies develop regurgitation and aspiration of feeds or gastric secretions soon after birth, with chemical pneumonitis and subsequent secondary bacterial pneumonia.

Anatomical types: Various anatomical variations of these defects are as follows **(Fig. 14.6)**:

- *Type I* (85%): Most common type, in which a fistula connects lower end of esophagus with trachea while upper end of esophagus is blind.
- *Type II* (8%): Both, the upper as well as lower end of esophagus are blind with no fistula.
- *Type III* (4%) is an H-type fistula, with no EA but a connecting tract between trachea and esophagus, usually at the level of carina. Frequently missed at birth, these cases present in infancy with recurrent aspiration.
- *Type IV* (<2%): A fistulous connection between upper esophageal pouch and trachea, with blind lower end of esophagus.
- *Type V* (<1%): Two separate fistulous tracts between blind upper and lower ends of esophagus, with EA.

Clinically, all cases except H-type, present within a few hours of birth with:

- Persistent, copious, fine, white, frothy bubbles of mucus in mouth,
- Recurrent episodes of coughing, cyanosis and choking at the time of feeding with progressive respiratory distress due to aspiration pneumonia,

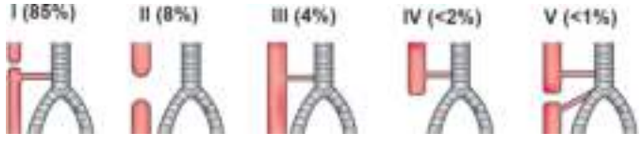

Fig. 14.6: **Anatomical types of TEF.**

- Progressive abdominal distension in type I, due to air passage from trachea to lower end of esophagus or *scaphoid abdomen* in type II/IV due to blind lower end.
- Failure or difficulty to pass a nasogastric tube at birth for gastric aspiration or feeding at birth.

Most of these babies are *preterms* and have history of maternal *polyhydramnios* due to impaired swallowing of amniotic fluid by fetus.

Children with *H-type fistula* are usually missed in neonatal period and present later with recurrent aspiration pneumonia.

Diagnosis: Early diagnosis of EA/TEF requires high index of suspicion, though routine check for esophageal patency after birth is not necessary in all newborns. Diagnosis may be confirmed by:

- *Plain chest and abdominal skiagram* after passing a nasogastric tube with radioopaque line to *see*—(a) the curled-up tube suggestive of blocked esophageal passage **(Fig. 14.7)**, (b) presence or absence of gas shadow in stomach, depending on whether lower end of esophagus is connected with trachea, and (c) presence or absence of aspiration pneumonia.
- H-type fistula is difficult to detect, although *milk scan and bronchoscopy* to *see* tracheal end of fistula or *video-esophagogram* may be useful.
- Abdominal USG and other relevant investigations are necessary to exclude associated anomalies.

Prenatal diagnosis is possible only in ~40% cases, which must be suspected in presence of maternal polyhydramnios and small or absent stomach bubble on USG. Fetal MRI is more reliable.

Treatment: EA/TEF should be operated as early as possible, at least within 24 hours of birth, before the development of aspiration pneumonia.

Pre-operative stabilization of these cases includes:

- Nursing in prone position to reduce the risk of aspiration,
- Continuous suction of the upper esophageal pouch,
- Maintenance of temperature and parenteral nutrition,
- Prophylactic antibiotics and
- Humidified oxygen or ventilatory support, if necessary.

Surgical options depends on the length of atretic esophageal segment and general condition of the patient, as follows:

- *Stable patients with small atretic defects* are usually taken for immediate corrective surgery with *trans-thoracic ligation of fistula with end-to-end esophageal anastamosis.* Oral feeding may be resumed after 8–12 days of primary anastamosis.
- *Sick children or those with long defects* are operated in two-stages-*initial gastrostomy* for decompression and later *primary repair,* which may require esophageal reconstruction surgery, using a gastric or colonic tube.

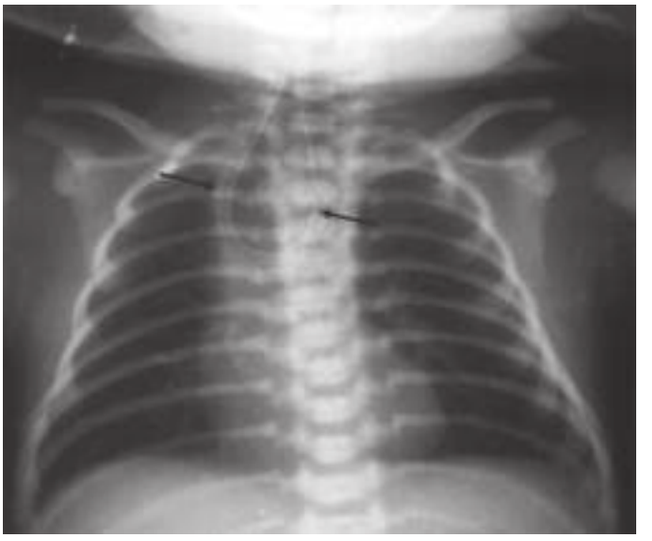

Fig. 14.7: Tracheoesophageal fistula
(*Note:* Arrows showing coiled-up nasogastric tube)

Outcome depends on the timing of surgery and presence of associated malformations. With first-day surgery before aspiration, survival rate is ~80%, though late complications, e.g. GERD or esophageal stenosis are common.

14.6.2 GASTROESOPHAGEAL REFLUX DISEASE (GERD)

Gastroesophageal reflux disease (GERD) denotes *recurrent regurgitation of gastric contents into esophagus* due to any cause, leading to persistent esophagitis by regurgitant acidic gastric content.

Etiopathogenesis: Mild GER is common in first year of life and after meals in older children, with no clinical consequence. Pathological GERD may result from:

1. *Incompetence of lower esophageal sphincter* due to: (a) abdominal location of esophagus, (b) abnormal angle of its insertion into stomach, (c) hiatus hernia, (d) inappropriate transient relaxation of sphincter during swallowing, crying or after drugs, e.g. theophylline, or (e) nasogastric tube *in situ*.
2. *Increased intra-abdominal pressure*, due to chronic cough, constipation and other causes.

Clinical manifestations of GERD begin in early infancy with a triad of: (a) recurrent vomiting/possetting, (b) recurrent chest infections, and (c) failure to thrive. Signs of esophagitis, e.g. dysphagia or sub-sternal pain may not be obvious in infants, while hematemesis is rare.

GERD has been claimed to be associated with acute life-threatening events (ALTE) or sudden infant death syndrome (SIDS), due to sudden choking by aspirated contents.

Diagnosis may be confirmed by:

- *Milk scan* showing slow gastric emptying and reflux of radiolabel contents, fed before the scan. It is also useful

to identify severity of reflux. However normal milk scan does not exclude GER, which is an intermittent event.

- *24-hour esophageal pH probe monitoring* to demonstrate acidic pH at lower end of esophagus is the most reliable indicator of GERD, though rarely indicated in routine cases.
- *Esophageal manometry* is also useful to identify intermittent relaxation of lower esophageal sphincter.
- *Barium swallow or esophagoscopy* is indicated in chronic cases to visualize esophagitis, strictures and anatomical abnormalities, e.g. hiatus hernia.

Management of GERD depends on its severity and includes:

- *Positioning:* Nursing the baby in semi-upright position, especially after feeds and during sleep, to promote gravity assisted emptying of esophagus.
- *Feeding* with thickened feeds, given as frequent but small boluses.
- *Acid suppressors:* Proton pump inhibitors (PPIs), e.g. lansoprazole (PO 0.7–1.4 mg/kg/day q24hr), or Esopantoprazole (PO 1–2 mg/kg/day q24 hr), etc. are first drugs of choice for GERD with erosive esophagitis. Empirical PPI therapy may also be used for short trial of 4–8 weeks in symptomatic children beyond infancy. H_2 receptor antagonists, e.g. Rantidine, though provide faster relief, are less effective and indicated only if PPIs are contraindicated.
- *Antacids* may be used for temporary symptomatic relief, but prolonged use should be avoided in children. Surface protectors, e.g. Sucralfate or alginates are not recommended for routine management of GERD in children.
- *Prokinetic agents* to enhance gastric emptying, e.g. metoclopramide or Domperidone (Both 0.15–0.20 mg/kg/d q8hr) may be used in *moderately severe* cases.
- Surgery, i.e. *fundoplication* is indicated only in very severe cases, refractory to medical therapy. Commonly used *Nissen fundoplication* involves wrapping of gastric fundus around intra-abdominal esophagus to act as additional valve, with success rate of >90%.

Prognosis: Most cases of GERD outgrow it by the end of first year, though complications, e.g. esophageal strictures, severe GIT hemorrhage, chronic lung disease and failure to thrive are common. GERD is considered as a triggering factor for acute asthmatic exacerbations and an important cause of *Difficult-to-treat asthma* in children.

Some other important esophageal disorders are as follows:

Achalasia is an esophageal motility disorder characterized by paucity of normal peristaltic waves and impaired relaxation of gastroesophageal junction, due to decreased number or sensitivity of ganglionic cells. Only < 5% of all cases present in childhood.

Clinically, most cases present in adolescence, with swallowing difficulties and GERD, leading to chronic esophagitis, recurrent aspiration and chronic lung disease.

Diagnosis usually rests on barium swallow, which reveals esophageal dilatation with tapering towards gastric junction. *Esophageal manometry* is diagnostic, showing lack of peristaltic changes and relaxation of lower esophageal sphincter on swallowing.

Treatment is mainly surgical with *Heller myotomy* or endoscopic *balloon dilatation* of lower esophageal sphincter, though drugs, e.g. nifedipine may be effective in some cases. Intra-sphincteric injection of Botulism toxin (botox) has been found effective for 4–6 months.

Esophagitis in children may be: (a) *Peptic* due to GERD, (b) *Infective* (Candida, HSV), usually in immunocompromised children, or (c) *Corrosive*; the last being most common, caused by accidental ingestion of household substances, e.g. acids, alkalis, detergents, etc.

Clinically, vomiting, retrosternal burning and dysphagia are typical features of esophagitis and severe or persistent esophagitis may cause stenosis with chronic dysphagia.

Treatment depends on the cause, though nasogastric lavage or induction of emesis is contraindicated in cases of suspected corrosive poisoning (Ch 27.6).

Esophageal foreign body, e.g. coins ingestion, is common in toddlers due to their inquisitive nature. Ingested bodies are usually lodged at any one of three normal constriction sites in esophagus-below the cricopharyngeal muscle, at the level of aortic arch or just above the diaphragm.

Clinically, these cases may present immediately with suggestive history or later with dysphagia, more pronounced with solids. Radio-opaque bodies are visible on X-rays, though diagnosis of radiolucent ones requires barium swallow or preferably, endoscopy.

Treatment: All symptomatic cases or those with history of ingesting sharp foreign bodies need immediate endoscopic removal, while blunt foreign bodies like coin, single magnet may be observed for up to 14 days for spontaneous clearance, if asymptomatic.

14.7 DIAPHRAGMATIC DISORDERS

Diaphragmatic disorders are usually congenital, though acquired defects due to direct trauma or neurological injury (diaphragmatic palsy) are not uncommon.

14.7.1 CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) denotes *'herniation of abdominal contents into the thoracic cavity* through an abnormal opening in diaphragm, e.g. posterolateral *foramen of Bochdalek* or antero-lateral *foramen of Morgagni'*.

Embryogenesis: Thoracic and abdominal cavities separate from each other by closure of posterolateral pleuro-peritoneal canals at 8th week of gestation. Failure of such closure leads to development of *Foramen of Bochdalek,* through which abdominal contents, usually a part of intestine, may herniate into thoracic cavity and compress the developing lung, leading to pulmonary hypoplasia and respiratory insufficiency of variable severity. Strangulation of herniated sac may also cause intestinal obstruction and sepsis.

Congenital anomalies, e.g. heart defects, esophageal/duodenal atresia, neural tube defects, renal anomalies, and chromosomal trisomies are present in ~20–30% cases.

Incidence: Diaphragmatic hernia is present in ~1: 2000 births. Most of them are on left side (70–85%). Bilateral hernia is seen in 5%, while isolated hernia through foramen of Morgagni is rare (<2%).

Clinical presentation depends on size of the hernial sac, severity of pulmonary hypoplasia and presence of associated anomalies.

A typical case presents in early neonatal period with-(a) progressive respiratory distress, (b) scaphoid abdomen, and (c) decreased breath sounds and presence of bowel sounds on affected side with shift of mediastinum on opposite side. Chest may be unusually prominent or bulging on affected side.

History of maternal polyhydramnios is common due to impaired absorption of amniotic fluid.

Children with smaller defects or herniation through foramen of Morgagni may present in later life with recurrent vomiting, respiratory infections and failure to thrive.

Diagnosis: Diaphragmatic hernia may be diagnosed prenatally on ultrasonography by 16–20 weeks. Postnatal diagnosis may be confirmed on *chest X-ray* showing-(a) presence of air-filled bowel loops on left side, (b) absence of the cupola of diaphragm on affected side, and (c) shift of mediastinum on opposite side **(Fig. 14.8)**. *Lateral view* may reveal intestines passing through the posterior portion of diaphragm.

Other useful investigations include *Barium* contrast studies to delineate the herniated bowel segments and *chest CT* to identify the severity of lung hypoplasia.

D/D: Radiological appearance is characteristic but may be rarely confused with-(a) pneumothorax, (b) staphylococcal pneumonia with pneumatoceles, (c) lung cysts and (d) eventration of diaphragm.

Management of diaphragmatic hernia is essentially surgical, involving reduction of herniated segment and repair of diaphragmatic defect, *as early as possible* after pre-operative stabilization.

Pre-operative stabilization requires – (a) nasogastric decompression, (b) fluid and electrolyte correction, and (c) ventilatory assistance after endotracheal intubation. *Bag and mask ventilation is contraindicated during resuscitation as air-distended herniated intestines may cause further respiratory embarrassment.*

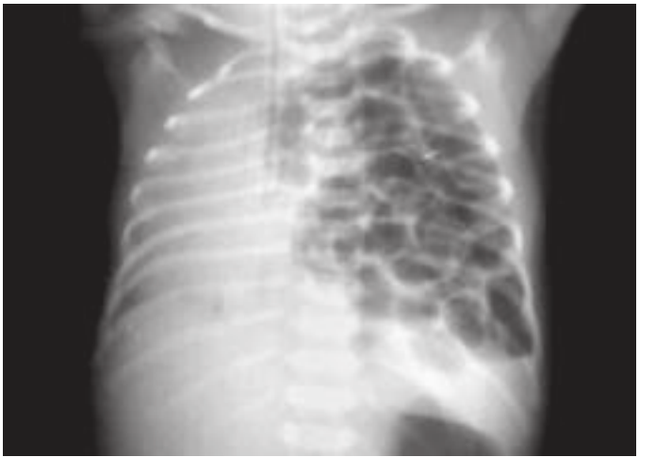

Fig. 14.8: Congenital diaphragmatic hernia.

Lung hypoplasia in these cases may lead to severe pulmonary hypertension with right to left shunt, which needs to be treated with vasodilators (dopamine, nitric oxide inhalation), surfactant and extracorporeal membrane oxygenation, if possible.

In antenatally diagnosed cases, *in utero* reduction of hernial sac or tracheal ligation to prevent egress of lung fluids and pulmonary hypoplasia, has been attempted.

Prognosis: Overall mortality is ~30–40%, being higher in cases with—(a) respiratory distress within 24 hours of birth, (b) severe lung hypoplasia, and (c) co-existing congenital anomalies. In operated cases, late effects like-(a) restrictive lung disease (b) GERD, (c) recurrence (~20–40%), and (d) thoracic cage deformities, (e.g. scoliosis) are common.

Other important diaphragmatic abnormalities are as follows:

Eventration, refers to *congenital hypoplasia of diaphragmatic muscles*, leading to elevation of entire hemidiaphragm *or* more commonly, the anterior crux into thoracic cavity. It is more common on left side.

Clinically, large eventration presents like diaphragmatic hernia with neonatal respiratory distress, while smaller defects may remain asymptomatic or manifest with recurrent chest infections in older children. Recurrent vomiting and abdominal pain after meals are common.

Diagnosis is established on chest X-ray, showing *'rainbow'* like elevation of diaphragm with smooth contour and *cloudy mottling appearance* of intestine below it **(Fig. 14.9)**. Fluroscopy may be useful to differentiate it from diaphragmatic hernia, showing paucity of diaphragmatic movements on affected side.

Fig. 14.9: **Eventration of diaphragm.**

Treatment involves *fundoplication* through abdominal or thoracic approach, though mild asymptomatic cases need no intervention.

Hiatus hernia denotes sliding or herniation of gastro-esophageal junction or a portion of stomach through normal or patulous esophageal opening in diaphragm, usually associated with severe GERD. Treatment is directed towards GERD and not for hernia. Patients with symptomatic giant hiatal hernias need surgical intervention.

14.8 GASTRIC DISORDERS

Stomach predominantly acts as a food-reservoir, though the process of digestion also begins here. Various digestive juices are secreted in stomach including hydrochloric acid and intrinsic factor by parietal cells, pepsinogen by chief cells and mucus as well as some hormones, (e.g. gastrin) by other specific cells.

Gastric acid (normal gastric pH 1–1.5) facilitates hydrolysis of proteins, conversion of ferric iron *into* ferrous form, and activation of pepsinogen into active pepsin. *Intrinsic factor of castle* is essential for vitamin B_{12} absorption. *Pepsin* initiates process of proteolysis, i.e. conversion of larger protein molecules into smaller peptides. Emulsification of fats and hydrolysis of triglycerides also begins in stomach, due to activation of *lingual lipase* and secretion of *gastric lipase*.

While gastric emptying starts soon after the entry of food, rate depends on the type of ingested food, with half-emptying time being ~15–20 minutes for liquids and ~90–120 minutes for solids.

Vomiting, hematemesis and abdominal pain are common manifestations of gastric disorders.

14.8.1 INFANTILE HYPERTROPHIC PYLORIC STENOSIS

Infantile hypertrophic pyloric stenosis (IHPS) denotes *narrowing of gastric outlet due to the unexplained thickening and hypertrophy of the pylorus muscle*, primarily the circular layers.

Incidence: IHPS is the commonest cause of gastric outlet obstruction (~1–4/1000 live births), more common in males (2–5:1), first-born babies and offspring of the parents (specially mothers) with history of IHPS.

Etiology: In IHPS, pyloric hypertrophy is minimal at birth and develops gradually over first few weeks. Many genetic, familial and environmental factors have been attributed for this hypertrophy, e.g. (a) curdled milk, leading to mucosal edema and secondary pyloric hypertrophy, (b) less number and maturity of ganglion cells, (c) elevated gastrin levels and (d) deficiency of nitric oxide in pyloric muscle.

Clinically IHPS usually manifests from 2nd to 3rd week of neonatal life with:

- Recurrent projectile vomiting of curdled milk, after 20–30 minutes of feeding. Vomiting is essentially non-bilious, occasionally streaked with blood, and increases gradually in frequency, amount and force. After vomiting, baby is hungry and wants to be fed again.
- Failure to thrive, dehydration and constipation due to persistent vomiting. Infant is typically anxious, anemic and irritable/lethargic.
- Abdominal examination may reveal *a firm, moveable, olive-shaped, supraumbilical lump on right side*, which can be rolled between fingers. Lump is better palpable from the left side and immediately after feeding. Visible peristalses from left to right side are common after feeds, to overcome obstruction **(Fig. 14.10A)**.

Fig. 14.10A: **Infantile hypertrophic pyloric stenosis: Abdominal lump.**

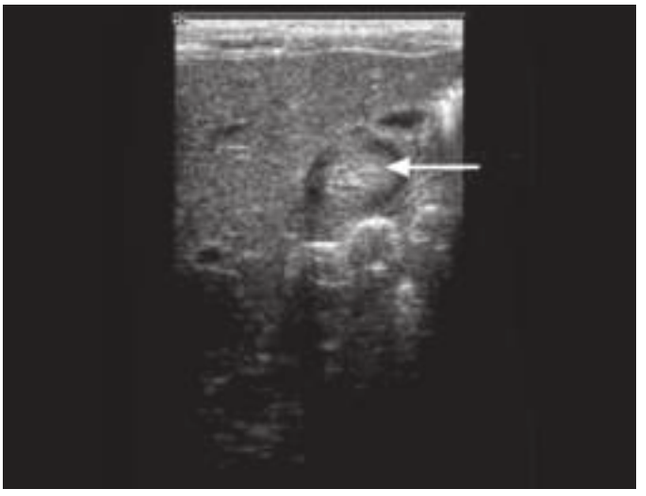

Fig. 14.10B: Infantile hypertrophic pyloric stenosis: Target (doughnut) sign on USG.

- Obstructive jaundice may develop in ~2%, due to pressure of hypertrophied pylorus on ampula of Vater.

Associated anomalies like Down syndrome, Turner syndrome and tracheoesophageal fistula may be present.

Diagnosis rests on typical appearance of pyloric lump, supported by:

- *Barium meal* showing—(i) long and narrow pyloric canal, (ii) *string sign*, i.e. passage of only a streak of barium, (iii) *double-track sign* due to crowding of mucosal folds in pyloric channel, and (iv) *Shoulder sign* due to bulging of pyloric muscles into antrum.
- Ultrasonography showing *Target (Doughnut) sign* due to hypertrophied ring of pyloric muscle around echogenic mucosa **(Fig. 14.10B)**. Pyloric muscle thickness of >13 mm and length of pyloric channel >17 mm on USG is pathognomonic.

Treatment: While these cases need surgery as early as possible, most of them are too sick at the time of diagnosis with dehydration and electrolyte disturbances and need to be stabilized before surgery.

Pre-operative management includes—(a) nasogastric decompression, (b) correction of dehydration/electrolyte disturbances and (c) IV alimentation.

Hypochloremic metabolic alkalosis is commonest electrolyte abnormality in IHPS, due to loss of chlorides in vomiting. Normal saline or N/2 dextrose saline with 30–50 mEq/L of potassium is preferred for initial parenteral therapy with close monitoring of urine output and serum bicarbonate levels. Untreated alkalosis also increases the risk of post-operative apnea.

Ramstedt's pyloromyotomy is the surgery of choice in IHPS, in which hypertrophied pyloric muscles are split without cutting the mucosa and spread apart till mucosa prolapses into the pyloric incision. Oral feeding may be initiated after 12–24 hours, though some vomiting due to pyloric wall edema may continue for a few days. *Laparoscopic pyloromyotomy* or *endoscopic balloon dilatation of pylorus* are other options.

TABLE 14.10: Causes of acute gastritis/ulcers

- *Drugs:* NSAIDs, iron, chloroquine, steroids
- *Septicemia:* Gm –ve infections, endotoxemia
- Dehydration/shock
- Severe hypoxia, e.g. acute respiratory failure
- *Cushing ulcers* – post-surgery, head injury
- *Curling ulcers* – burns

Other important gastric disorders are as follows:

Acute gastritis is usually caused by drugs, e.g. chloroquine or stress ulcers in critically sick children **(Table 14.10)** and presents with recurrent vomiting, epigastric pain and hematemesis in severe cases.

Treatment includes—(a) *Antacids*, (b) H_2 *receptor antagonists*, e.g. Ranitidine (4–6 mg/kg/day q12hr), (c) *Proton-pump inhibitors*, e.g. omeprazole, and (d) *mucosal-coating agents*, e.g. sucralfate.

Chronic gastritis *(peptic ulcer disease)* in children has been strongly correlated with *H. pylori* infections, though family history of peptic disease is present in 25–50% cases. *Zollinger-Ellison syndrome* is a rare cause of multiple duodenal ulcers and diarrhea, due to gastrin-producing islet-cell tumor of pancreas.

Helicobacter pylori is a gram-negative, *urease-producing* organism, which colonizes ~50% children by 10 years of age and lives in the mucus overlaying gastric antrum. Infection is acquired by man-to-man transmission via feces, vomitus, saliva, etc. in overcrowded and unsanitary conditions. Although frequently associated with duodenal ulcers, whether the organism causes the ulcer or simply prevents its healing, is unclear.

Clinically, most *H. pylori* infections in childhood are asymptomatic, though some may present with recurrent abdominal pain.

Diagnosis is established by—(a) endoscopic *mucosal biopsy* from ulcer site using *rapid urease test*, or (b) *breath test*, to demonstrate urease production by increased excretion of radio-labeled CO_2 after ingestion of $C^{14/13}$ labelled urea.

Treatment is recommended only in symptomatic cases with triple-drug therapy for 2 weeks to eradicate infection. It includes an oral combination of clarithromycin (250–500 mg) or amoxicillin (500–750 mg) *with* metronidazole (250–500 mg) *and* PPI, e.g. omeprazole (20–30 mg), using lower range of doses mentioned against each drug for children 15–24 kg and higher range for those >25 kg.

Bezoars, i.e. an *accumulation of exogenous matter in stomach or intestine*, are more common in mentally challenged children and in females. Depending on type of matter, bezoars are called *trichobezoars* (hair), *phytobezoar*

Fig. 14.11: **Trichobezoar (plain X-ray).**

Fig. 14.12A: **Duodenal atresia (double-bubble sign).**

(plant/animal material), *lactobezoar* (casein/calcium of top milk), etc.

These cases usually present in second decade with recurrent abdominal pain, vomiting, palpable lump in left hypochondrium and sub-acute obstruction. Failure to thrive is common.

Abdominal X-ray may show bezoars in plain or barium-contrast films **(Fig. 14.11)**, though endoscopy is useful for diagnosis as well as removal. Lactobezoars usually resolve spontaneously after 24–48 hours.

14.9 INTESTINAL MALFORMATIONS

Congenital malformations of lower gastrointestinal tract may be divided into three categories—(a) *small bowel malformations*, e.g. atresia, malrotation, etc., (b) *colorectal malformations*, e.g. Hirschsprung disease or anorectal anomalies, and (c) *abdominal wall defects* with gut herniation.

14.9.1 SMALL BOWEL MALFORMATIONS

Small bowel malformations are leading causes of intestinal obstruction in newborns and young infants, though many of them present in later life or remain asymptomatic throughout the life.

Duodenal atresia: Duodenal atresia is rare (~1:10,000 live births) but important defect, characterised by *developmental failure of the recanalization of duodenal lumen* after solid phase of intestinal development, producing stenosis, atresia or a mucosal web in the duodenal lumen, usually at the site of papilla of vater.

Chromosomal abnormalities, e.g. Down syndrome are present in ~25% cases, while >30% have other gut malformations, e.g. malrotation, esophageal atresia, anorectal anomalies, etc. or congenital heart diseases. Half of these cases are preterms. Polyhydramnios is present in >50% cases, due to failure of the absorption of amniotic fluid.

Clinically, these cases present within 24 hours of birth with—(a) bilious vomiting/gastric aspirate *without* abdominal distension, and (b) visible peristaltic waves in upper abdomen. Jaundice is present in 1/3rd cases due to blockade of ampula of Vater.

Diagnosis rests on X-ray abdomen showing pathognomonic *double-bubble sign*, i.e. one air-fluid level in the distended stomach and another in the first part of distended duodenum. Rest of the gut has no air shadows **(Fig. 14.12A)**.

Prenatal diagnosis is possible on USG, while postnatal USG is necessary before surgery to exclude other malformations or causes of duodenal obstruction, e.g. annular pancreas, peritoneal bands, volvulus, etc.

Management: Immediate *duodenoduodenostomy or duodenojejunostomy* is necessary in all cases, after *preoperative stabilization* with nasogastric decompensation, fluid/electrolyte correction, etc. and *exclusion of other malformations*. Postoperative oral feeds may be started after ~1 week, after disappearance of duodenal ileus.

Jejunoileal atresia: Jejunoileal atresia is twice more common than duodenal atresia and have been attributed to intrauterine infections or vascular accidents.

These defects are of four types—*type I*, with an intraluminal diaphragm; *type II*, with a solid cord between proximal and distal segments; *type III,* with blind loops on both ends of bowel with mesenteric defects; and *type IV,* with multiple atretic segments. Type III is most common (35%).

Clinically, these defects invariably present within 24–48 hours with meconium ileus and acute intestinal

Fig. 14.12B: **Jejuno-ileal atresia (Triple bubble sign).**

obstruction. Polyhydramnios is present in ~ 25% cases. **Diagnosis** rests on plain X-ray abdomen, showing three fluid levels (*Triple-bubble sign*, **Fig. 14.12B)**, meconium ileus (*ground-glass appearance* in right lower quadrant) and/or evidence of perforation, i.e. gas under diaphragm. Presence of peritoneal calcifications suggests meconium peritonitis.

Treatment involves immediate surgical exploration with resection-anastomosis or proximal jejuno/ileostomy, after pre-operative stabilization.

Malrotation (Volvulus): Most of the mid-gut in early fetal life lies outside the abdomen cavity, but re-enters later with a rotation around the axis of superior mesenteric artery, which allows placement and fixation of intestinal structures at normal locations. Malrotation or non-rotation leads to abnormal location of these structures, commonest defect being the failure of the cecum to move in right lower quadrant.

Volvulus refers to an acute or recurrent symptomatic complication of malrotation, which need immediate intervention.

Clinically, most cases of malrotation (60–80%) present in infancy as volvulus with acute intestinal obstruction, while rest may present as chronic obstruction with recurrent abdominal pain and vomiting. However, ~25–50% cases with mild defects remain asymptomatic or present beyond childhood.

Diagnosis usually depends on USG or barium contrast studies. Plain X-rays are often non-specific.

Treatment: Surgical intervention is indicated in all diagnosed cases irrespective of age, usually along with incidental appendectomy.

Meckel's diverticulum: Meckel's diverticulum is a 3–6 cm out-pouch of the ileum along the anti-mesentric border, ~50–75 cm away from ileocecal junction. It represents *attenuated omphalomesenteric duct, which* connects the yolk sac with developing embryo before development of placenta.

Pathologically, it is a true diverticulum with all intestinal layers, lined by the heterotopic gastric mucosa. Pancreatic tissue or jejunal/colonic mucosa may also be present.

Incidence: Meckel's diverticulum is the *commonest* congenital malformation of gut, present in 1.5–2.0% of normal population, more common in males (2:1). It may also be associated with other gut malformations, e.g. esophageal atresia, anorectal anomalies, etc. *or* Crohn disease.

Clinically most cases are asymptomatic. Symptomatic cases usually present in first two years of life with complications, e.g. (a) intermittent painless rectal bleeding, (b) acute intussusception with diverticula as its lead point, or (c) acute abdominal pain due to *diverticulitis* or impacted roundworms in diverticula. Rarely, tumors, e.g. carcinoid tumor may originate from diverticula in late life.

Diagnosis: A radionucleotide scan with Tc^{99m} to delineate gastric mucosa is the best diagnostic method to detect Meckel's diverticulum with >85% sensitivity and specificity (*Meckel's scan*). Sensitivity may be further enhanced with prior administration of cimetidine, pentagastrin or glucagon.

Other investigations, e.g. rectosigmoidoscopy may be necessary to exclude other causes of rectal bleeding.

Management: Open or laparoscopic *wedge resection of the diverticulum or segmental resection of the ileum bearing the diverticulum* is indicated in all symptomatic cases after pre-operative stabilization. In asymptomatic, incidentally detected diverticula, resection is advisable in cases with—(a) diverticular length >2 cm, (b) younger age <40 years and (c) presence of heterotopic mucosa.

Peutz-Jeghers syndrome is a rare autosomal dominant disorder, characterized by multiple gastric and intestinal polyps with perioral and oral hyperpigmentation and presenting with recurrent abdominal cramps, intussusception and occasional gastrointestinal bleeding.

14.9.2 HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease (*congenital megacolon*) is characterized by the *absence of ganglionic cells* in a variable length of colon, proximal to anorectal junction. Consequently, the involved segment fails to propel normal peristalsis, leading to physiological obstruction.

Aganglionic segment is usually limited to rectosigmoid junction, i.e. classic short-segment disease (75%), but may also involve a longer segment (10%), full-length colon (10%) or rarely, even a part of ileum (<3%). However, in some cases of ultra-short-segment (USS) disease, only internal sphincter is involved.

Incidence: Hirschsprung disease is seen in ~1:5000 live births, more common in males (4:1) and fullterms. It is uncommon in preterms. *Recurrence risk is ~6%.*

Etiopathogenesis: Normally, the neuroenteric cells in embryonic neural crest migrate in fetal life to form muscular *(Auerbach's)* and submucous *(Meissner's)* nerve plexi of bowel walls. Hirschsprung's disease is a multifactorial disorder due to failure of this migration, which normally occurs in cephalocaudal manner from proximal to distal bowel.

Genetic defects may involve multiple genes which encode proteins involved in RET signaling pathway *(RET, GDNF,* and *NTN) or* endothelin type B receptor pathway *(EDNRB, EDN3,* and *EVE-1).*

Physiological obstruction due to impaired peristaltic movements in aganglionic segment leads to gradual stasis and dilatation in proximal colon with risk of secondary infections, i.e. enterocolitis.

Clinically, severe disease may present at birth with delayed passage of meconium though most cases manifest beyond 2nd week of life with—(a) chronic constipation, (b) pellet or ribbon-like stools, (c) abdominal distension, and (d) intermittent diarrhea or enterocolitis. Gradually, these children develop failure to thrive and other signs of malabsorption, e.g. edema and anemia.

Per-rectal examination is nearly diagnostic with—*(i) normal anal tone, (ii) empty rectum despite constipation and (iii) explosive discharge of foul-smelling fecal matter and gases on withdrawal of finger*. Fecoliths may be palpable on abdominal examination.

Diagnosis: While per-rectal findings are highly suggestive, following investigations are necessary to confirm the diagnosis and assess the extent of bowel involvement before surgery:

- *Barium enema* revealing—(i) dilated proximal colon, (ii) constricted distal colon, (iii) a funnel/cone shaped zone of transition between them, and (iv) incomplete evacuation of barium even after 24 hours, in late X-ray films **(Fig. 14.13)**. However, a normal barium enema does not exclude Hirschsprung disease.
- *Anorectal manometry* is highly reliable (90%) but technically difficult procedure in newborns, which reveals absence of normal relaxation in internal sphincter, after distension of rectum.
- *Rectal biopsy* is the *gold standard* for diagnosis, which may be done pre-operatively (submucosal suction biopsy, at least 2 cm above the dentate line) or during surgery (full thickness biopsy, to assess extent of involvement). Histopathologically, it reveals—(i) absence of ganglionic cells, (ii) presence of hypertrophied nerve bundles and (iii) elevated *Acetyl cholinesterase* levels on special staining. Rectal biopsy may be false normal in USS disease.

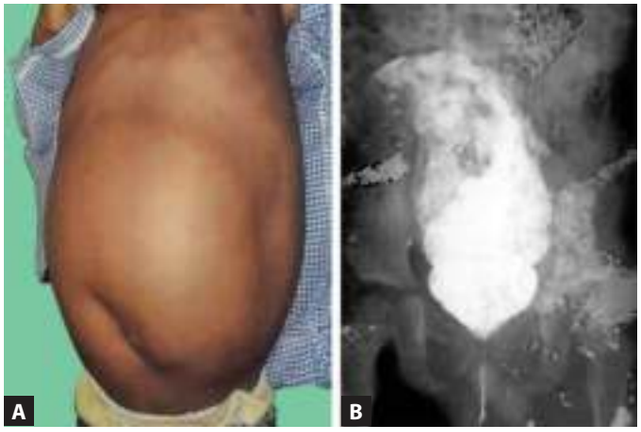

Fig. 14.13: Hirschsprung's disease: (A) Abdominal distension; (B) Barium enema.

TABLE 14.11: Congenital megacolon vs functional constipation

	Cong. megacolon	*Functional constipation*
Clinical		
Age of onset	<1 month	>1 year
Stools	Ribbons/pellets	Normal/hard
Diarrhea	Intermittent	None
Encopresis	Rare	Common
Failure to thrive	Yes	No
Abd. distension	Yes	Minimal
Per-rectal examination		
Anal tone	Tight	Patulous
Rectum	Empty	Fecoliths
Post-PR evacuation	Immediate	Late or none
Investigations		
Ba. enema	Transition zone	No TZ
Internal sphincter*	Tight	Relax
Rectal biopsy	Absent ganglions	Normal

*on anorectal manometry, **PR:** Per-rectal examination; **TZ:** Transition zone

D/D of Hirschsprung's disease includes other causes of constipation in newborns and young infants (Ch 14.4.4), specially—(a) functional or habitual constipation **(Table 14.11)**, (b) hypothyroidism, and (c) anorectal malformations.

Management: Definitive management is essentially surgical, after pre-operative stabilization with-(a) correction of fluid and electrolyte disturbances, (b) treatment of acute enterocolitis with appropriate antibiotics, and (c) provision for adequate nutrition.

Surgical options depend on the length of aganglionic segment and general condition of newborn. Direct corrective surgery may be performed in cases with small lesions in good health, though most cases require

a *two-stage procedure*—immediate temporary *colostomy followed by definitive repair* after 6–12 months. Efforts are made to preserve anal canal and sphincter mechanisms to achieve continence. Various corrective procedures are used depending on the severity of lesion and experience of surgeons, including:

- *Duhamel's pull-through operation*, i.e. transabdominal or laparoscopic construction of a new rectum, by bringing down normally innervated colon behind the aganglionic segment.
- *Boley's endorectal pull-through operation*, i.e. stripping the mucosa of aganglionic segment and bringing down the normally innervated proximal colon through the residual muscular cuff.
- *Classic Swenson's procedure*, i.e. excision of involved segment with end-to-end anastamosis between proximal bowel and rectum, 1–2 cm above the dentate line, is no longer preferred.
- USS disease needs only the excision of a strip of rectal muscle, including internal anal sphincter.
- Hirschsprung's disease involving whole length of colon needs ileal-anal anastamosis.

Prognosis: With timely management, prognosis is usually excellent, though complications like- (a) fecal incontinence (b) leaks/stenosis at anastamotic site (c) perineal abscesses/fistulas and (d) colostomy problems, e.g. enterocolitis are common.

14.9.3 ANORECTAL MALFORMATIONS

Anorectal malformations (ARMs) include a group of heterogeneous developmental defects involving rectum and anal canal with absence, stenosis or ectopic opening of anus and/or fistulous connections with urogenital tract. These defects are present in ~1/1000 live births

Embryogenesis: Rectum and anal canal develop from common cloaca along with lower urogenital tract, which separate with each other by formation of a urogenital septum by 7–8th week. ARMs represent defects in the formation of urogenital septum or failure of its fusion with cloacal membrane.

Continence in these cases depends on involvement of: (a) *neurogenic components*, i.e. sacral outflow from $S_{2\text{-}4}$, (b) *myogenic components*, i.e. levator ani and external sphincters, and (c) *sensory perception* of pain, touch, temperature and propioception.

Classification: ARMs are best classified according to their relationship with the main muscle of continence, i.e. levator ani, (which is present as a sling around the rectum and controls the flow of feces along with external sphincter) as *high, intermediate* or *low* defects **(Table 14.12)**. *Recto-vestibular and recto-urethral fistulas are commonest ARMs in females and males respectively.*

Clinical spectrum: While most ARMs, e.g. imperforate anus are diagnosed at birth during routine orificial examination, many are missed in first 24–48 hours and present with-(a) failure to pass meconium, (b) passage of meconium from abnormal sites, e.g. urine or vagina, (c) gradual abdominal distension with signs of intestinal obstruction. Rarely, some malformations, e.g. anal stenosis, presents in older children with chronic constipation and fecaloma.

TABLE 14.12: Classification of anorectal malformations

- **Supralevator (HIGH) anomalies**
  - Anorectal agenesis
  - Persistent Cloaca (in females)*
  - Rectal atresia (normal anal canal/opening)
- **Infralevator (LOW) anomalies**
  - Ano-rectal membrane (imperforate anus)
  - Ectopic anus (perineal fistulas)
  - Anal stenosis
  - Ano-vulval fistula
  - Recto-vaginal fistula
- **Translevator (intermediate) anomalies**
  - Anal agenesis
  - Recto-vestibular fistula (commonest ARM in females)
  - Recto-urethral fistula (commonest ARM in males)
  - Recto-vesical fistula

*Rectum, vagina and urinary tract fuse to form a common channel, opening as a single orifice behind the clitoris.

Perineal examination may help to identify the type of defect and localize ectopic anal opening. While perineum is usually flat without median raphe and anal dimple in high types, presence of median raphe and anal dimple indicate low or intermediate defects with relatively spared sphincteric mechanisms and better post-operative chances for continence.

High ARMs are frequently associated with sacrospinal deformities (>25%), urogenital malformations (>50%) and other gut malformations, which should be excluded before surgery.

Diagnosis aims to-(a) identify the precise anatomical defect before surgery and (b) search for associated urological, spinal and neurological problems. Important investigations include:

- *Ultrasonography* is the preferred choice to differentiate between high and low ARMs as well as to identify associated urological abnormalities. A distance from rectal pouch to perineum <10 mm indicates low imperforate anus, while a distance of >15 mm suggests high defects. Spinal canal may also be scanned by USG for a latent tethered cord during first 3 months of life, though MRI is more reliable.
- *Invertograms* have been conventionally used for diagnosis of ARMs, though gradually being replaced with USG. Invertogram should be performed at least 12 hours after birth to allow intestinal gases to reach till most distal part of rectal pouch. Baby is held upside down (inverted) or knee-chest position for 3 minutes, before X-ray exposure. Location of gas shadow in the

Fig. 14.14: **Anorectal malformations (Invertogram).**

rectal pouch is then compared with pubococcygeal and puboischial lines, (i.e. lines representing levator ani muscle) to differentiate between low or high ARMs. When the rectal gas pouch in invertogram is >1 cm away from skin, patient probably has high/intermediate defect and needs initial colostomy before corrective surgery **(Fig. 14.14)**.

Treatment: The choice of surgical procedure depends on the type of defect, general condition of patient and associated urological or neurospinal defects.

Low malformations like simple imperforate anus may be managed with single-step *Anoplasty* with *transpositioning for fistulous tracts* in neonatal period, followed by repeated anal dilatations, till the normal anal size is achieved.

High/intermediate defects need a two-step surgery, involving preliminary colostomy followed by definite corrective repair after 6–12 months. Corrective surgery involves a pull-through procedure to bring the colon below the level of levator ani sling (for continence), to open it at expected anal site and to close the fistulous tracts.

Prognosis depends on the type of defect and co-existing defects. Success rate for fecal continence is excellent in low-defects (>80–90%) and moderate (50–60%) in intermediate defects. However, children with persistent cloaca of >3 cm length or recto-vesical fistula rarely achieve adequate continence. Surgical complications include anorectal stenosis, prolapse and recurrence of fistula.

14.9.4 ABDOMINAL WALL DEFECTS

While not the intestinal malformations in true sense, abdominal wall defects are important causes of the herniation of intestines or other abdominal viscera in newborn or young infants. Some important abdominal wall defects are as follows:

Umbilical hernia due to incomplete closure of the fascia of umbilical ring, presents with herniated omentum or bowel, *covered with skin.* Umbilical hernia of <1.5 cm usually close spontaneously by 4 years of age and complications, e.g. intestinal incarceration are rare.

Surgical closure is advisable if defect exceeds 1.5 cm at 2 years of age. Manual reduction with strapping over the ring does not accelerate closure of defect and is no longer advised.

Omphalocele, i.e. herniation of abdominal viscera through umbilical and supraumbilical portions of abdominal wall at birth, denotes incomplete migration of bowel from the umbilical coelom. Herniated organs are *covered with a peritoneal sac*, which may rupture *in utero* or at birth. Associated anomalies are common, e.g. gut malformations, CHDs and Beckwith-Wiedemann syndrome. Primary closure is possible for small defects, while larger defects need two-stage repair.

Gastroschisis is the herniation of the variable length of intestines or other abdominal viscera, *without a covering sac*, through a para-umbilical defect. Eviscerated organs may be covered by a gelatinous matrix of greenish material at birth. Most of these cases are preterm and ~20% have other congenital anomalies. Gastroschisis is a surgical emergency, though single-stage repair is rarely possible.

Inguinal hernia denotes *protrusion of a part of abdominal viscera, usually the intestine through inguinal canal.*

Incidence of inguinal hernia in children is estimated to be ~1–3% live births, more common in males (4–8:1) and preterms. About 99% of inguinal hernias are indirect and more common on right side (60%). Direct inguinal hernia or femoral hernia is rare in children.

Etiologically, *patency of processus vaginalis* is the principle defect in inguinal hernia, seen in ~80–90% at birth and ~50% at 1 year. Calcitonin-gene related polypeptide (CGRP) plays an important role in its closure. Other contributing factors for hernia include: (a) chronic cough, (b) connective tissue disorders, e.g. Ehlers-Danlos syndrome, (c) undescended testis, and (d) ascites.

Clinically these cases present with inguinal swelling that increases on crying or straining. *Silk glove sign*, i.e. silky feeling of processus vaginalis on rubbing over the spermatic cord may be present. Hydrocele, due to patent processus vaginalis, usually co-exists as scrotal swelling.

Complications of hernia include: (a) incarceration, (b) obstruction, (c) gangrene, and (d) testicular damage.

Management is essentially surgical with open or laparoscopic *herniotomy and closure of hydrocele sac.* As ~10–15% cases may later develop contralateral hernia, routine exploration on other side for patent processus vaginalis is advisable in boys <1 year and in all girls with left-sided hernia.

14.10 ACUTE DIARRHEA

Diarrheal disorders are second commonest cause of morbidity and mortality in preschool children, after acute respiratory infections. Since normal frequency of stools varies significantly in children, diarrhea is defined as 'a *change in the usual frequency or consistency of stools'*. Presence of blood or mucus in stools denotes *dysentery* (Ch 10.8).

Diarrheal disorders may be classified as:

- *Acute diarrhea*, lasting for <14 days; discussed in this chapter
- *Persistent diarrhea,* i.e. continuation of an acute diarrheal episode for >14 days (Ch 14.11)
- *Chronic diarrhea* of >14 days duration, due to disorders of malabsorption (Ch 14.12).

Incidence: Usually underreported, acute diarrhea accounts for ~30% of hospital admissions and ~15% of deaths in under-5 children. NFHS-5 (2019–21) reveals that ~7% under-five children in India had diarrhea during preceding two weeks of survey visit.

Epidemiology: Acute diarrhea is most common in 6 months-3 years age-group, specially in children with following ***risk factors***—(a) top feeding, (b) contaminated water supply, (c) low socioeconomic status, (d) poor sanitation and excreta disposal, (e) unhygienic food habits, (f) malnutrition, and (g) vitamin A deficiency.

Diarrhea and malnutrition have a cause-effect relationship. While diarrhea is common in malnourished children due to—(a) gut mucosal atrophy, and (b) colonic overgrowth of bacteria due to impaired immune defence; each diarrheal episode worsens the nutritional status due to—(a) anorexia, (b) poor absorption, (c) increased nutritional requirements and sometimes, (d) misconceived starvation of child due to fear of increasing diarrhea after feeding.

Etiology: More than 90% of infantile diarrhea are infective in origin **(Table 14.13)**.

Rotavirus is the commonest cause of acute diarrhea in infants and toddlers, responsible for >50% and ~25–30% episodes, respectively. Seven serotypes are known to cause human disease, the commonest in India being G1P8, responsible for ~60% cases.

Infection is acquired feco-orally, usually in 3–24 months age-group and during winter or spring season. Over half of the cases are asymptomatic. Symptomatic infection is self-limiting within 3–5 days but persistent diarrhea due to secondary lactose intolerance is not uncommon.

Bacterial diarrhea: *E. coli,* with its four sub-types, i.e. enterotoxigenic (ETEC), enteropathogenic (EPEC), enteroadherent (EAEC) and enteroinvasive (EIEC), is the second commonest (25%) cause of diarrhea in Indian children. Of these, ETEC is most common, with serotype

TABLE 14.13: Common causes of acute diarrhea

- **Infective diarrhea**
  - *Viral:*
    Rotavirus (25–50%)
    Others: Astroviruses, enteroviruses
  - *Bacterial:*
    E. coli, (25%)
    V. cholerae (5–10%)
    C. jejuni (5–10%)
    Shigella/Salmonella (5–10%)
  - *Protozoal:* Giardiasis, amebiasis
  - *Parasitic:* Intestinal helminthes
  - *Opportunistic:* Candida, spore-forming protozoa*
- **Parenteral diarrhea:** Non-GIT infections, e.g. ARI, UTI, otitis media
- **Non-infective diarrhea**
  - *Drug-induced:* Antibiotics, laxatives, iron
  - *Toxins:* Food poisoning**, heavy metals
  - Food allergy
  - *Others:* Overfeeding, psychogenic diarrhea

*Cryptosporidium, isospora bacilli, cyclospora, microsporidia
**Due to pre-formed toxins, e.g. *Staph. aureus, C. difficile*

E-0159 emerging as an important cause of cholera-like outbreaks. EPEC is more common in urban children or as Traveller's diarrhea, while EAEC or EIEC usually present as bacillary dysentery.

Other bacterial pathogens, e.g. *V.cholerae, Shigella and Salmonella infections* accounts for 10–15% cases. *Camplyobactor jejuni*-a zoonotic infection, transmitted by excreta-contaminated food/water, is an emerging cause of acute infantile diarrhea.

Protozoal diarrhea: *Amoebiasis* is relatively less common in children than *Giardiasis*—a leading cause of diarrhea in malnourished children. Spore-forming protozoa, e.g. *cryptosporidium, isospora, cyclospora* and *microsporidia* are predominant causes of recurrent diarrhea in immunocompromised children, though small outbreaks of mild diarrhea are common even in normal children.

Parenteral diarrhea denotes increased gut motility in extraintestinal infections, e.g. otitis media, ARI or UTI, which usually disappears spontaneously or after treatment of primary infections.

Food poisoning is an important cause of acute diarrhea, when multiple children and/or adults are affected simultaneously after common food ingestion.

Pathogenesis-wise, diarrhea may be broadly divided into following categories:

- ***Secretory diarrhea*** by exotoxin-producing pathogens, e.g. cholera or ETEC, due to stimulated production of adenylyl cyclases and cyclic AMP/GMP leading to increased ATP activity and active secretion of sodium and water in gut lumen.
- ***Osmotic diarrhea***, i.e. passive outflow of water, due to increased osmotic load in gut, e.g. in lactose intolerance.

- ***Invasive diarrhea*** (dysentery) due to actual mucosal invasion, e.g. EIEC, EAEC and Shigella infections or *adhesion of pathogens* to mucosal cell walls without destruction, e.g. EPEC.
- ***Hypermotility diarrhea*****,** due to parenteral infections or non-infective causes, e.g. drugs, overfeeding, psychogenic causes, etc.

Pathophysiology: *Dehydration and electrolyte disturbances are most important complications of diarrhea,* due to excess loss of water and electrolytes (mainly sodium) in stools. While initial losses are mainly from extracellular fluid compartment (ECF), consequent changes in plasma osmolality lead to redistribution of body fluids, as follows:

- When water and sodium loss is nearly proportional as in osmotic diarrhea, serum osmolality is maintained, leading to *isotonic dehydration* (50% of total diarrhea).
- When sodium loss is disproportionately more than the water loss as in secretory diarrhea, serum osmolality falls leading to *hypotonic dehydration* (30–40%). In these cases, extracellular hypotonicity moves water from ECF to ICF, accentuating ECF dehydration and hypovolemia. Consequently, signs of dehydration are relatively more marked than the actual fluid loss in hypotonic dehydration.
- Rarely, and specially when dehydration is erroneously treated with concentrated ORS or hypertonic parenteral fluids, serum osmolality rises to cause *hypertonic dehydration* (5%). In these cases, extracellular hypertonicity withdraws water from ICF to ECF, leading to cellular dehydration. Signs of dehydration are relatively less prominent than actual fluid deficit in hypertonic dehydration.

Severe ECF depletion and hypovolemia leads to compensatory responses, e.g. peripheral vasoconstriction (cold skin, dry mucosa), hyperdynamic circulation (weak-thready pulse), oliguria, and finally, the hypotension/shock. As considerable amount of potassium and bicarbonates (intestinal pH is alkaline) is also lost in stools, *hypokalemia* and *acidosis* is common in diarrhea-induced dehydration.

Diagnostic assessment of a child with diarrhea may be divided into: (a) clinical assessment of the severity of dehydration, (b) clinical assessment of the etiology, and (c) relevant laboratory investigations.

- **Assessment of dehydration:** Important indicators of the severity of dehydration (as mild, moderate) or severe are given in **Table 14.14**. However this assessment may be unreliable in:
  - *Malnourished children,* due to overestimation of turgor loss in wasted marasmus and underestimation in edematous kwashiorkor.
  - *Chubby children*, due to underestimation of turgor loss. Urine output is the most reliable indicator of dehydration in malnourished or obese children.

TABLE 14.14: Assessment of severity of dehydration

Feature	*Mild*	*Moderate*	*Severe*
Behavior	Alert	Drowsy*	Stupor/coma
Thirst	Thirsty	Marked	Absent
Eyeballs	Normal	Sunken	Sunken
Tears	Present	Absent	Absent
Tongue	Dry	Dry	Parchmenty
Skin turgor	Normal	Lost*	Lost
Pulse	Normal	Rapid	Thready
Respiration	Normal	Rapid	Acidotic
BP	Normal	Normal	Hypotension
Urine output	Normal	Oliguria	Anuria
*Weight loss***	3–5%	6–10%	9–15%

*Irritability and doughy skin in hypernatremic dehydration.
**Higher % of wt loss in infants.

  - *Hypernatremic dehydration,* due to relative preservance of ECF that leads to underestimation of dehydration. Presence of hyperirritability and doughy skin are strong indicators in these cases.
  - *Hyponatremic children* are at risk of developing early circulatory failure and shock despite lesser fluid and weight loss due to water movement from ECF to ICF.

  According to IMNCI guidelines, dehydration in children with diarrhea is classified as (a) severe dehydration, (b) some dehydration, and (c) no dehydration, based on four indicators—(1) general condition; (2) eye balls, (3) ability to drink water and (4) skin turgor **(Table 29.2)**.

  "*Severe dehydration*" is indicated by presence of *any two* of the following four signs: (a) lethargy/unconsciousness, (b) sunken eyes, (c) inability to drink, and (d) very low skin turgor; While "*Some dehydration*" is indicated by *any two* of following four signs: (a) restlessness and irritability, (b) sunken eyes, and (c) thirsty, drinks eagerly, and (d) low skin turgor. Absence of enough signs suggests "*no dehydration*".
- **Clinical assessment of etiology:** Viral, bacterial and protozoal diarrhea may be distinguished up to certain extent on the basis of age, nutritional and immune status, seasonal trends, clinical features and appearance of stools **(Table 14.15)**. Some important indicators are as follows:
  - Large-watery diarrhea in apparently healthy infant or toddler suggests rotavirus infection. Perianal excoriation is common.
  - Rice-water stools indicate cholera and entero-toxigenic *E.coli* infection.
  - Presence of blood/mucus in stools with high fever, toxic look and cramps suggest bacterial etiology.
  - Watery, foul-smelling stools with/without blood, in school-going children may be amebic in origin.
  - Watery or bulky diarrhea with fat globules, specially in malnourished children suggest giardiasis.
- **Laboratory evaluation** in diarrhea includes:

- ***Stool examination,*** specially for pH, reducing sugar, fecal leukocyte count, fat globules, parasitic cysts/ova. Hanging-drop preparation is essential in rice-water stools to exclude cholera.
- ***Stool cultures*** are of limited value due to poor specificity, but indicated in—(a) suspected cholera, (b) critically sick children to exclude nosocomial infection, and (c) immunocompromised states to exclude opportunistic pathogens.
- ***Specific investigations:*** Virological diagnosis of rotavirus by electron microscopy or ELISA test is possible, but rarely available. ELISA tests to detect ETEC or vibrio toxins are also available.
- ***Supportive investigations*** including serum electrolytes, blood gas analysis and renal functions, e.g., blood urea or serum creatinine, are necessary in severe dehydration.

Management of acute diarrhea includes—(I) fluid replacement therapy, (II) nutritional management, (III) specific antidiarrheal agents, and (IV) treatment of associated infections and other complications.

I. Fluid replacement therapy is the cornerstone of management in acute diarrhea, to prevent and correct dehydration. The mode of fluid replacement (oral *vs.* parenteral) depends on severity of dehydration and child's willingness or tolerance (vomiting) for oral fluids.

WHO guidelines (2005) regarding fluid therapy in childhood diarrhea **(Fig. 14.15)**, are based on three options:

- ***Plan A*** to prevent dehydration in children with "*No dehydration*" providing oral rehydration solution (ORS) at home as follows—50–100 ml after each stool in children < 2 years, 100–200 ml after each stool in 2–10 years old and ad libitum in older children.
- ***Plan B***, i.e. supervised ORS administration in the hospital for children with *some dehydration*. The amount of the ORS to be given during first 4 hours depends on the age of the child, as stated in **Fig. 14.15**.
- ***Plan C***, i.e. parenteral rehydration in cases with severe dehydration (see Parenteral fuild therapy below).

Frequent re-evaluation and necessary modifications in fluid therapy is essential in all cases. Some important aspects of oral and parenteral fluid therapy are discussed here:

Oral rehydration therapy is the preferred mode of fluid replacement in diarrhea for—(a) prevention of dehydration, and (b) correction of mild to moderate dehydration. It may be safely used in all cases of diarrhea except those with—(a) paralytic ileus (when oral feeding needs to be withheld), and (b) altered sensorium (risk of aspiration). Children with vomiting may be given oral fluids after anti-emetic therapy.

Oral rehydration solution (ORS) is one of the most important medical advance in last century, which has reduced the diarrhea-related mortality by >80%.

Principle of ORS therapy in diarrhea is based on following facts:

- Large amount of fluids are lost in diarrhea, which needs to be replenished with fluids.
- Substantial amount of sodium and other electrolytes are also lost in diarrhea. As sodium is the principle determinant of ECF osmolality, its presence is a must in any ORS.
- Water absorption in gut is largely passive, dependent on active sodium absorption.
- Absorption of glucose and amino acids are carrier-dependent and remain largely intact in most cases of diarrhea.
- Carrier mechanisms for sodium absorption are interlinked with glucose/amino acid absorption and co-administration of glucose or amino acids in ORS facilitates sodium/water absorption.
- Since excess intake of glucose may cause osmotic diarrhea, 1:1 molar ratio of glucose and sodium concentration in ORS is most appropriate to maximize sodium reabsorption with minimal osmotic load.
- As potassium and bicarbonates losses are also common in GIT fluid loss, ORS should also contain minimum required concentration of these electrolytes.

WHO-ORS contains 75 mEq/L of sodium with osmolality of 245 mEq/L, in composition as given in **Table 14.16**. It

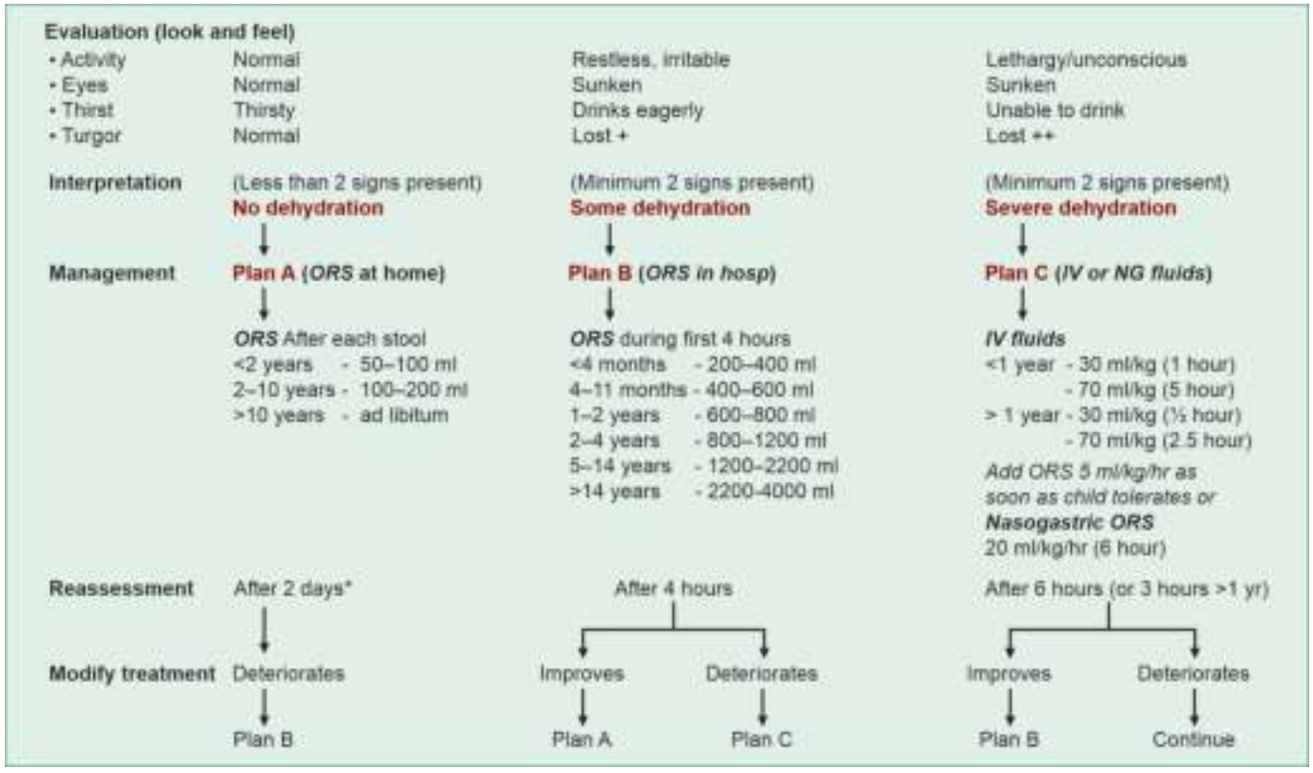

Fig. 14.15: WHO/National task force guidelines for management of diarrhea in children.

*Teach mother about danger signs or dehydration and ask to report immediately

**Give 1 packet of ORS in plan A and 2 packets in plan B for home use, before sending home

Source: WHO (2005): The treatment of diarrhea: A manual for physicians and other senior health workers.

is supplied free of charge by the government at health centers and is also available commercially.

Preparation and storage: WHO-ORS must be prepared hygienically, mixing one packet of ORS in one liter (~5 glass) of potable, clean water. Once prepared, it should be stored in a clean container and may be used till 24 hours. Pre-packed ORS has a shelf-life of 2 years. Smaller packs of ORS, to be dissolved in 200 ml are also available commercially, as also ready-to-use solutions.

Dosage and administration: It may be fed with spoon or a large cup *ad libitum* (as much as desired) for prevention of diarrhea, with minimum quantities as stated in **Figure 14.15** for Plan A and B in children with dehydration.

TABLE 14.16: Composition of WHO-ORS

Constituents	*Weight (gm/dl)*	*Electrolytes*	*(mmol/L)*
Sodium chloride	2.6	Na^+	75
Potassium chloride	1.5	K^+	20
Tri-sodium citrate	2.9	Citrate	10
Glucose	13.5	Cl^-	65
Water	1000	Glucose	75
Osmolality			245

Side-effects: WHO-ORS is extremely safe, except potential risk of hypernatremia due to use of wrongly concentrated ORS. In addition, mothers may erroneously perceive ORS as replacement for regular feeding, which should be continued in all cases.

Modified ORS: Various other ORS preparations with different composition have been developed to maximize sodium/water absorption or reduce the risk of hypernatremia/osmotic diarrhea in special situations. Some are as follows:

- ***Resomal*** (*Re*hydration *so*lution for *Mal*nourished children) with 45 mEq/L of sodium, is preferred in malnourished children due to higher risk of hypernatremia. Not commercially available in India, it may be prepared by diluting one pack of WHO-ORS in 2 liters of water and adding 50 gm of sucrose as well as 40 ml of mineral-mix solution (Ch 6.1).
- ***Enriched or super ORS*** is prepared by—(i) addition of certain amino acids, e.g. glycine, L-alanine or glutamine in standard ORS; *or* (ii) replacement of glucose with a starch preparation, e.g. pre-cooked or puffed rice powder (~ 50 gm/L). While amino acids enhance the sodium co-transport and reabsorption (independent of glucose-based transport), starch-based preparations reduce the risk of osmotic diarrhea

by slower release of glucose. While these variants might be marginally superior in cholera, no significant benefits over WHO-ORS have been observed in non-choleric diarrhea and tend to affect the palatability or cost of preparation.

- ***ORS in very young infants:*** Although WHO-ORS may be safely used in all children, a diluted preparation (1 pack in 1.5 liter of water) may be used in very young infants <2 months, to avoid osmotic load. However, breastfeeding is usually adequate in these cases and ORS is rarely required.

Home-based ORS substitutes: Following fluids may be used as temporary alternatives of ORS, in order of preference:

- ***Salt and sugar solution (SSS)*** by mixing a two-finger pinch common salt (~0.8 gm) and one heaped tsf of sugar (~8 gm) in one glass of water (~200 ml). However, sodium/sugar content in SSS is unreliable and it should be avoided as far as possible, unless WHO-ORS is not readily available.
- ***Food-based home fluids***, e.g. salted-rice kanji, dalwater, butter-milk, lemon sherbat or coconut water may be used as adjuvant or temporary alternative for ORS. However, these fluids have no definite electrolyte concentrations and start fermenting after 6–8 hours in tropical climate.

Plain glucose water may cause osmotic diarrhea and should never be used as ORS, as also the sweet tea, coffee, canned fruit juices and carbonated drinks.

Parenteral fluid therapy is required in cases with—(a) severe dehydration, (b) persistent vomiting/abdominal distension, and (c) altered sensorium; and aims to correct fluid/electrolyte deficit till minimum safe limit, when ORS may be continued for further correction and maintenance. Some important aspects of parenteral fluid therapy in diarrrhea are as follows:

- ***Route:*** Although a secure IV access is must for parenteral fluid administration, intra-osseous infusion (Ch 32.3) may be used for rapid fluid correction in emergency, till IV access is obtained. Nasogastric infusion (20 ml/kg/hr) is also useful in this situation.
- ***Composition:*** Ringer lactate (Na^+ 131 mEq/L) is preferred choice for parenteral fluid therapy in diarrhea, though normal saline (Na^+ 154 mEq/L) may also be used as an alternative. *Plain dextrose fluids are ineffective and may aggravate hyponatremia.* Potassium (2 mEq/kg; upto maximum 40 mEq/L) must be added in IV infusion, but only after baby has passed urine, to avoid hyperkalemia.
- ***Amount*** of fluid infusion depends on the severity of dehydration. **WHO-Plan C** provides necessary guidelines for routine IV fluid volumes **(Table 14.17)**.
- ***Monitoring:*** All cases on IV fluids should be closely monitored to decide changing needs for fluids/electrolytes, possibility of switch-over to ORS and ***complications***, e.g. overhydration, electrolyte disturbances, infection, thrombophlebitis or local extravasation.

TABLE 14.17: WHO Plan C - IV fluid therapy in diarrhea

Age of child	*Volume and rate of infusion*
Infants	30 ml/kg in 30 minutes, followed by 70 ml/kg in 2.5 hours
Post-infancy	30 ml/kg in 1 hour, followed by 70 ml/kg in 5 hours

II. Specific anti-diarrheal therapy includes: (a) antimicrobial agents, (b) zinc supplements, (c) prebiotics or probiotics, and (d) antisecretory agents, e.g. racecadotril. Others antidiarrheal agents like *adsorbents/binding agents* (kaolin, pectin) are no longer used and *antimotility agents* (loparamide, diphenoxylate) are contraindicated in children due to risk of paralytic ileus.

- ***Antimicrobial therapy:*** Since most cases of acute diarrhea are viral and self-limiting, empirical antimicrobial therapy is of limited use and may lead to development of chronic carrier state or antibiotic-associated diarrhea. However, antimicrobials are indicated in: (a) suspected cholera or bacillary dysentery, (b) co-existing septicemia or systemic infections, and (c) toxic, malnourished or immunodeficient children.

  Some commonly used antimicrobial agents in diarrhea, based on the standard treatment guidelines of IAP (2022) are given in **Table 14.18**.
- ***Zinc supplementation*** has been shown to promote mucosal healing and reduce the severity and duration of diarrhea. WHO/IAP/GOI strongly recommend elemental zinc supplements to all children with diarrhea as PO 20 mg/day (10 mg/day in infants <6 months of age) for 14 days.
- ***Probiotics and prebiotics*** have a potential role in treatment of childhood diarrhea, specially antibiotic-

TABLE 14.18: Antimicrobial therapy in bacterial diarrhea

Shigella	IV Ceftriaxone 50 mkd × 2–5 days PO Cefixime 8 mkd × 2–5 days PO Ciprofloxacin 20–30 mkd × 2–5 days
Salmonella*	IV Ceftriaxone 50 mkd × 2–5 days PO Azithromycin 10 mkd × 3 days PO Ciprofloxacin 20–30 mkd × 2–5 days
ETEC	PO Azithromycin 10 mkd × 3 days PO Cefixime 8 mkd × 5 days
Cholera	PO Doxycycline 2–4 mkd single dose** PO Azithromycin 20 mkd single dose PO Ciprofloxacin 20 mkd single dose

Source: Standard treatment guidelines for acute watery diarrhea, IAP 2022.

associated diarrhea. These agents inhibit the growth of pathogenic flora and promote re-colonization with normal non-pathogenic flora.

Probiotics are viable bacteria, e.g. lactobacilli or yeasts, e.g. saccharomyces, present in fermented dairy products, e.g. curd, yogurt, lassi, etc. or available commercially. These agents: (i) competitively inhibit the binding sites for pathogenic bacteria, (ii) acidify gut to inhibits pathogenic growth, (iii) restore non-pathogenic flora, (iv) stimulate secretory IgA production, and (v) modify toxin receptors in gut. Efficacy of probiotics depends on the dose and the strain/s used for therapy, which is not yet standardized.

Prebiotics are food ingredients, e.g. banana, sorghum, lactulose, bran, isabgol, etc., which largely remain undegraded in gut and: (a) stimulate growth of normal gut flora, (b) prevent growth of pathogenic organisms by acidification of gut, and (c) maintain epithelial integrity.

- ***Anti-secretory agents:*** *Racecadotril* (PO 1.5 mg/kg/dose q8hr)-an oral encephalinase inhibitor, may be useful to reduce the stool volume in *secretory diarrhea*, though there is no uniform consensus regarding its use in children. It prevents inactivation of endogenous encephalins-cyclic AMP inhibitors in gut, thus reducing active fluid/electrolyte secretion from gut.

III. *Nutritional management:* Diarrhea is major precipitating factor for malnutrition in children. Hence, it is recommended that:

- Breastfeeding should be continued uninterrupted.
- Contrary to general perception, no dilution of animal/formula milk is necessary in top-fed children during diarrheal episodes.
- Children on regular diet should be fed with small frequent meals of energy-dense foods.
- Post-recovery, oral intake should be enhanced to 125% of normal caloric requirements.

National Control Of Diarrheal Diseases Programme (NCDDP)

NCDDP, started as a disease-specific program in 1978 is currently a component of *Reproductive, Maternal, Newborn, Child and Adolescent Health strategy* (RMNCH+A), delivered as per Integrated Management of Neonatal and Child Illnesses (IMNCI) guidelines.

Components: Important activities under this program include:

- *Standard cases management guidelines* for general use **(Fig. 14.15)**.
- *Promotion of preventive measures*, e.g. breastfeeding, hygiene and ORS therapy.
- *Free supply of WHO-ORS*, with a printed logo for easy identification **(Fig. 14.16)**.

Fig. 14.16: ORS logo.

- Setting-up of *diarrhea training and treatment units* (DTTUs)
- Research, surveillance and manpower training

Diarrhea training and treatment units (DTTUs) have been established under this program at medical colleges and major hospitals to: (a) streamline practice of standard cases management guidelines on regular basis, (b) train faculty members, medical students and other health personnel, and (c) educate mother about home management of diarrhea, including demonstration of ORS making and administration.

Mini-DTUs and *ORT corners* have been established at smaller primary health centers to implement standard cases management guidelines and maternal education.

Despite these targeted efforts, NFHS-5 (2019–21) revealed that ORS and Zinc supplements were received by only 60% and 30% of under-five children respectively, who had diarrhea in preceding two weeks of survey.

14.11 PERSISTENT DIARRHEA

Persistent diarrhea refers to "*prolonged continuation of an acute diarrheal episode beyond 14 days*", usually due to diarrhea-induced gut injury.

While two terms-*persistent diarrhea* and *chronic diarrhea* are often used interchangeably, later one is usually a manifestation of primary malabsorption defect–a heterogeneous group of congenital or acquired gut disorders, characterized by impaired digestion and/or absorption of ingested nutrients and discussed in next chapter 14.12.

Some important differences between persistent and chronic diarrhea are given in **Table 14.19**.

Etiopathogenesis: Some amount of transient gastrointestinal mucosal injury is inevitable in acute diarrhea, which usually recovers rapidly and spontaneously after cessation of primary insult.

Persistent diarrhea indicates—(a) *excessive mucosal damage* during acute phase, or (b) *impaired repair* during recovery, with or without persistence of infection.

Disaccharides (Lactose) intolerance is one of the leading cause of persistent diarrhea, discussed later in chapter.

TABLE 14.19: Persistent vs chronic diarrhea

	Persistent	*Chronic (MAS)*
Duration	>2 weeks	Longer
Cause	Post-infective	Non-infective*
Common age	<2 years	Any
Malabsorption	Effect	Cause
Course	Persistent	Recurrent
Stools	Watery	Cause-specific
Dehydration	Common	Uncommon
Malnutrition	Risk factor	Effect

*although secondary infection is common

Risk-factors for persistent diarrhea include—(a) younger age <2 years, (b) severe malnutrition, (c) vitamin A deficiency, (d) top-feeding, (e) bacterial diarrhea due to enteropathogenic organisms, (f) milk–protein allergy, (g) co-existing systemic infection.

Clinically, apart from persistent diarrhea, these cases also present with secondary complications, e.g. (a) dehydration, (b) dyselectrolytemia, (c) progressive malnutrition. Secondary lactose intolerance is common.

IMNCI classifies these cases as: (a) severe persistent diarrhea with dehydration, and (b) persistent diarrhea without dehydration.

Diagnostic evaluation in these cases aims to identify risk–factors for persistence of diarrhea and its complications. Specific tests for malabsorption (Ch 14.12) though frequently abnormal, are usually unnecessary in these cases, as malabsorption is the effect and not the cause of persistent diarrhea. Important diagnostic investigations include:

- *Stool examination* for pH and reducing sugar (secondary lactose intolerance), microscopy (parasitic/protozoal etiology) and cultures for unusual pathogens, e.g. spore-forming protozoa and Candida.
- *Base-line evaluation* for secondary effects, e.g. hemoglobin (anemia), serum electrolytes, blood sugar (hypoglycemia) and blood cultures to exclude systemic infection.
- *Other investigations,* e.g. colonoscopy are indicated only in cases with intractable diarrhea.

Management of persistent diarrhea includes—(a) correction of dehydration and dyselectrolytemia*, (b) treatment of co-infections and metabolic complications*, (c) nutritional management, and (d) micronutrient supplementation. (*as in acute diarrhea).

- **Nutritional management** is the cornerstone of therapy in persistent diarrhea, considering inevitable development of secondary malabsorption defects after prolonged mucosal injury. *Lactose intolerance* is the predominant absorption problem in these cases, while more severe cases may also develop fat intolerance. Protein absorption is often preserved till late stages.

Fig. 14.17: Dietary plan for persistent diarrhea.

In infants <4 months, persistent diarrhea is unlikely and continuation of breastfeeding is the best option in these cases. In top-fed children of this age group, a lactose-free formula may be used for 1–2 weeks to overcome problem of lactose intolerance.

In older infants and children, dietary management depends on the amount of lactose-load that they can tolerate. Most children, despite moderate lactose intolerance, tolerate low-lactose diet, if given in small frequent feeds.

Accordingly, a step-wise approach is recommended in dietary management of persistent diarrhea **(Fig. 14.17)** with three different types of therapeutic diets **(Table 14.20)** to provide nutrition, till recovery. Each diet differs in its lactose or other carbohydrate content. Success or failure of each step is assessed by change in stool frequency and weekly weight gain.

- ***Diet plan A*** (Low-lactose diet) is recommended as initial therapy to all but very severe cases and should be started as soon as baby starts accepting oral feeds. It includes feeding with low-lactose foods, e.g. milk-rice gruel, milk-sooji gruel, curd-rice, puffed rice, *dalia,* etc. in small, frequent (6–7) feeds, to provide ~110 cal/kg/day initially, which may be further gradually increased to ~150 cal/kg/day by 2 weeks. Diet A may also be given via nasogastric tube in reluctant children. Animal milk must be reduced to <50–60 ml/kg.
- ***Diet plan B*** (Lactose-free diet) is needed in children, who do not improve on diet A. This is a complete lactose-free diet with low-starch content, e.g. a cereal and glucose mixture, with egg or commercial proteins. Animal as well as human milk is eliminated totally.
- ***Diet plan C*** (Monosaccharide-based diet) is rarely required in <10% cases, who do not recover on diet B. It contains only glucose along with egg/chicken/

TABLE 14.20: Representative diets in persistent diarrhea

	Diet A	*Diet B*	*Diet C*
Milk	1/3 katori	–	–
Egg *or* (chicken)*	–	1¾ (2½) tsf	2½ (5) tsf
Puff rice powder#	4 tsf	2 tsf	–
Sugar	½ tsf	¾ tsf	¾ tsf
Oil	½ tsf	1 tsf	1 tsf
Water (add to)	100 ml	100 ml	100 ml
Calories	96	78	60
Proteins	2.4	2.3	3

*volume in parentheses is for chicken, #can be substituted by cooked rice

commercial proteins, with added oil. Cereals are also completely eliminated from the diet, along with milk.

Change-over from one to other diet plan depends on clinical response, as follows:

Step-up (Diet A>B>C) is indicated in cases with: (a) marked increase in stool frequency (>10/day) after at least 48 hours of initial diet, (b) appearance of dehydration anytime, or (c) failure of weight gain till 7th day. In rare cases of failure despite diet C, total parenteral nutrition is indicated.

Step-down (diet C>B>A> home diet) should be allowed only after 7 days of satisfactory clinical response, to permit enough time for mucosal recovery.

A baby is fit for discharge, only when: (a) stools are of normal consistency with frequency of <2/day, (b) home-diet has been introduced and well tolerated, (c) weight gain is satisfactory.

- **Micronutrient supplementation** is essential in all cases of persistent diarrhea, usually in double doses of regular RDA. However, iron should be added only after control of diarrhea.

Essential micronutrient supplements include: (a) single dose of Vitamin A 2,00,000 IU (1,00,000 IU in infants), and (b) oral zinc 20 mg/day (10 mg/day < 6 months of age) for 2 weeks. Some workers also advise potassium and magnesium supplements in early stages, given orally or parenterally.

Disaccharide (lactose) intolerance: Disaccharidase enzymes, essential for digestion/absorption of various carbohydrates are located in the brush borders of epithelial cells of small intestinal mucosa. While congenital deficiency of these enzymes is very rare (commonest being sucrase-isomaltase deficiency), secondary deficiency is common due to acquired insults to intestinal epithelium, e.g. in diarrhea, malnutrition and prolonged antibiotic therapy.

Lactose intolerance is the commonest cause of persistent or intractable diarrhea in Indian children, due to deficiency of *lactase*-an enzyme, essential for lactose absorption.

Etiology of lactose intolerance may be divided into three categories:

a. *Secondary lactase deficiency* due to transient mucosal injury in acute diarrhea, malnutrition or prolonged antibiotic therapy is the commonest cause of temporary lactose intolerance in childhood.
b. *Congenital or inherited lactase deficiency* is known but extremely rare.
c. *Ontogenic lactase deficiency:* Normally, lactase levels rise in late fetal life, remain high during first 2–3 years and then decline gradually due to reducing milk intake in diet. Hence, ontogenic lactose intolerance is common in preterms, early infancy and children >3 years. Indians have lower lactase levels than western population, probably due to less milk consumption.

Pathogenesis: In lactase deficiency, lactose cannot be hydrolyzed into absorbable monosaccharides, i.e. glucose and galactose. Consequent accumulation of unabsorbed sugars in distal intestines leads to:

- *Hyperosmolarity* of luminal contents causing osmotic diarrhea, and
- *Fermentation* of sugar into gases (H_2, CO_2, and methane) and organic acids, causing gaseous abdominal distension, borborgymi and acidic, frothy stools.

Clinically, most cases present as unusual persistence of diarrhea after an acute viral episode, with:

- Watery, frothy, explosive stools,
- Bloating abdominal distension and borborgymi,
- Perianal excoriation, due to acidic stools.

Laboratory diagnosis depends on:

- *Acidic pH* of stools (normally alkaline),
- *Reducing sugars in stools* on Benedict test*
- *Breath-hydrogen test* revealing high hydrogen content in expired air (>15 ppm) due to excess carbohydrate fermentation in gut.
- *Enzyme assays* on mucosal biopsy, though rarely necessary.

****Benedict test***: Add 8–10 drops of saline-stool suspension in 5 ml of Benedict reagent and heat the mixture. A change of color from blue to orange or brick-red indicates presence of reducing sugar. Prior hydrolysis of stool sample with hydrochloric acid is needed to detect presence of sucrose, which is not a reducing sugar.

Management of these cases includes:

- *Reduction in lactose load:* Lactose intolerance is almost always secondary, transient and partial. Hence, management of these cases includes partial or complete withdrawal of milk for 5–7 days, to allow recovery of damaged brush borders and enzyme activity. Although most cases tolerate low-lactose diet (Diet A), severe/refractory cases may need lactose-free diet (Diet B) for 2–3 days, followed by gradual re-introduction. Soya-milk can also be used during this period.

- *Supplementation of lactase* enzyme in diet, by adding specific lactase preparation (2–3 drops in one litre of milk) 2–3 hours before consumption is useful, provided the milk is not re-heated before consumption. Use of yogurt/curd, which contains lactase-producing bacteria, is also beneficial.

14.12 MALABSORPTION SYNDROMES (CHRONIC DIARRHEA)

Malabsorption syndrome (MAS) is a *heterogeneous group of acquired or congenital disorders characterized by impaired digestion and/or absorption of all or some of the ingested dietary nutrients*. Clinically these disorders present with: (a) chronic or intractable diarrhea, (b) failure to thrive, and (c) signs of multiple or specific nutrient deficiencies, e.g. steatorrhea, edema, anemia, vitamin deficiencies, etc.

Transient malabsorptive defects secondary to post-infective diarrhea-induced mucosal injury (persistent diarrhea) are excluded from this definition.

Etiopathogenesis: Proximal half of small intestine is the most important site for absorption of proximate principles, e.g. proteins, fats and carbohydrates, while water and electrolytes are absorbed throughout its length. Bile salts and vitamin B_{12} are selectively absorbed at terminal ileum. Iron is mainly absorbed in duodenum and proximal jejunum.

Intraluminal digestion depends on exocrinal pancreatic enzymes (lipase, trypsin, chymotrypsin and others) and bile-salts from liver. Two important intestinal enzymes from proximal intestinal mucosa-secretin and cholecystokinin, released in response to the arrival of food, provoke these exocrine secretions.

Digestion and absorption of ingested nutrients is a complex and continuous process (Ch 14.1), dependent on the adequacy of-(a) digestive enzymes, (b) absorptive gut surface and (c) specific transporter mechanisms and enzyme activity, necessary for absorption of nutrients. These functions are deranged in MAS **(Table 14.21)** with impaired absorption of one or more nutrients.

According to the type of absorptive defects, MAS may be broadly divided into two categories:

a. *Generalized MAS* involving defective assimilation of multiple nutrients, due to loss of intestinal surface, mucosal integrity or motility disorders. Fat malabsorption is the earliest event in generalized MAS, characterized by *steatorrhoea*, i.e. foul and bulky stools with fat globules.

b. *Selective MAS*, limited to malabsorption of only one or two nutrients, due to specific defects in absorption mechanisms or transport enzymes, e.g. fat malabsorption in biliary disorders, protein malabsorption in amino acid transport defects, zinc malabsorption in acrodermatitis enteropathica, etc.

TABLE 14.21: Causes of chronic diarrhea (MAS)

Generalized malabsorptive states
- Chronic non-specific (Toddler's) diarrhea
- Impaired intestinal mucosal integrity
  - *Infective:* Post-enteritis, giardiasis, tuberculosis
  - *Allergic:* Food allergy, celiac disease, T. sprue
  - *Inflammatory bowel diseases:* Crohn disease, U. colitis
  - *Drugs:* Methotrexate, neomycin
- Reduced absorptive surface
  - Congenital short bowel syndrome
  - Surgical resection of large bowel segment
- Motility disorders (bacterial overgrowth)
  - Stagnant loop syndrome
  - Sub-acute intestinal obstruction
  - Irritable bowel syndrome
  - *Iatrogenic:* Laxatives, cholestyramine, antibiotics

Selective malabsorptive states
- Intestinal enzyme defects
  - *Carbohydrates:* Disaccharidase (lactase) deficiency
  - Amino acid transport defects, e.g. Hartnup disease
  - *Fat:* Abetalipoproteinemia
  - *Vitamin:* Pernicious anemia, folate malabsorption
  - *Minerals:* Chloride-loosing enteropathy, A. enteropathica
- Pancreatic disorders (fat and protein)
  - Cystic fibrosis
  - Chronic pancreatitis
  - *Isolated enzyme defects:* Lipase, trypsinogen
- Hepatic disorders (fat and fat-soluble vitamins)
  - *Cholestatic disorders:* Biliary atresia, gallstones
  - Chronic liver disease
  - Primary bile acid absorption defects

*U. Colitis: Ulcerative colitis,
A. enteropathica: Acrodermatitis enteropathica

Diagnostic evaluation in MAS aims not only to identify possible etiology but also the extent of its effect on health, e.g. nutrient deficiencies. It includes:

- **Clinical evaluation,** with special reference to:
  - Age of onset,
  - Relationship with introduction of cow-milk, wheat, egg, etc. in diet
  - Preceding history of acute/recurrent diarrhea,
  - Aggravation on selected foods (allergic)
  - Family history (enzyme defects, celiac disease)
  - Past history of GIT surgery/disease/drugs
  - Presence of abdominal pain, melena, vomiting, etc.
  - Signs of selective nutrient deficiencies, e.g. edema.
- **Stool characteristics**
  - Foul-smelling and bulky (fat-malabsorption)
  - Large and watery (congenital channelopathies)
  - Frothy, explosive diarrhea (carbohydrate malabsorption).

  Stools are generally large and pale with offensive odor in small bowel diarrhea, while small volume, often associated with blood and mucus in large bowel disorders.

- **Malabsorption tests:** Some important tests for malabsorption are as follows:
  - ***Fat malabsorption*** is characterized by bulky-foul smelling stools with *steatorrhoea*, i.e. presence of fat globules visually or on microscopy after sudan-red staining. *Quantitative estimation of total fat excretion* over 72 hours on a controlled diet (>5 gm/day) is a sensitive indicator of fat malabsorption.
  - ***Carbohydrate malabsorption*** is characterized by *watery and frothy stools* with *acidic pH* (<5.6) and *positive Benedict test* for reducing sugar. As sucrose is not a reducing sugar, stool sample should be hydrolyzed by hydrochloric acid before testing.
  - ***Protein malabsorption*** cannot be assessed directly as proteins are normally present in stool, though most of them are derived from bacterial sources rather than dietary proteins. Low *serum albumin* levels and high spot *stool 1-antitrypsin levels* indicate protein-loosing enteropathy.
  - ***D-xylose absorption test***: D-xylose is a pentose sugar absorbed mainly in upper small intestines. A blood concentration of < 25 mg/dl of xylose after one hour of oral dose (14.5 gm/m^2) indicated proximal bowel lesion.
  - ***Positive Schilling test*** despite intrinsic factor supplementation, indicates terminal ileum disease, as vitamin B_{12} is absorbed in distal bowel (Ch 19.4.2).
- **Etiological investigations:** Considering the diverse etiology, investigations in chronic diarrhea are recommended in a sequential manner **(Table 14.22)**.

TABLE 14.22: Investigations in MAS

Step I. *(Preliminary screening tests)*
- ***Stool examination***
  - Gross for fat globules, blood and volume
  - Microscopic for fat globules, ova and cysts
  - Biochemical for pH, reducing sugar
  - Cultures for common/opportunistic infections
- ***Blood examination***
  - CBC/PS for typing of anemia, acanthocytes
  - S. proteins for hypoproteinemia
  - Baseline electrolytes
- ***Radiological investigations***
  - Contrast barium studies
  - USG abdomen

Step II. *(Specific diagnostic tests)*
- Quantitative 72-hour fat excretion for steatorrhoea
- Breath hydrogen test for lactose intolerance
- Stool electrolytes for Cl-loosing enteropathy
- Sweat chloride test *for* cystic fibrosis
- D-xylose absorption test *for* proximal bowel disease
- Schilling test *for* distal bowel disease
- Upper GIT endoscopy/small bowel biopsy
- Colono/sigmoidoscopy/biopsy

Step III *(Rarely warranted)*
- *Hormonal studies:* VA peptides, gastrin, secretin, etc.

Management of MAS depends on etiology, though general principles are same as for persistent diarrhea, including nutritional management.

Celiac disease *(Gluten-sensitive enteropathy, nontropical sprue)* is one of the commonest causes of chronic diarrhea and MAS in children above 2 years.

Etiologically, celiac disease is a T-cell mediated autoimmune inflammatory disorder, representing small-bowel hypersensitivity to *gliadin fraction of gluten*, i.e. primary wheat protein. *Tissue Transglutaminase* (tTG) is an enzyme present in intestinal epithelium, which deamidates gliadin to stimulate the immune system and initiate inflammatory process in celiac disease.

Genetic predisposition is well known as: (a) over 90% cases are positive for HLA-DQ2 or DQ8 haplotype, (b) similar family history is present in ~10% cases, (c) nearly 100% concordance in monozygotic twins, and (d) higher risk in some genetic disorders, e.g. Down syndrome, Turner syndrome, diabetes mellitus, autoimmune thyroiditis, etc.

Clinically, these children present at ~6 months of age after introduction of wheat-products in complementary diet with: (a) chronic diarrhea as large, pale bulky stools, (b) recurrent vomiting, and (c) failure to thrive; with intermittent worsening of symptoms (*Celiac crisis*). Onset of diarrhea before introduction of wheat products is against the diagnosis of celiac disease.

On examination, abdominal distension, short stature and generalized wasting are consistent features, along with pedal edema due to hypoproteinemia and clubbing in severe cases. Extra-intestinal manifestations, specially refractory iron deficiency anemia, are common in older children. Silent disease may be present in first-degree relatives with asymptomatic histopathological changes.

Diagnosis is confirmed on small bowel biopsy to demonstrate characteristic villous atrophy along with repeat biopsy 1–2 years after gluten withdrawal, to show normalization of histology.

However, *quantitative serum anti-tissue transglutaminase IgA antibody* (IgA-tTG) is the screening test of choice as per ESPGHAN 2020 guidelines with sensitivity and specificity of 91–100%. Diagnosis of celiac disease can be made without duodenal biopsy, if—(a) IgA-tTG titers are >10 times of upper normal limit, (b) anti-*endomysial antibody* is also positive, and (c) there is definite clinical response to gluten-free diet. Biopsy is necessary for diagnosis in absence of quantitative IgA-tTG values.

Treatment includes exclusion of gluten-containing cereals (wheat, rye, barley) from diet, which provides symptomatic relief in 2–4 weeks with resumption of weight gain. Wheat is the major source of gluten in diet and all wheat-based foods should be completely avoided in celiac disease, replacing them with rice or maize-based foods. A short course of steroids may be indicated during celiac crisis.

Tropical sprue is a disease of unknown etiology (probably hypersensitivity), with diffuse chronic inflammation of small intestines, seen in many tropical countries including India. Intestinal microbial infection has been proposed as the initiating even, which leads to mucosal injury, gut stasis and bacterial overgrowth.

Clinically, these cases present with intermittent watery diarrhea/steatorrhea, severe anorexia, failure to thrive, multiple nutrient deficiencies and mild fever. Small bowel biopsy may be needed to exclude celiac disease and other causes of MAS. Most episodes respond well to antibiotics and folate/vitamin B_{12} supplementation.

Cow-milk protein allergy (CMPA) is common in developed countries (2–5%) and is being increasing recognized as an important cause of chronic diarrhea in under-five Indian children.

Etiologically, CMPA is more common in children with similar family history and top-feeing in early infancy. It may present as—(a) IgE-medicated allergic reaction with urticaria, vomiting and hypotension soon after the consumption of milk, or (b) delayed hypersensitivity reaction with long indolent course of intestinal malabsorption.

Clinically, CMPA presents with recurrent bloody or watery diarrhea on cow milk exposure, occasionally associated with GERD, hematemesis and severe anemia. Respiratory and skin allergies are present in ~30–50% cases.

Diagnosis must be suspected in a case with family history and eosinophilia and confirmed by the *challenge test*, i.e. disappearance of symptoms on elimination of cow-milk from diet for 1–2 weeks, which reappear on re-exposure. Positive skin prick test and elevated IgE levels suggest IgE-mediated disease.

Treatment involves removal of all animal milk and milk-products from the diet, replaced by extensively hydrolyzed formula (EHF) or soya milk, though ~10% may have concomitant soy allergy.

Nearly, half of the children outgrow CMPA by 1 year and >95% by 5 years of age. Breastfeeding may be continued despite mild symptoms, though mother must be advised to avoid consuming milk/milk-products during lactation period. Micronutrient supplements are necessary and trial-introduction of milk feeds should be attempted after first year.

Food allergy, other than CMPA, are uncommon contrary to popular belief and usually present with extra-intestinal rather than intestinal manifestations. All adverse reactions to foods are not allergies.

Commonly implicated allergens include egg, peanuts and food-additives, e.g. preservatives (sodium meta bisulfite) coloring agents (tartrazine) and flavouring agents (monosodium glutamate or Azinomoto).

Clinical spectrum of food allergy is extremely wide, including gastrointestinal, respiratory and cutaneous manifestations, including serious *anaphylactic* reactions.

TABLE 14.23: D/D Crohn disease vs ulcerative colitis

	Crohn disease	*Ulcerative colitis*
Site of lesion	Anywhere in GIT	Colon only
Abd. pain	++	+
Dysentery	+	++
Perianal lesions	+++	–
Serology	ASCA+ve	P-ANCA+
Barium studies	String sign	Lead pipe colon
Endoscopy	Skip lesions	Diffuse colitis
Biopsy	All layers involved	Limited to mucosa

Diagnosis depends on—(a) appearance of symptoms after introduction of suspected food item in diet, (b) relief of symptoms after elimination of that item, and (c) reappearance of symptoms on re-introduction in the diet (*challenge test*). However, challenge tests should be avoided in cases with severe allergic reactions. Skin-prick tests are unreliable to identify the causative food, unless substantiated by strong cause-effect relationship.

Management of food allergy includes—(a) symptomatic treatment of acute attacks, and (b) elimination of suspected food item from diet, but only if strong correlation has been established.

Inflammatory Bowel diseases (IBDs) includes two important intestinal diseases-*Crohn disease (CD)* and *Ulcerative colitis (UC)*, both characterized by chronic mucosal inflammation with intermittent exacerbations and remissions **(Table 14.23)**. Another ~10% cases cannot be classified in these two categories and are termed as *Indeterminate colitis*.

Early onset IBD in young children is generally considered as a different phenotype than adult-onset disease, due to strong genetically attributable risk.

Incidence: Children and adolescents years account for ~25% of all IBDs with mean age of presentation as ~11–12 years.

Etiologically, IBDs represent inappropriate immune response to environmental factors in a genetically susceptible host as:

- Many causative genes have been identified for IBD, e.g. *NOD2* and *IBD5, and*
- More than half of these cases have specific antibodies, e.g. anti-*saccharomyces cerevisiae* antibodies (ASCA) in CD and perinuclear antineutrophil cytoplasmic antibodies (P-ANCA) in UC.

Pathologically, CD may involve *any part* of gut, including terminal ileum and upper colon (50–70%), upper GIT (30–40%) and perianal lesions (15–20%). In contrast, lesions in UC are usually limited to colon and rectum, sparing rest of the GIT.

Further, UC lesions are in continuity with each other, while those in CD have normal intervening mucosa (*skip lesions*).

Clinical manifestations of both IBDs usually begin in late adolescence, with a waxing and waning course of variable severity, as follows:

- Recurrent crampy abdominal pain with sticky diarrhea dominates in CD, while UC usually presents with recurrent dysentery and tenemus.
- Constitutional symptoms, e.g. fever, anemia, weight loss, easy fatiguability are present in both IBDs, though growth failure is more prominent in CD.
- Extra-intestinal manifestations are present in 20–30% of both IBDs, including arthritis, uveitis, aphthous ulcers, cholangitis, erythema nodosum, etc. Clubbing is common.
- Perianal lesions, e.g. fistula, abscess, tags, etc. and complications like subacute obstruction due strictures or deep seated abscesses are common in CD.

Diagnosis must be considered in any case with history of recurrent/persistent abdominal pain and/or dysentery/sticky diarrhea, for >4 weeks. Inflammatory markers, e.g. ESR, CRP are usually elevated. Fecal Calprotectin level is a reliable screening test to differentiate IBD from functional abdominal pain.

Confirmation requires: (a) upper GI endoscopy with biopsy, (b) colonoscopy with ileal intubation and biopsy in all cases, with CT/MRI to assess the severity of IBD. Multiple biopsies are required from different sites for correct diagnosis. Important investigational differences between CD and UC are as follows:

- Endoscopy reveals deep, irregular ulcers with normal intervening mucosa (*skip lesions*) in CD and concentric diffuse colitis with acutely inflamed and friable mucosa in UC.
- Barium studies may show thick ileal folds with narrowed lumen (*string sign*) and linear ulcers (*cobblestone appearance*) in CD and loss of haustral markings with thickening of mucosal folds (*lead-pipe colon*) in UC.
- Histopathology reveals *transmural* inflammation of all intestinal layers with non-caseating granuloma in CD and only mucosal involvement with cryptitis or crypt abscesses in UC.

Management includes: (a) treatment of acute attacks, and (b) maintenance of remissions, as follows.

Ulcerative colitis in acute phase is generally treated with a 5-Aminosalcylate (5-ASA) drug, e.g. S*ulfasalazine* (PO 50–75 mg/kg/day q8hr), though steroids, e.g. prednisolone (PO 1–2 mg/kg/day q24hr) are used in severe cases, till remission is achieved. Rare refractory cases require treatment of acute attack with monoclonal antibodies, e.g. infliximab *or* calcineurin inhibitors (Cyclosporine/Tacrolimus), under expert guidance.

Once remission is achieved, it may be maintained with long-term use of 5-ASA or immunomodulators, e.g. azathioprine or 6-mercaptopurine in cases with ASA intolerance or poor response. Rare cases need Infliximab for maintenance.

*Surgery i*s indicated in selected cases of: (a) treatment failure or treatment dependence, or (b) toxic megacolon, with a two-step procedure of colectomy and pouch formation with ileostomy as the first step, followed by ileostomy closure.

Crohn disease in acute phase is treated with steroids, e.g. Prednisolone (PO 1–2 mg/kg/day q24hr) for 2–4 weeks followed by slow tapering over 8 weeks. Exclusive enteral nutrition (EEN) is the treatment of choice for only luminal CD, while metronidzaole and/or ciprofloxacin are used for perianal lesions. Monoclonal antibodies, e.g. Infliximab may be used in non-responsive cases.

Once achieved, remission may be maintained with immunomodulators, e.g. azathioprine, 6-mercaptopurine or methotrexate (with folic acid). Rare cases need Infliximab for maintenance.

Surgery is indicated in non-responsive localized CD resect areas with macroscopic disease, e.g. ileocolonic area with right hemicolectomy. Surgery is also needed for intestinal strictures, perforation, intra-abdominal abscesses and perianal fistula. However, recurrence is common.

Prognosis: Most IBDs respond well to medical treatment during initial attacks, though intermittent exacerbations are common. Toxic megacolon is the most important complication in acute stage. Some cases may develop colonic cancers after 10–15 years.

Abdominal tuberculosis or "*Koch's abdomen*" refers to *tubercular involvement of intestines, peritoneum and mesenteric lymph nodes,* excluding involvement of other abdominal organs, e.g. kidney, gonads and adrenals.

According to site of localization, it may be classified as peritoneal, nodal and intestinal **(Table 14.24)**. Intestinal infection tends to localize at *ileocaecal region* due to relative stasis and large lymphoid tissue.

Pathogenesis: GIT tuberculosis is usually acquired hematogenously during intermittent bacteremia from a pulmonary focus, though abdominal lymph nodes may be involved via retrograde lymphatic spread from mediastinal nodes. Direct GIT infection, as seen in Bovine tuberculosis, is very rare in India.

TABLE 14.24: Types of abdominal tuberculosis

- **Peritoneal**
  - Exudative peritonitis (TB ascites)
  - Adhesive or plastic peritonitis
  - Miliary peritonitis
- ***Nodal:*** Mesentric TB *(T. mesenterica)*
- **Intestinal**
  - Hypertrophic ileocecal
  - Ulcerative

Clinical presentation depends on the site and nature of lesions. Intestinal tuberculosis present with:

- Intermittent episodes of diarrhea/constipation, due to subacute obstruction,
- Abdominal pain and/or distension with typical *doughy* feel and presence of ascites,
- Constitutional features, e.g. low-grade fever, anorexia and weight loss.

Hepatomegaly, ascites and abdominal lump suggestive of mesenteric lymph nodes or ileocaecal mass may be present.

Complications, e.g. intestinal obstruction, fistula formation, peritoneal cold abscesses are common while perforation and hemorrhage is rare in intestinal disease.

Diagnosis usually rests on USG or contrast-enhanced CT (CECT) showing (a) concentric bowel thickening with contracted cecum, distorted ileocecal angle and short strictures in *intestinal disease*, (b) conglomerate lymph nodes of >1 cm with central necrosis in *nodal disease,* and (c) mesenteric thickening >15 mm with ascites in *peritoneal disease*. Rarely, focal granuloma may be present in liver or other organs. Barium meal with follow-through has been conventionally used for diagnosis of intestinal tuberculosis, though rarely used at present **(Fig. 14.18)**.

Peritoneoscopy is highly sensitive and specific (>93% and 98% respectively) for diagnosis of peritoneal tuberculosis, showing hyperaemic and thickened peritoneum, whitish miliary nodules, adhesions and ascites.

All attempts should be made to confirm bacteriological diagnosis with drug sensitivity/resistance testing, from ascetic fluid or CT-guided peritoneal/node biopsy (Ch 10.13).

Fig. 14.18: Abdominal tuberculosis (barium follow-through). Note pulled-up ileocecal region with strictures. (***Courtesy:*** Dr S Malik)

Treatment includes specific antitubercular therapy according to drug sensitivity profile along with supportive treatment (Ch 10.13). Surgery is indicated in only in-(a) non-resolving intestinal obstruction, (b) perforation peritonitis, abscess or (c) fistulous communication, preferably after antitubercular therapy.

Toddler's diarrhea *(chronic non-specific diarrhea)* is the commonest and self-limiting cause of chronic diarrhea in infancy, with onset between 6 months and 3 years of age.

First morning stool is usually well formed but the frequency (4–6/day) and liquidity increases as the day progresses, sometimes containing mucus and undigested food. Dehydration or failure to thrive is typically absent. Similar family history is common and symptoms may be precipitated by teething or common infectious illnesses. Excessive ingestion of fruit juices or non-absorbable sugars has been implicated in etiology.

Diagnosis involves exclusion of more serious causes. No specific treatment is required except dietary modification (high-fibre, high-fat, low-carbohydrate diet). Problem resolves spontaneously by 3–4 years of age.

Other important but uncommon causes of MAS are as follows:

Chronic malnutrition is a common cause of MAS, due to—(a) intestinal villous atrophy, more prominent in Kwashiorkor, (b) bacterial overgrowth in upper intestine due to relative immunodeficiency, (c) suboptimal exocrinal pancreatic functions. Vitamin A supplements are beneficial to some extent in these cases.

Immunodeficiency disorders, congenital (SCID, IgA deficiency) or acquired (HIV, malignancy, iatrogenic) are emerging as important cause of chronic diarrhea and malabsorption, either due to primary disease or secondary infections. Giardiasis and rotaviral infections are common cause of chronic infective diarrhea in these cases, apart from opportunistic infections, e.g. Candida, Cryptosporidium, Isospora, CMV, *Mycobacterium avium* intracellulare, etc.

Chronic liver disease may lead to fat malabsorption due to impaired secretion of bile acid and bile salts in duodenum. Apart from primary disease, these cases present with steatorrhea and signs of fat-soluble vitamin deficiency, e.g. vitamin A (skin and ocular xerosis), vitamin E (progressive spinocerebellar degeneration with peripheral neuropathy), vitamin D (resistant rickets) and vitamin K (bleeding diathesis).

Pancreatic disorders: *Cystic fibrosis* is the commonest cause of malabsorption due to exocrinal pancreatic insufficiency, followed by *Juvenile tropical pancreatitis* (Ch 14.16). *Shwachman-Diamond syndrome* is a rare cause of pancreatic steatorrhea with failure to thrive and neutropenia or chemotaxis defects.

Cystic fibrosis is an autosomal recessive defect in salts and water secretion by epithelial cells, leading to desiccation of exocrinal secretions. While meconium ileus is the earliest presentation in ~10–20%, older cases present with steatorrhea, recurrent respiratory illnesses, salty-skin and other complications (Ch 16.10).

Structural intestinal defects are rare causes of MAS, commonest being Blind-loop syndrome and short bowel syndrome.

Blind loop syndrome denotes abnormal stasis of small intestinal contents, due to—(a) congenital malrotation, bands or diverticula, or (b) acquired postoperative adhesions or chronic inflammatory bowel disorders. Stasis allows bacterial overgrowth in upper small bowel, which deconjugate bile salts (fat malabsorption), cause brush border injury (disaccharide intolerance) and bind Vitamin B_{12} to prevent its absorption. Clinicoradiological indicators of chronic intestinal obstruction are often absent. Oral metronidazole or non-absorbable antibiotics, e.g. neomycin or gentamycin, may be used for temporary control followed by operative correction.

Short bowel syndrome with loss of at least 50% of small bowel, may be congenital or postoperative. Resultant decrease in absorptive surface leads to fat and carbohydrate malabsorption. Management of these cases is a complex issue and involves total parenteral nutrition during acute phase, followed by gradual introduction of enteral feeding. Exposure to enteral nutrients facilitates compensatory growth of remaining bowel. Non-absorbable antimicrobials, anti-motility drugs and cholestyramine may be useful in select cases. Long-term prognosis is poor unless prolonged TPN is possible to allow gradual bowel growth. Many of these patients may ultimately require small intestinal transplant.

Specific absorption/transports defects for many nutrients are known, although rare. Some important ones include:

Abetalipoproteinemia is rare autosomal recessive deficiency of β-lipoproteins, essential for chylomicron formation. These cases present with: (a) failure to thrive and steatorrhea since early infancy, (b) neuroocular manifestations beyond first decade, (c) acanthocytosis in peripheral smear and (d) abnormal lipid profile, i.e. extremely low cholesterol, LDL and VLDL levels. Treatment involves replacement of long-chain fats with medium-chain triglycerides in the diet, which do not require chylomicrons for absorption, along with fat-soluble vitamin supplements in large doses (Ch 11.6.2).

Chloride-loosing enteropathy is a rare congenital defect in ileal chloride transport, presenting as severe watery diarrhea since birth with dehydration and unique pattern of dyselectrolytemia-*hypokalemia with hypochloremic alkalosis*. Diagnosis rests on stool electrolytes with chloride content exceeding sum of the sodium and potassium contents. Treatment is supportive.

Acrodermatitis enteropathica, an inherited defect of zinc malabsorption, presents with—(a) chronic diarrhea, (b) mucocutaneous lesions, and (c) failure to thrive. Oral zinc supplements (1–2 mg/kg/d) lead to rapid improvement. (Ch 6.9)

Amino-acid transport defects are rare malabsorption defects for select amino acids, important ones including: *Cystinuria* (no diarrhea) and *Hartnup disease* (Ch 11.6.1).

Glucose-galactose malabsorption is a rare autosomal recessive defect of glucose-galactose transport across the intestinal brush borders, which presents soon after initiation of breastfeeding with chronic diarrhea, abdominal distension and dyselectrolytemia. Strict dietary restriction of glucose-galactose with use of fructose-containing formula feeds is essential for survival.

14.13 ACUTE INTESTINAL OBSTRUCTION

Acute intestinal obstruction (AIO) is a common surgical emergency in newborns and infants due to congenital malformations, though subsequently it is less common in children than in adults.

Etiologically AIO may be broadly classified as *dynamic*, i.e. mechanical obstruction to intestinal flow or *adynamic*, i.e. paralytic ileus with absent or reduced peristaltic movements **(Table 14.25)**.

Clinical presentation depends on etiology and severity of obstruction and may be acute or sub-acute, with three common features: (a) absolute or relative constipation, (b) progressive abdominal distension, and (c) persistent vomiting or increased gastric aspirate.

Signs of dehydration and dyselectrolytemia due to impaired gut absorption and increased third-space losses appear soon. Fever is a late feature, suggestive of secondary infection or colonic overgrowth of pathogens.

On examination, visible peristaltic movements with increased bowel sounds (due to increased contractility

TABLE 14.25: Causes of intestinal obstruction

- **Mechanical (Dynamic)**
  - ***Intrinsic***
    - Congenital atresia/stenosis of intestines
    - Anorectal malformations
    - Meconium ileus
    - Foreign body, e.g. coins, bezoars, worms
  - ***Intramural***
    - Intussusception
    - Hypertrophic ileocecal TB
    - Hirschsprung disease
  - ***Extrinsic***
    - Volvulus (malrotation of gut)
    - Congenital bands/strictures/loops/duplications
    - Post-inflammatory or surgical adhesion
- **Adynamic (Paralytic ileus)**
  - Septicemia
  - *Metabolic:* Hypokalemia, poisoning
  - Exhaustion (post-diarrhea, late obstruction)

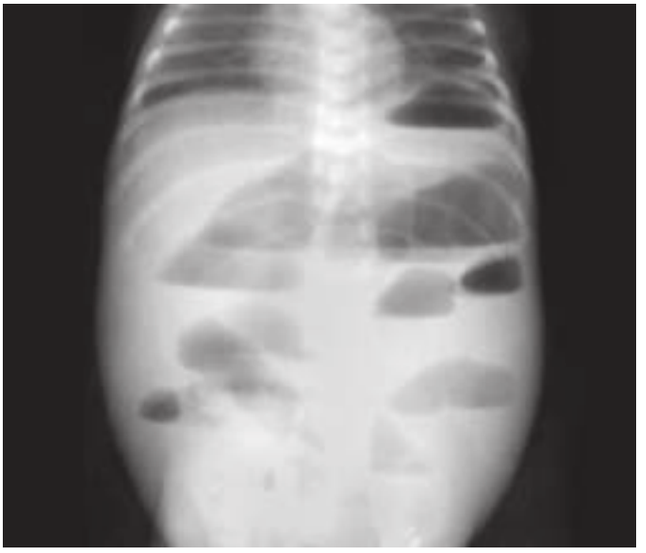

Fig. 14.19: **Intestinal obstruction: Multiple fluid levels on X-ray abdomen in standing position.**

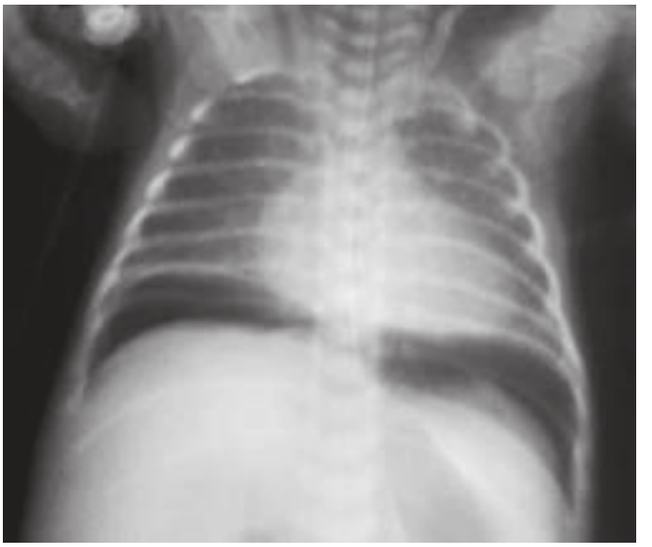

Fig. 14.20: **Intestinal perforation: Gas under diaphragm on X-ray abdomen in standing position.**

of proximal segment to overcome obstruction) indicates mechanical obstruction, while absent bowel sounds suggest paralytic ileus-either primary or after exhaustion of gut musculature in mechanical obstruction.

Diagnosis: Presence of multiple air-fluid levels on standing abdominal X-ray is diagnostic of AIO **(Fig. 14.19)**. Important etiological clues include:

- ***Age:*** While intestinal atresias, meconium ileus and necrotizing enterocolitis are dominant causes of AIO in newborns; volvulus, septic paralytic ileus and less severe congenital malformations, e.g. bands and adhesions are more common in infancy. Beyond infancy, intussusception is the commonest cause in all pediatric age groups, followed by paralytic ileus.
- ***Clinical course:*** While intestinal malformations, intussusception and volvulus present with sudden obstruction, sub-acute or recurrent obstruction in Indian children generally indicates abdominal tuberculosis, worm infestations or Hirschsprung disease.
- ***Specific clinical features,*** include presence of bile in vomiting/gastric aspirate in duodenal or high jejunal obstruction or passage of red-currant jelly per rectum in intussusception. Per-rectal exam is extremely valuable to identify Hirschsprung disease.
- ***Specific radiological features***, e.g. ground-glass appearance in meconium ileus, double-bubble sign in duodenal atresia, single grossly dilated loop in volvulus, gas under diaphragm in intestinal perforation **(Fig. 14.20)**, etc.

Management of AIO may be conservative or surgical, depending on probable cause and general condition of the patient.

Conservative management is indicated in—(i) critically sick children, (ii) surgically uncorrectable lesions, or (iii) for pre-surgical stabilization and includes: (a) gastric decompression by stopping the oral feeds and continuous nasogastric suction, (b) fluid and electrolyte correction, (c) supportive therapy including prophylactic antibiotics.

Intussusception is the commonest cause of AIO in children aged 3 months-5 years, due to telescoping of a proximal intestinal segment (*intussceptum*) into distal segment (*intussuscipiens*), leading to ileoileal or iliocolic intussusception. A causative association with rotavirus vaccine, suspected earlier, is unlikely with new-generation vaccines.

Clinically, these cases present with a triad of (a) Abdominal pain, (b) red-currant jelly stools with blood and mucus, and (c) palpable mass in some cases.

Diagnosis depends on USG showing "*Doughnut sign*" or "*Bull's eye sign*", due to central lead point encircled by concentric alternating echogenic (mucosa, muscularis) and hypoechoic (submucosa) bands. Barium enema may show "*Claw sign*" in colonic intussusception, due to irregular filling defects.

Treatment includes either conservative reduction under USG guidance by hydrostatic enema or air insufflations; or surgery in cases of failed conservative reduction or suggestion of bowel gangrene.

14.14 ACUTE APPENDICITIS

Acute appendicitis is less common in Indian children than in western counterparts, probably due to high fiber diet. It is most common in 6–10 years age group, with male preponderance (3:2).

Etiopathogenesis: Acute appendicitis usually begins with obstruction of appendicular lumen by fecoliths/worms/seeds, etc., leading to obstruction in mucus flow (mucocele) and secondary infection, followed by gangrenous necrosis of walls, perforation and peritonitis.

While perforation may be sealed by protective omentum (appendicular lump) in older children, generalized peritonitis is more common in younger children due to thinner and smaller omentum. Rarely, infection may reach appendix during hematogenous septicemia from distant sites.

Clinically, typical cases present with a specific sequence of symptoms: (a) abdominal pain, followed by (b) vomiting, followed by (c) fever, developing over 24–48 hours.

Characteristically, appendicular pain begins in periumbilical region and gradually migrates to right iliac fossa after 2–6 hours. Generalized pain indicates development of peritonitis. Constipation is common, though irritation of sigmoid colon or urinary bladder by inflamed appendix may cause diarrhea and dysuria, respectively.

Clinical examination may reveal:

- *Tenderness at McBurney's point*—the junction of lateral 1/3rd and middle 2/3rd of a line joining anterior superior iliac spine to umbilicus,
- *Psoas sign,* i.e. pain during flexion or hyperextension of the hip.
- *Tender mass in right iliac fossa*, composed of inflamed appendix, cecum, terminal ileum and omentum,
- Signs of generalized peritonitis.

Diagnosis rests on clinical suspicion with polymorphonuclear lekocytosis and must be confirmed on USG, showing dilated (>6 mm) tubular, aperistaltic, thick-walled appendix, with/without intraluminal fluid or fecoliths. USG also helps to exclude other causes of acute abdomen, including pelvic inflammatory disease in girls.

Abdominal CT scan is indicated in doubtful cases to confirm the diagnosis as well as detect/localize the perforation or intra-abdominal abscesses.

X-ray abdomen is of little value in diagnosis of appendicitis *per se*, but may reveal calcified appendicolith, air-fluid level in cecum, signs of small bowel obstruction, and pneumoperitoneum.

Treatment depends on the stage of diagnosis, as follows:

- *Non-perforated cases* need immediate appendicectomy, preferably laparoscopic, after pre-operative stabilization.
- *Perforated cases* with appendicular mass or peritonitis must be managed conservatively for 7–10 days, followed by interval appendicectomy after 10–12 weeks.

Pre-operative stabilization and conservative management includes: (a) nasogastric decompression, (b) fluid/electrolyte correction, and (c) antibiotics, including metronidazole for anerobic infections.

Prognosis: Overall mortality is <1% with surgery before perforation. Perforation is more common in younger children and carries poorer prognosis. Other complications include intra-abdominal abscesses, intestinal obstruction, and rarely, infertility due to obstruction of fallopian tubes.

14.15 PERIANAL DISORDERS

While anorectal malformations have been discussed in Ch 14.9, some important acquired problems of anorectal region are as follows:

Anal fissures, i.e. small lacerations at mucocutaneous junction of the anus, are common in infancy and early childhood due to forceful passage of hard stools in constipated children. Constipation and anal fissure are inter-related, as children with anal fissure avoid defecation to prevent pain, which further exacerbates constipation and hard stools.

Clinically, these cases present with painful defecation and passage of hard stools laced with bright-red color on the surface.

Diagnosis involves local examination revealing the fissure and sometimes a peri-anal skin tag, due to chronic inflammation. Crohn's disease must be excluded in cases with recurrent anal fissures.

Management aims to break to constipation – fissure-constipation cycle, by use of stool softners/laxatives in response-adjusted doses and encouragement of regular evacuation habits. Fissures tend to recur in habitually constipated children.

Rectal prolapse denotes exteriorization of rectal mucosa through the anus. When this extrusion includes all layers of rectal wall, it is termed as *Procidentia.*

Etiologically, rectal prolapse is common in 1–5 years age group, with following predisposing factors: (a) severe malnutrition, (b) acute/persistent diarrhea, (c) constipation, (d) meningocele, (e) pertussis, (f) chronic inflammatory bowel disorders, e.g. ulcerative colitis, and (g) postoperative cases of anorectal malformations.

Clinically, rectal prolapse may be painless or painful and reducible or non-reducible. Severe cases may develop congestion, edema and ulceration of exteriorized portion.

Management includes: (a) manual reduction of protruding mass, facilitated by warm compresses, (b) treatment of primary cause, (c) ensuring adequate nutrition, and (d) surgical correction in severe cases or procidentia.

Perianal abscesses are relatively common and self-limiting in infancy, probably caused by extension of infection from underlying crypts. However, these

abscesses in children beyond 2 years are usually associated with a significant predisposing illness, e.g. Crohn's disease, Hirschsprung disease or immunodeficiency disorders.

Most perianal abscesses are polymicrobial in etiology, commonest being *E.coli, Staph. aureus* and anaerobes.

Clinically, these children present with variable severity of fever, rectal pain, painful defecation and signs of perianal cellulitis. Many cases in infancy may be completely asymptomatic.

Treatment: Perianal abscesses in infants are usually self-limiting, though abscess drainage and/or fistulotomy is required in selected cases. Older children with predisposing factors require more aggressive treatment with antibiotics, excision/drainage and treatment of underlying cause.

14.16 PANCREATIC DISORDERS

Embryologically, pancreas develops as an evagination from primitive duodenum and drains in it via a main duct, i.e. *duct of Wirsung,* though an accessory duct, i.e. *duct of Santorini* is also present in 15% population.

Physiologically, pancreas has endocrinal function to secrete insulin from *islets of Langerhans* as well as exocrine function to secrete over twenty digestive and absorptive enzymes, e.g. lipase (for fat), trypsin and chymotrypsin (for proteins). Clinical features of malabsorption appear only after ~90% of pancreatic activity is lost. Pancreatic enzymes, specially lipase, are low in newborns, leading to poor fat tolerance in them.

Exocrinal pancreatic insufficiency is commonly seen in cystic fibrosis, though other causes include pancreatitis, severe malnutrition, Schwachman syndrome (neutropenia, failure to thrive and malabsorption) and inherited enzyme deficiencies.

Acute pancreatitis in children is usually caused by: (a) viral infections, e.g. mumps, (b) blunt abdominal trauma, or (c) drugs, e.g. antiretrovirals agents.

Clinically, it presents with acute epigastric pain, persistent vomiting, fever and significant fluid-electrolyte imbalance. *Acute hemorrhagic pancreatitis*, seen in adults with shock, is rare in children.

Diagnosis depends on the presence of any two of the following three findings: (a) abdominal pain compatible with pancreatic origin, (b) elevation of serum amylase/lipase >3 times of the upper normal limit, and (c) imaging studies suggestive of acute pancreatitis. Presence of organ failure, e.g. respiratory distress, shock, DIC and renal failure suggests moderate to severe disease.

Management is mainly conservative with nasogastric suction, fluid and electrolyte correction and pain relief with NSAIDs or paracetamol. Antibiotics are not required except in acute infected necrotizing pancreatitis and surgery is rarely indicated in acute phase, except to drain an abscess. Uncomplicated cases usually recover in 3–4 days.

However, many children are prone for recurrent pancreatitis, i.e. more than two episodes with at least one-month symptom-free interval.

Pseudocyst of pancreas is a sequel of acute pancreatitis, though uncommon in children. These cases present with palpable abdominal mass with/without ascites or jaundice, after 2–4 weeks of acute illness. Diagnosed on USG/CT, no treatment is necessary for small lesions, while large pseudocysts need percutaneous or laparoscopic drainage.

Chronic or recurrent pancreatitis in children may be *idiopathic,* e.g. juvenile tropical pancreatitis or *secondary* to autoimmune, hereditary (cystic fibrosis) or metabolic disorders or congenital malformations. Many of them present with fat malabsorption (exocrine dysfunction) or diabetes mellitus (endocrinal dysfunction).

Diagnosis of chronic pancreatitis requires *suggestive imaging finding,* e.g. altered echotexture of pancreas with/without calcifications and dilatation, strictures or calculi of the pancreatic duct, along with one of the following three criteria: (a) abdominal pain consistent with pancreatic origin, (b) evidence of exocrine pancreatic insufficiency, or (c) evidence of endocrinal pancreatic insufficiency.

Etiological evaluation also includes sweat chloride test, USG/CT, magnetic resonance cholangiopancreatography (MRCP) and endoscopic retrograde cholangiopancreatography (ERCP).

Treatment depends on the cause, along with supportive therapy, oral pancreatic enzyme replacement and management of diabetes. Endoscopic treatment may be required for pseudocysts, ductal lesions and calculi.

Juvenile tropical pancreatitis is the commonest cause of chronic pancreatitis in children or adolescents of developing countries. In India, maximum cases have been reported from Kerala, though the incidence has declined in recent years.

Etiology is uncertain, probably related to pancreatic injury in malnutrition, trace-element deficiencies, e.g. Vitamin A, C, zinc, copper, manganese, selenium; or consumption of an unidentified substance in *cassava tapioca*-staple diet in endemic areas.

Clinically, these cases present with recurrent abdominal pain in childhood and pancreatic calculi and/or diabetes mellitus in adolescence. While persistent steatorrhea is uncommon due to poor dietary intake in affected population, fat intolerance is obvious on excessive intake. On examination, these children are typically emaciated with distended abdomen, parotid enlargement and sometimes, a cyanotic hue on lips.

Diagnosis is often missed as functional abdominal pain, till pancreatic calculi are visible on abdominal X-rays. Confirmation requires USG/CT/MRI and ERCP (dilated pancreatic duct).

Treatment is largely supportive including avoidance of fat in diet, oral pancreatic enzyme replacement and management of Diabetes. Endoscopic treatment may be required for ductal lesions and calculi.

14.17 DISORDERS OF GALLBLADDER

Embryologically, biliary tree develops from a ventral evagination of the primitive foregut into septum transversus and includes biliary canaliculi, and ductules, hepatic ducts, gallbladder and common bile duct, which ultimately opens at ampulla of Vater in duodenum along with pancreatic duct.

Physiologically, biliary tree transports the hepatic products, i.e. bile to the gut, while gallbladder acts as a reservoir.

Obstructive jaundice is the pathognomonic manifestation of biliary tract disorders (Ch 15.3). While neonatal cholestatic syndromes have been discussed elsewhere (Ch 12.14), other important biliary tree disorders in older children are as follows:

Acute hydrops is the sudden distension of gallbladder in absence of stones, congenital malformations and bacterial infection. Round worms, prolonged fasting, total parenteral nutrition and enteric fever are common causes of acute hydrops, presenting as right upper quadrant pain, tenderness (*Murphy sign*) and palpable mass, with or without fever, vomiting and jaundice.

USG reveals distended echo-free gallbladder without dilatation of biliary tree and most cases may be managed conservatively.

Acute acalculous cholecystitis is uncommon in children, seen as a part of generalized septicemia due to any cause, (e.g. enteric fever) or following blunt abdominal trauma. While clinical features are usually indistinguishable from acute hydrops, presence of high fever with chills, primary septicemia and leukocytosis indicate infective etiology and need for surgical exploration. Diagnosis is usually confirmed on laparotomy and cholecystectomy is often needed.

Cholelithiasis (gallstones): Gallstones in children are commonly *pigment stones* (>70–80%), seen in cases with: (a) hemolytic anemia, (b) chronic liver disease, e.g. Wilson disease, (c) history of neonatal cholestasis, and (d) prolonged total parenteral nutrition. *Cholesterol stones* are rare in children, seen in adolescent obese girls with idiopathic biliary dyskinesia.

Clinically, these cases may be asymptomatic or present with recurrent upper right quadrant abdominal pain and/or intolerance to fatty foods.

Diagnosis is confirmed on USG and cholecystectomy is the treatment of choice along with operative cholangiography to exclude other calculi in common bile duct. Presence of gallstones in the bile duct is often associated with acute biliary colic and obstructive jaundice, best diagnosed on MRCP or ERCP. Hemolytic anemia should be excluded in all cases.

Choledochal cysts, i.e. *congenital cystic dilatations of common bile duct*, present with recurrent cholestatic jaundice, progressive biliary obstruction or biliary cirrhosis. A diverticula of the common bile duct or dilatation of intra-duodenal portion of common duct is termed as *choledochocele*. Choledochal cysts are classified from Type 1–5 as per *Todani classification*, the type 5 termed as *Caroli disease* with intrahepatic cystic lesions. *Caroli syndrome* refers to caroli disease with congenital hepatic fibrosis.

Clinically, most cases present in childhood with a triad of-abdominal pain, right quadrant mass and cholestatic jaundice. Young infants and children may also present with biliary peritonitis due to spontaneous bile duct perforation.

Diagnosis rests of USG, though MRCP is advised before surgery to delineate the lesions.

Treatment involves primary excision of cyst with Roux-en-Y choledochojejunostomy, advocated even in asymptomatic cases due to risk of malignant transformation in later life.

14.18 DISORDERS OF PERITONEUM

Peritoneal disorders may be inflammatory (peritonitis) or non-inflammatory (ascites).

Acute peritonitis is either *spontaneous* or *secondary* **(Table 14.26)**. While spontaneous peritonitis denotes peritoneal infection via hematogenous/lymphatic route from a source outside the abdomen, secondary peritonitis denotes extension of infection from an abdominal viscera.

Etiology: Spontaneous bacterial peritonitis (SBP) is usually caused by a single pathogen, e.g. *S. pneumoniae, S. fecalis, Staph. aureus* or gram negative organisms, e.g. *E.coli* and *Kleb. pneumoniae*. secondary peritonitis is usually *polymicrobial*.

TABLE 14.26: Causes of peritonitis

- **Primary (spontaneous)**
  - Generalized septicemia
  - Infected ascites, e.g. nephrotic syndrome, cirrhosis
- **Secondary (extended infection or perforation)**
  - *Intestines:* Obstruction, appendicitis, diverticulitis
  - Umbilical sepsis in newborns
  - *Liver:* Hydatid cyst, pyemic/amebic abscess
  - *Biliary:* Cholecystitis, worms, gallstones
  - Acute pancreatitis
  - *Lymph node:* Tuberculosis
  - *Foreign body:* VP shunt
  - Traumatic/post-surgical infection

SBP is an important complication of nephrotic syndrome, usually caused by capsulated organisms due to complement deficiency. On the other hand, peritonitis associated with ventriculoperitoneal shunt is usually caused by *Staph. epidermidis*, *Staph. aureus* and *Candida albicans.*

Clinically, acute bacterial peritonitis presents with high fever, diffuse abdominal pain and vomiting. On examination, these cases appear toxic with following typical features:

- *Silent abdomen*, i.e. restricted breathing movements to avoid pain,
- *Rebound abdominal tenderness*, guarding and/or board-like rigidity,
- *Diminished or absent bowel sounds*.

Free fluid may be present and circulatory shock is common. Loss of liver dullness indicates pneumoperitoneum. Presence of ascites in nephrotic syndrome or cirrhosis with pain or fever favors diagnosis of spontaneous peritonitis.

Diagnosis must be suspected clinically, supported by polymorphonuclear leukocytosis and abdominal skiagram showing generalized haziness with sparse bowel gas shadows. Presence of free air under diaphragm (perforation) or multiple air-fluid levels (obstruction) indicate secondary peritonitis. USG with abdominocentesis is indicated in all cases to confirm the presence of fluid and differentiate ascites from peritonitis (proteins >2.5 gm/dl, cell count >250 cells/mm^3 with polymorphonuclear predominance), as well as for microbiological studies.

Management is largely conservative and includes:

- *IV antibiotic therapy*, which must be started immediately and empirically with Cefotaxime and an aminoglycoside, modified after culture reports. Additional IV metronidazole is recommended in secondary peritonitis. Therapy should be continued for 7–10 days.
- *Supportive measures* include no oral feeds, nasogastric decompression, fluid and electrolyte correction, parenteral nutrition and treatment of shock with volume expanders and vasopressors.
- *Surgical intervention* is needed only for underlying perforation or if peritoneal abscesses have developed.

Tubercular peritonitis, common in Indian children, results from spread of infection from regional lymph nodes and presents as a subacute peritonitis or ascites. Despite larger fluid collection, abdominal signs are less marked than in bacterial peritonitis and ascitic fluid is typically straw colored exudate with lymphocytic hypercellularity and cobweb formation on standing. USG/CT may reveal underlying abdominal lymphadenopathy or intestinal tuberculosis. Treatment includes specific anti-tubercular therapy with or without steroids (Ch 10.13, 14.12).

Fig. 14.21: Ascites.

Ascites denotes accumulation of any fluid within peritoneal cavity **(Fig. 14.21)**. However, this term is generally reserved for serous and sterile fluid collections, while exudative ascites is referred as peritonitis.

Etiology: Congenital malformations of thoracic duct or hydrops fetalis are common causes of ascites in newborns. In older children, it may be mechanical (altered hydrostatic:oncotic pressure balance), inflammatory or traumatic in origin **(Table 14.27)**.

TABLE 14.27: Causes of ascites in children

Transudative ascites

- ↓ ***Plasma oncotic pressure*** *(hypoproteinemia)*
  - *Hepatic:* Cirrhosis, acute liver failure
  - *Renal:* Nephrotic syndrome
  - *Nutritional:* PEM
- ***Hydrostatic pressure***
  - *Cardiac:* CCF, pericardial effusion
  - *Vascular:* Budd-Chiari syndrome
  - *Hepatic:* Congenital hepatic fibrosis
  - Portal hypertension
- ***Miscellaneous***
  - VP shunt
  - Peritoneal dialysis
  - Connective tissue disorders (Serositis)

Exudative ascites *(peritonitis)*

- ***Primary***
  - Tubercular peritonitis
  - Spontaneous bacterial peritonitis
- ***Secondary***
  - Intestinal perforation
  - Pancreatitis or ruptured pancreatic duct
  - Biliary tree anomalies/injury (Biliary ascites)
  - Urinary tract anomalies/injury (Urinary ascites)

Hemorrhagic ascites

- Malignancies
- Traumatic (penetrating or blunt abdominal trauma)
- Splenic rupture

Chylous ascites

- Thoracic duct anomalies or injuries

Diagnosis: Abdominal distension is the hallmark of ascites, though other causes, e.g. gaseous distension, organomegaly or *pot belly* must be excluded. Depending on the amount of fluid collection, various clinical signs include:

- *Flank fullness* and *Puddle sign* (<50 ml fluid)
- *Shifting dullness/horse-shoe dullness* for moderate ascites, and
- *Fluid thrill* in large ascites.

Investigations: USG is the best tool to detect minimal ascites and for diagnostic paracentesis. Important characteristics of ascitic fluid include:

- ***Color:*** Watery (transudate), straw-colored (tubercular), hazy or pus (bacterial peritonitis), bloody (traumatic/hemorrhagic), milky-white (chyle), greenish (biliary), tea-colored (pancreatitis).
- ***Proteins:*** Transudative (<2.5 gm/dl) or exudative (>2.5 gm/dl). As ascitic fluid hypoproteinemia is common in generalized hypoproteinemic states including SAM. A more informative test is to calculate serum: ascitic fluid albumin ratio. A ratio of >1.1:1 suggests portal hypertension.
- ***Leukocyte count*** of >500 cells/mm^3 indicates exudative pathology, specially if >50% of them are polymorphs.

Other tests, e.g. bacterial and tubercular culture (peritonitis), triglycerides (chylous ascites), amylase (pancreatic etiology), LDH (spontaneous bacterial peritonitis) are also useful in diagnosis.

Management: Apart from treatment for primary cause, general management of ascites includes:

- *Bed rest* to decrease the discomfort as well as reduce renin-angiotensin activity, which is higher in upright position.
- *Dietary restriction* of sodium, though fluid restriction is not necessary unless serum sodium is <120 mEq/L.
- *Diuretics,* preferably potassium-sparing ones, e.g. spirolactone may be used in severe cases with caution to avoid hypovolemia.
- *Therapeutic abdominocentesis* carries the risk of infection in sterile ascites and recommended only in cases with marked discomfort and respiratory distress. Infected peritoneal fluid must be treated as peritonitis, discussed earlier.

CHAPTER

15

Disorders of Hepatobiliary System

Aditi Dharap, Prachi S Karnik, Mukesh Agrawal

15.1 BASIC CONSIDERATIONS

Embryologically, liver develops from two sources: (a) *Biliary tree and hepatocytes* from ventral evagination of the primitive foregut (endoderm) into mesodermal septum transversus, and (b) *Kupffer cells and supporting elements*, e.g. endothelial cells, fibrous tissue and blood vessels from the mesoderm itself.

Anatomically, basic architecture of liver parenchyma may be broadly divided into two elements: (a) *hepatic lobules*, i.e. pentad arrangement of hepatocytes with a central vein and surrounding sinusoids, and (b) *portal triads* containing portal venules, hepatic arterioles and biliary canaliculi. A thick limiting plate of connective tissue separates hepatic lobules and portal triads from each other.

The biliary system includes biliary canaliculi, and ductules, hepatic ducts, gallbladder and common bile duct, which ultimately opens at ampulla of Vater in duodenum along with pancreatic duct.

Vascular supply: Liver is a highly vascular structure with dual blood supply—via *portal circulation* (75%) and via hepatic artery of *systemic circulation* (25%). *Portal vein* is formed by the fusion of splenic and superior mesenteric veins and carries most of the gastrointestinal blood flow to liver for metabolism of absorbed nutrients. It also supplies about half of the oxygen demand of liver, while remaining half is supplied by hepatic arteries. Branches of portal vein and hepatic artery are present in portal triad along with bile ducts, from where they traverse through limiting plates to enter venous sinusoids surrounding hepatocytes and drain into central hepatic vein. Liver does not have a capillary system (but sinusoids).

Physiologically liver plays a vital role in—(a) synthesis, storage and metabolism of various nutrients, (b) detoxification of metabolites, drugs and hormones and (c) excretion of certain substances in gut **(Table 15.1)**. Liver is also a major site for hematopoiesis in fetal life.

Laboratory evaluation in liver disease aims to confirm the diagnosis of liver disease as well as to assess its course. Important components of hepatic evaluation include:

TABLE 15.1: Physiological functions of liver

- **Bilirubin metabolism** (conjugation/excretion)
- **Carbohydrate metabolism**
  - Glycogen storage (Glucose > Glycogen)
  - Lipogenesis (Glucose > Lipids)
  - Neoglucogenesis (Amino acids > Glucose)
  - Glycogenolysis (Glycogen > Glucose)
- **Protein metabolism**
  - Protein synthesis (Amino acids > Proteins)*
  - De-amination (Amino acids > Ammonia > Urea)
- **Lipid metabolism**
  - Formation and utilization of fatty acids
  - Synthesis and esterification of cholesterol
  - Synthesis of phospholipids and triglycerides
  - Formation and conjugation of bile salts
- **Hormone metabolism**
  - Detoxification of steroids
  - Degradation of enzymatic proteins
- **Drug metabolism and excretion**
- **Reticulo-endothelial function**
  - Phagocytosis via Kuppfer cells
  - Immunoglobulin synthesis

*e.g. albumin, clotting factors, transport-proteins, etc.

a. **Imaging procedures** for evaluation of anatomical lesions and excretory function:

- *Ultrasonography* is a baseline investigation for evaluation of hepatic size, focal lesions, e.g. abscesses, portal hypertension and biliary tract abnormalities. CT/MRI is more useful to delineate small focal lesions and tumors. MR cholangiography is valuable in assessment of pancreatico-biliary disorders.
- *Radionucleotide liver scan* is used for diagnosis of focal lesions (Tc^{99} sulfur colloid scan) or assessment of excretory functions (Tc^{99m} iminodiacetic acid-IMIDA scan).
- *Other* imaging procedures, e.g. angiography, and endoscopic retrograde cholangiography (ERCP) are used in selected cases.

b. **Liver function tests (LFTs):** As the liver has large functional reserve, biochemical abnormalities usually

precede clinical manifestations. Important liver function tests include:

- *Tests for metabolic or synthetic dysfunction*
  - Serum bilirubin (unconjugated fraction)
  - Prothrombin time and INR*
  - Serum proteins, specially albumin.
  - Serum ammonia (in acute cases)
- *Tests for hepatocellular injury***
  - Serum aspartate aminotransaminase (AST/SGOT)
  - Serum alanine aminotransferase (ALT/SGPT)
- *Tests for cholestasis*
  - Serum alkaline phosphatise (ALP)
  - Serum gamma-glutamyl transpeptidase (GGT)***
  - Serum bilirubin (conjugated fraction)
- *Tests for immune dysfunction*
  - Altered gammaglobulin levels
  - Presence of antinuclear antibodies

*INR (International Normalized ratio) is the ratio of patient's prothrombtin time compared to control value, raised to the power international sensitivity index.

**AST and ALT are intracellular enzymes, released on cellular injury. ALT is mainly present in liver cells, while AST is also present in muscles and some other tissues. Hence, elevated ALT is more reliable indicator of hepatocellular injury than AST.

***GGT is more reliable indicator of cholestatic disease than ALP, which is also high in growing children due to bone isoenzyme fraction. GGT is normally high in newborns and infants < 6–9 months.

c. **Liver biopsy** is *indicated* in—(a) chronic liver disease or cirrhosis, (b) suspected metabolic or infiltrative disease, (c) unexplained, persistent icterus or abnormal liver function tests. However, it is *contraindicated* in—(i) acute liver failure, (ii) bleeding disorders, (iii) congestive hepatomegaly or vascular malformations of liver, and iv) suspected hydatid disease. Normal prothrombin time is an essential prerequisite for liver biopsy. (Ch 32.6)

15.2 HEPATOMEGALY

Liver is normally palpable up to 2 cm in first two years of life, though *Riedel lobe* may be palpable even in older children. A palpable liver does not necessarily mean hepatomegaly and may be *pushed-down* by thoracic pathology, e.g. pneumothorax *or visceroptosis* in cases of ligamental laxity, e.g. rickets. Hence, it is always preferable to record *liver span* by localizing the upper border (by percussion) and lower border (by palpation).

Normal liver span is ~5 cm in newborns and ~7 cm in older children. A liver span of >8 cm in childhood is abnormal.

Etiology: Hepatomegaly may be-(a) infective, (b) metabolic, (c) hematologic, (d) infiltrative, or (e) congestive in origin, apart from rare congenital malformations **(Table 15.2)**.

TABLE 15.2: Cause of hepatomegaly

- **Infective Hepatomegaly**
  - *Viral:* Hepatitis A–E, HIV, EBV
  - *Bacteria:* Typhoid, sepsis, abscess, tuberculosis
  - *Spirochetal:* Leptospirosis
  - *Protozoa:* Amoebic hepatitis
  - *Parasitic:* Malaria, kala-azar
  - Intrauterine infections
- **Autoimmune hepatitis**
- **Congestive hepatomegaly**
  - *Cardiac:* CCF, pericarditis
  - *Pre-cardiac:* Budd-Chiari syndrome
- **Compensatory hepatomegaly (↑ erythropoiesis)**
  - Hemolytic anemia
  - Nutritional anemia
- **Metabolic/storage disorders**
  - *Carbohydrates:* Glycogen storage disorders
  - *Fat:* Gaucher/Niemann-Pick disease
  - *Mineral:* Indian childhood cirrhosis, Wilson disease
  - *Protein:* Tyrosinemia, Reye syndrome
- **Cholestatic syndromes**
- **Infiltrative hepatomegaly**
  - Leukemia, lymphoma
  - Hepatic tumors (primary/metastatic)
  - Histiocytosis
- **Congenital cysts, malformations and CHF**
- **Miscellaneous**
  - Physiological (<2 years)
  - *Displaced liver:* Visceroptosis, pneumothorax
  - Drug-induced Hepatitis

CHF: Congenital hepatic fibrosis

D/D between various causes of hepatomegaly **(Table 15.3)** depends on:

- *Characteristics*, e.g. (i) size, (ii) consistency, (iii) surface, (iv) margins, (v) tenderness, and (vi) vascularity, e.g. bruit or pulsations
- *Age:* Hepatomegaly in newborns and young infants usually indicate intrauterine infections, septicemia, cholestatic syndromes and metabolic disorders, while hemolytic anemia and congestive hepatomegaly is more common in older infants and toddlers. Viral hepatitis and other infective causes predominate in school children.
- *Co-existing splenomegaly* usually indicates portal hypertension, hemolytic anemia, chronic infections, metabolic disorders or infiltrative disorders, e.g. leukemia. Isolated hepatomegaly is mainly infective (viral hepatitis, abscess) or congestive in origin (cardiac failure).
- *Associated findings*, e.g. jaundice (viral hepatitis), pallor (hemolytic anemia, leukemia), lymphadenopathy (malignancy), ascites (chronic liver disease), etc. provide vital diagnostic clues in hepatomegaly.

TABLE 15.3: D/D Broad causes of hepatomegaly

	Infective	*Metabolic*	*Hematological*	*Congestive*	*Infiltrative*

15.3 JAUNDICE

Jaundice (Icterus) is a clinical diagnosis with *yellowish discoloration of sclera, mucus membranes and skin*, due to elevated serum bilirubin levels. Normal serum bilirubin levels are 0.3 –0.8 mg/dl with predominant unconjugated fraction (unconjugated:conjugated ratio > 8:1). However, icterus is clinically visible, only when serum bilirubin levels exceeds 2.0 mg/dl.

Normal bilirubin metabolism and neonatal jaundice is discussed in Chapter 12.13. Present section mainly pertains to post-neonatal jaundice.

Etiology: Common causes of post-neonatal jaundice may be divided into—(a) *hemolytic jaundice* due to increased bilirubin production, (b) *hepatic jaundice* due to impaired bilirubin metabolism, and (c) *obstructive* or *cholestatic jaundice* due to inadequate bilirubin excretion **(Table 15.4)**.

Diagnostic evaluation: Clinical differentiation between three broad groups—hemolytic, hepatic and obstructive jaundice, is the first step in evaluation of jaundice **(Table 15.5)**, followed by relevant laboratory studies for specific etiology. Important diagnostic clues include:

- *Course:* Hepatitis A is the commonest cause of short duration, self-limiting icterus (<2–3 weeks) in Indian children, while prolonged icterus indicates chronic liver disease or congenital hemolytic anemia. Recurrent jaundice is common in chronic liver diseases or choledochal cysts.
- *Relevant history* related to adverse environmental factors (infective hepatitis), similar family history (hemolytic anemia, metabolic disorders) or previous treatment (drug-induced).

TABLE 15.4: Causes of jaundice (Post-neonatal)

Hemolytic jaundice
- *Congenital:* Hereditary spherocytosis, thalassemia
- *Drug/toxins:* Quinine (in G6PD deficiency)
- *Acquired:* Malaria, polycythemia, transfusions
- *Micro-angiopathic:* Hemolytic-uremic syndrome

Hepatic jaundice
- *Infective:* Viral hepatitis, leptospirosis, malaria,
- *Drug/toxins:* Isoniazid, rifampicin, valproate
- *Chronic liver disease:* Chronic active hepatitis, cirrhosis
- *Metabolic:* Wilson disease
- *Familial:* Crigler-Najjar syndrome, Gilbert syndrome

Obstructive jaundice
- Neonatal hepatitis
- Intrahepatic biliary atresia
- *Extrahepatic causes:*
  - Biliary tree-extrahepatic biliary atresia
  - Gallbladder-gallstones, choledochal cyst
  - Porta hepatis-tubercular nodes, portal fibrosis
  - Ampulla of Vater-worms, pyloric stenosis
- *Inherited:* Dubin-Johnson/Rotor syndrome*

*Conjugated jaundice, but not due to obstructive etiology

- *Itching and clay-colored stools* strongly indicate obstructive jaundice, though these features are not uncommon in recover phase of infective hepatitis.
- *Coexisting splenomegaly* with pallor indicates hemolysis—congenital or acquired (malaria, sepsis).
- *Signs of metabolic liver dysfunction*, e.g. edema, ascites, steatorrhea, etc. indicates hepatic jaundice.
- *Liver function tests* differentiate between hemolytic, hepatic and obstructive jaundice, though further investigations are needed to pinpoint exact etiology.

TABLE 15.5: D/D Broad types of jaundice

Features	*Hemolytic*	*Hepatic*	*Obstructive*
Age of onset	Infancy[1]	Any age[4]	Infancy[7]
Duration of icterus	Persistent[2]	Acute[5]	Acute, recurrent[8]
Family history	Present	Absent[6]	Absent[9]
Past history	Drugs[3], Transfusions	Viral infections	Drugs, Hemolytic anemia[10]
Itching	Absent	±	Marked
Stool color	Normal	Normal	Clay colored
Urine color	Normal	Dark	Dark
Splenomegaly	Marked[1]	± Mild	± Mild
Anemia	Marked	±	±
Serum bilirubin	Unconjugated	Mixed	Conjugated
SGOT/PT	Normal	Elevated	Normal
SGGT	Normal	Normal/Elevated	Elevated
Serum alkaline PO_4	Normal	Normal/Elevated	Elevated
Urine urobilinogen	++	+	Absent

[1] except G6PD deficiency, [2] or recurrent (G6PD def./sickle cell disease), [3] in G6PD deficiency, [4] HAV after 3–5 years, Wilson disease after 5 years, [5] persistent in chronic liver disease, [6] present in Wilson disease and other metabolic causes, [7] or in late childhood (gallstones), [8] recurrent in choledochal cyst, gallstones, [9] except in hemolytic gallstones, [10] due to gallstones

15.4 VIRAL HEPATITIS

Acute hepatitis is a clinical syndrome of heterogeneous etiology **(Table 15.6)**, characterized by abrupt onset of clinical jaundice and/or laboratory evidence of hepatic dysfunction, e.g. elevation of bilirubin and liver enzymes. Most of these cases are due to infection by hepatotropic viruses, discussed in this chapter.

Viral hepatitis refers to *primary infection of the liver due to heterogeneous group of specific hepatotropic viruses, designated as A-G*. Hepatitis due to other viruses, e.g. CMV, HSV, EBV, etc. is generally excluded from this terminology.

While liver pathology in all hepatotropic viral infections is nearly similar during acute stage (centrilolobular necrosis and periportal infiltration without destruction of normal architecture); route of infection, severity/duration of disease and later course differs significantly **(Table 15.7)**.

TABLE 15.6: Common causes of acute hepatitis

- **Infective:**
  - *Hepatotropic viruses:* HAV, HBV, HCV, HEV
  - *Other viruses:* CMV, EBV, dengue
  - *Bacterial:* Septicemia, enteric fever, leptospirosis
  - *Others:* Amoebiasis, malaria, brucellosis
- **Drugs and Toxins:**
  - *Drug-induced:* INH, Rifampicin, Valproate
  - *Poisoning:* Paracetamol, pesticides
- **Metabolic:**
  - Reye syndrome
  - *Others:* Wilson disease*
- **Others:**
  - Autoimmune hepatitis*
  - Budd-Chiari syndrome
  - Acute cholestatic syndromes

*Acute manifestation of chronic disease

Hepatitis A (HAV) is the commonest cause of viral hepatitis in children, though clinical disease is mild, self-limiting and generally benign. Complications, e.g. acute liver failure or chronic liver disease are extremely rare.

Epidemiology: HAV is excreted in stools of a clinical or subclinical case and transmitted via *feco-oral route* by ingestion of contaminated water/food.

High-risk factors: Focal outbreaks are common in summer and rainy season, specially in unsanitary slums with contaminated water supply. Though no age is immune, HAV is rare <2 years due to less risk of exposure, with highest risk in school-children.

Clinical manifestations: Incubation period varies from 15 to 45 days. HAV infection is relatively mild in children than in adults and presents as anicteric or icteric disease.

Anicteric hepatitis accounts for >80% of HAV infections, presenting as low-grade fever, vomiting, diarrhea, mild tender hepatomegaly and borderline liver function tests abnormalities for 1–2 weeks.

Icteric hepatitis indicates more severe hepatic injury, with appearance of jaundice after few days of prodromal symptoms and more moderate hepatomegaly. Symptoms tend to improve once the jaundice sets in, which lasts for 2–3 weeks. Mild pruritis is common, specially in recovery phase.

TABLE 15.7: Common hepatotropic viral infections

Feature	*HAV*	*HBV*	*HCV*	*HEV*
Incubation (days)	15–50	50–150	15–180	20–60
Agent (virus)	RNA	DNA	RNA	RNA
Route of infection	Ent	Pnt/Prnt	Prnt	Ent
Extra-hepatic signs	Nil	+	+	Nil
Complications	Rare	Common	Common	Rare
Treatment	NS	NTdA	DAAs	NS

Ent: Enteral; **Prnt:** Pareteral; **Pnt:** Perinatal; **NS:** Non-specific; **NTdA:** Nucleos(t)ide analogues; **DAA:** Direct acting antivirals

Diagnosis may be confirmed by presence of anti-HAV IgM antibodies in second week. Elevated anti-HAV IgG has no diagnostic value for acute disease, merely indicating past infection or vaccination.

Liver function tests are indicated as base-line parameter, though serial testing is unnecessary in clinically improving case. Serum alkaline phosphatase may be elevated in recovery phase due to transient cholestasis.

Presence of bile salts and pigments in urine is a simple screening method in hepatitis**,** tested by *Hay's sulfur test* and *Fouchet test* respectively (Ch 21.2).

D/D includes other causes of acute hepatitis **(Table 15.6)**, closest being HEV and drug-induced hepatitis.

Treatment: HAV hepatitis is self-limiting, without specific therapy except nutritious high carbohydrate diet and avoidance of excessive fat. Complications, e.g. fulminant hepatic failure are extremely rare, except in cases with pre-existing liver disease (<1%). Some cases may develop prolonged *cholestasis* waxing and waning course but with eventually complete recovery.

Prevention of HAV depends on:

- *Public health measures*, i.e. improvement of sanitation and potable water supply. Patients are contagious from 2 weeks before to about a week after the onset of jaundice.
- *Personal protection*, i.e. use of boiled or UV exposed water, specially during epidemics,
- *Active immunization* with either two doses of inactivated HAV vaccine in second year of life at 6–18 months interval *or* a single dose of Live HAV vaccine at 12 months of age. While not yet included in National Immunization schedule, IAP recommends HAV immunization to *all* children, specially those with—(a) chronic liver disease, or (b) institutionalized care, e.g. orphanages.

  Catch-up immunization is recommended till 10 years, while pre-vaccination screening for HAV antibodies is advised before vaccination in older children (>10 years) due to substantial chance of natural infection and immunity by this age.
- *Post-exposure prophylaxis* is indicated in household contacts within 10 days of exposure, preferably with initiation of HAV vaccination. Immunoglobulins (IM 0.02–0.06 ml/Kg) may be used in infants or immunocompromised children.

Hepatitis B (HBV), though less common than HAV, is an important health problem due to higher risk of late complications, e.g. chronic liver disease, cirrhosis and hepatocellular carcinoma. India is in the intermediate risk zone of HBV prevalence, with chronic carrier rate of ~3–4%.

Epidemiology: HBV, also referred as *Dane particle*, is a DNA virus containing many antigens, most important being a surface antigen (*HbsAg*), a core antigen (*HbcAg*) and a non-structural antigen (*HbeAg*).

Persons with chronic HBV infection are primary reservoir of infection. Children are usually infected from mothers (*perinatal/vertical transmission*), though *horizontal transmission* via parenteral route, i.e. transfusions, accidental needle pricks, drug abuse *or* sexual contact is not uncommon.

Risk of perinatal transmission is highest when mother is both HbsAg and HbeAg positive (70–90%), than in HbeAg negative mothers (25%), if HB vaccine with/without immunoglobulins (HBIG) is not given within 24 hours.

Clinical spectrum: Perinatal HBV infections are generally asymptomatic in childhood, despite potential risk for future liver disease. A symptomatic case presents after an incubation period of 50–180 days, with:

- *Non-specific prodrome*, e.g. lethargy, anorexia and malaise
- *Icterus* in <25% cases, lasting for ~ 4 weeks,
- *Extra-hepatic manifestations* of probable immune etiology, e.g. arthralgia/arthritis, rash or papular acrodermatitis (*Gianotti-Crosti syndrome*), glomerulonephritis and aplastic anemia, for 2–3 weeks.

Unless complicated by fulminant liver failure, acute episode lasts for 4–6 weeks.

Complications: HBV infection is associated with considerable early and late morbidity, including (a) acute fulminant liver failure in 30%, (b) chronic liver disease, including cirrhosis in 40% and (c) hepatocellular carcinoma in <5–10%. Except acute liver failure, other complications may develop even in asymptomatic cases or carriers.

Infections acquired before 5 years of age are more likely to become chronic carriers-defined as HbsAg positivity beyond 6 months. Risk of chronic carrier state after HBV infection is >90% in perinatally infection *versus* 5% in adults infections.

Diagnosis is serological and various markers are used to define chronicity and infectivity of the infection **(Fig. 15.1)**.

HBsAg is the first serological marker to appear after infection, present in almost all infected children. Clinical significance of other seromarkers includes:

- Persistence of HBsAg indicates a carrier state or chronic infection, while its disappearance within 3–6 months indicates resolution of infection.
- Presence of HBeAg indicates high infectivity and HBeAg positive mothers are more likely to transfer infection to their baby.
- Anti-HBcAg is the most useful marker to differentiate HBV immunized *vs* infected children. While anti-HBsAg is present in both, anti-HBcAg is positive only in natural infection.
- Presence of anti HBeAg antibodies indicates lesser risk of infectivity.

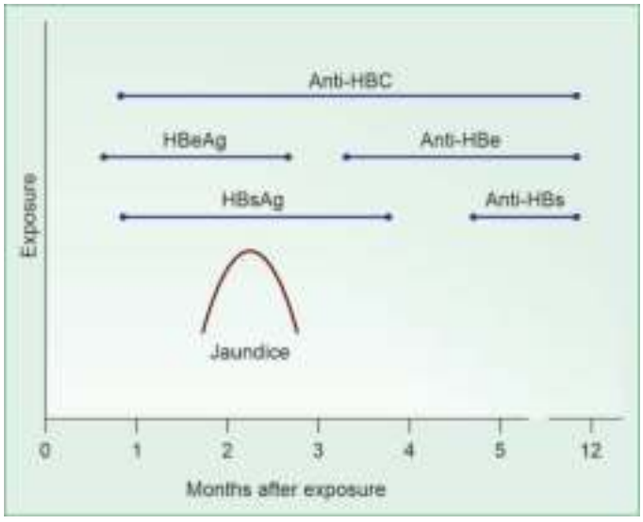

Fig. 15.1: **Natural course and sero-markers in HBV infection.**

Treatment of *acute HBV infection* is entirely supportive, including monitoring for acute hepatic failure. For treatment of chronic HBV infection, *see* Ch 15.8.

Prevention of HBV revolves around pre-and post-exposure immunization as well as strict screening of transfusion products.

- ***Infants born to HbsAg positive mothers*** should receive HB vaccine as well as HBIG (0.5 ml each, at different sites) as early as possible, preferably within 12 hours of birth, followed by HB vaccine after 1 and 6 months (or three doses as in NIS/IAP schedule). Efficacy of perinatal HBV prophylaxis is 90–95%.

  However, all children should be re-screened after 1 year for HBsAg as well as anti-HbsAg. While presence of anti-HbsAg indicates that the baby is immune, *HbsAg positivity without anti-HbsAg indicates infection without immunity and probability of progressive liver disease.* Re-vaccination is needed if both markers are negative. Breastfeeding by HBsAg positive mother, unless she is also HbeAg positive, does not increase the risk of transmission.
- ***Routine immunization*** with four doses are given in national immunization schedule at birth as stand-alone vaccine and 6, 10 and 14 weeks as pentavalent vaccine. HB vaccine is specially indicated in children with hemolytic anemia or haemophilia on multiple transfusions. Catch-up immunization in older unimmunized children or adults is indicated with three-dose 0,1, 6 months schedule.

Hepatitis C (HCV) is an emerging transfusion-related infection, which has already infected ~ 3% of world population. Exact incidence in India is not known due to limited diagnostic facilities, though HCV screening for all blood products is compulsory here since 1998.

Epidemiology: HCV infection in children is almost always transmitted via infected blood transfusion. Perinatal risk of transmission from viremic mothers is only ~ 5%.

Clinical spectrum is milder than HBV disease. Most cases are asymptomatic in early stage and clinical jaundice is seen in <25%. However, 20–50% cases progress to develop chronic liver disease, cirrhosis and hepatocellular carcinoma after many years. Chronic infection may also be associated with small vessel vasculitis and extrahepatic manifestations in adults.

Diagnosis of acute HCV disease is possible with HCV-PCR (RNA) assay after 2 months of age/exposure while serological tests turn positive only after 3–4 months of clinical illness. HCV-RNA should be repeated at ~3 years of age in children with positive serological tests to confirm chronicity of infection.

Treatment aims to clear viremia, improve liver histology and reduce the risk of chronic liver disease. Genotyping of virus is important before therapy as response may vary.

All children >3 years of age with HCV, irrespective of the genotype, must be treated with a fixed-dose combination of directly acting antivirals (DAA) including Sofosbuvir with Velpatasvir, for 12 weeks. Other DAAs or interferon/pegylated interferon therapy may be used in children with selected genotypes, including combination therapy in non-responders.

Sequential estimation of HCV-RNA is essential to monitor the therapeutic response.

Prevention: No vaccine is available against HCV and screening of donor blood remains the most effective preventive intervention.

Hepatitis D (HDV) is considered a defective RNA virus, which depends entirely on HBV for its replication. HDV infection may be either a co-infection with HBV or a super-infection, leading to acute exacerbation of chronic HBV infection. Chronic liver disease is more common, when both infection co-exist. HDV has not been isolated and diagnosis depends on detecting specific IgM antibodies.

Hepatitis E (HEV), like HAV, is a fecooral infection through contaminated water, more common in adults than children. Clinical presentation is limited to acute liver disease, which is more severe in adults, specially pregnant women. Pediatric infections are usually mild and sub-clinical. Chronic sequelae are unknown. Diagnosis rests on presence of anti-HEV IgM antibodies and treatment is symptomatic.

Hepatitis G (HGV): Advances in the molecular technology lead to identification of two newer hepatic viruses-hepatitis GB virus (HGBV-C) and hepatitis G virus (HGV). Present evidence suggests that both of them are close variants of same species, transmitted through blood transfusions or organ transplants. No serological test is presently available for diagnosis and clinical spectrum or management is yet to be defined.

15.5 ACUTE HEPATIC FAILURE

Acute hepatic failure (AHF) is a life-threatening event, characterized by *rapidly progressive hepatocellular dysfunction and multisystemic manifestations*, e.g. *encephalopathy, coagulopathy, hemodynamic disturbances and dyselectrolytemia*.

While acute liver failure may also develop in cases with pre-existing chronic liver disease, AHF is usually defined as:

- Biochemical evidence of liver dysfunction for < 8 weeks duration,
- Coagulopathy with INR >1.5 in patients with encephalopathy or >2.0 in those without encephalopathy, not corrected by vitamin K, and
- No evidence of chronic liver disease.

Depending on the onset and course, liver failure is classified as *fulminant* (<1 week), *acute* (1–4 weeks), *subacute* (4 weeks to 6 months) and *chronic* (>6 months).

Etiology: AHF in children is usually infective, toxic or metabolic in origin **(Table 15.8)**. Viral hepatitis, autoimmune hepatitis and metabolic disorders, e.g. Wilson disease are predominant causes of AHF in children. However, 30–40% cases are idiopathic.

Cases with pre-existing liver disease may also develop AHF due to superimposed insult lie viral, toxic or drug-induced hepatic injury.

Pathologically, AHF is characterized by massive necrosis of hepatocytes, loss of normal hepatic architecture and occasionally cholestasis, apart from features of primary disease.

Pathogenesis: Sudden and severe impairment in metabolic and excretory liver functions is the hallmark of AHF. Gastrointestinal bleeding, hypoglycemia, hypokalemia, drug therapy, abdominal paracentesis and high protein meal are common *precipitating factors* for AHF in cases with pre-existing liver disease.

TABLE 15.8: Important causes of AHF in Indian children

- **Infective (60–90%)**
  - *Viral hepatitis:* HAV, HEV, HBV, others.
  - Leptospirosis
  - Fulminant bacterial septicemia
- **Drug and toxins: (6–8%)**
  - *Drugs:* INH, rifampicin, Na valproate, anesthetics
  - *Poisoning:* Paracetamol, heavy metals
- **Metabolic**
  - Reye syndrome
  - Wilson disease
  - *Inborn errors:* Galactosemia, tyrosinemia
  - Indian childhood cirrhosis
- **Ischemic/hypoxic**
  - Circulatory shock
  - *Vascular obstruction:* Budd-Chiari syndrome
- **Malignancies** *(primary/metastatic)*

EBV: Epstein-Barr virus, **CMV:** Cytomegalovirus

Hyperammonemia due to impaired detoxification of ammonia into urea is the most important cause of hepatic encephalopathy, characterized by severe cerebral edema and intracranial hypertension.

Clinically important features of AHF include:

- *Encephalopathy* of variable severity-subtle mental changes, e.g. altered personality and abnormal sleep pattern, are earliest indicators of hepatic encephalopathy, which may rapidly progress to coma **(Table 15.9)**. However, presence of encephalopathy is not essential for diagnosis of AHF in children.
- *Progressive deep jaundice*, though highly suggestive, is also not essential, as many cases succumb before the appearance of jaundice.
- *Other signs of hepatic damage* include: (i) *fetor hepaticus*, i.e. ammonical breath odor and intractable vomiting due to hyperammonemia, (ii) bleeding tendency due to deficiencies of vitamin K dependent clotting factors, (iii) dyselectrolytemia with metabolic acidosis, (iv) ascites due to hypoproteinemia, and (v) diarrhea due to fat malabsorption
- *Hepatomegaly* may or may not be present. *Absence of hepatomegaly or rapid reduction in liver size is a bad prognostic indicator in AHF.*
- *Secondary complications* are common, e.g. fulminant infections due to impaired immunity, renal failure (acute tubular necrosis), pulmonary complications (aspiration, pulmonary edema), etc.

Laboratory investigations are needed to identify the cause as well as to monitoring progression of liver damage and include:

- *Hematological*:
  - CBC (leukocytosis, thrombocytopenia)
  - Coagulation profile, e.g. prothrombin time

TABLE 15.9: Stages of hepatic encephalopathy

Stage	*Findings*
I	• Alternate spells of lethargy and euphoria • Reversal of day-night cycle • Asterixis, i.e. flapping tremors • No EEG changes
II	• Drowsiness, confusion or agitation • Wide mood swings • Fetor hepaticus • *EEG:* Gen. slowing (with θ waves)
III	• Stupor, confused • Absent or Incoherent speech • Rigidity, hyperreflexia, extensor plantars • *EEG:* Marked abnormality (triphasic waves)
IV	• Deep coma • Decerebrate/decorticate posturing • Areflexia and flaccidity • *Response to pain:* Present **(IVA)** absent **(IVB)** • *EEG:* B/L slowing, Delta waves, EEG silence

- *Biochemical:*
  - LFT, e.g. serum bilirubin, AST/ALT, GGT/ALP
  - Serum ammonia (elevated in encephalopathy)
  - Serum proteins (reduced with altered A:G ratio)
  - Serum electrolytes, e.g. Na^+, K^+, HCO_3^-, Ca^{++}
  - Blood glucose (hypoglycemia)
  - Blood gas analysis (metabolic acidosis)
- *Microbiological*: Cultures, viral serology
- *EEG* to confirm/monitor encephalopathy
- Specific etiological investigations

Management of AHF is non-specific and aims to provide life support and prevent/treat complications till spontaneous recovery. All patients need intensive care and monitoring. Important measures include:

- ***Stabilization*** of hemodynamic status with fluid therapy, volume expanders, e.g. plasma, and vasopressor agents.
- ***Continuous monitoring*** for—(a) vital signs, (b) intake/output, (c) neurological assessment, (d) biochemical parameters, e.g. electrolytes, blood gases, blood sugar, PT/INR, LFT, (e) urine output and renal functions, and (f) sepsis.
- ***Gut sterilization*** to reduce ammonia production, produced due to breakdown of food-proteins or blood, by ammonia-producing microbial flora. Important measure to prevent it include:
  - PO Rifaximin (20–30 mg/kg/day) or Neomycin to eliminate ammonia-producing organisms
  - PO Lactulose (10–50 ml 4 hourly) to produce acidic media and reduces activity of organisms, dose must be adjusted to produce 2–4 loose motions per day.
- ***Fluid/electrolyte therapy*** is guided by intake-output record, central venous pressure monitoring and electrolyte estimation. Generally, N/2 saline in DW 10% with 15 mEq/l of potassium is used to provide 90% of total maintenance fluid requirements. However, volume and composition of IV fluids needs to be modified according to electrolyte status, specially to keep sodium levels between 145–155 mEq/l. *Hypoglycemia, hypokalemia and metabolic acidosis are very common* and need to be treated promptly.
- ***Cerebral edema*** is the major cause of mortality and needs to be treated promptly by IV Mannitol (0.5–1 g/kg/dose) or hypertonic saline, and controlled ventilation to prevent CO_2 retention. *Steroids are contraindicated*. There is some evidence that early encephalopathy may be reversed by a benzodiazepine antagonist – *Flumazenil.*
- ***Coagulopathies*** must be treated with fresh frozen plasma, platelets and IV vitamin K supplements (5–10 mg/day). Blood transfusion should be avoided, if possible. Cryoprecipitate may be used in low-fibrinogen states (<100 mg/dl). Plasmapheresis is useful to eliminate anticoagulant and fibrinolytic products, produced during hepatic injury.
- ***Esophageal variceal bleeding*** may require endoscopic sclerotherapy or ligation in emergency, though IV Octreotide (1–10 µg/kg 12 hourly) may be useful, if endoscopy is not possible. Antacids or proton pump inhibitors may also benefit in GIT bleeding.
- ***Treatment of other complications***, e.g. ascites, renal failure (dialysis) and infections. Empirical antibiotic therapy, though controversial, is preferable in all cases, which must be modified after cultures. *N-acetyl cysteine*-A glutathione precursor (IV infusion 100 mg/kg/d) may or may not be useful even in non-acetaminophen induced AHF, due to anti-inflammatory, antioxidant, inotropic, and vasodilating effects.
- ***Removal of toxic metabolites*** by activated charcoal, plasmapheresis or exchange transfusion may be attempted in non-responsive cases.
- ***Liver transplantation***, is the final option in refractory cases, with success rate of 60–80%.

Prognosis: Overall mortality in AHF is very high (70%), but still better in children than in adults. Bad prognostic factors include—(a) rapid onset of encephalopathy within 7 days of icterus, (b) prothrombin time >50 seconds, (c) serum bilirubin >17.5 mg/dl, (d) stage IV coma, and (e) multi-organ failure.

15.6 LIVER ABSCESS

Pyogenic liver abscesses are not uncommon in children, Solitary liver abscesses in the right lobe are more common than multiple abscesses or solitary left lobe abscesses.

Etiologically, liver abscesses usually develop as a part of generalized sepsis, as ascending infection from gastrointestinal disease or localized lesions after intra-abdominal infection, trauma or surgery.

Most common pathogenic organisms include *Staphylococcus aureus, Streptococcus* spp., *Escherichia coli, Salmonella,* and anaerobic organisms. *Entamoeba histolytica* is an important cause of liver abscess in India, though more common in adults.

Clinically these children present with fever, chills, vomiting and abdominal pain in right hypochondrium with tender hepatomegaly. Jaundice is uncommon.

Complications include spontaneous rupture in peritoneum, pericardium or pleural space or metastatic abscesses at other sites.

Diagnosis rests on USG/CT followed by guided percutaneous aspiration to confirm the microbial etiology **(Fig. 15.2)**. Presence of elevated right hemidiaphragm with leukocytosis indicates possibility of liver abscess in a clinically suspected case.

Treatment: Drainage and appropriate antibiotics are mainstays of treatment in liver abscess.

Initial antibiotic regimen should be directed against gram-positive aerobes, gram-negative bacilli, and

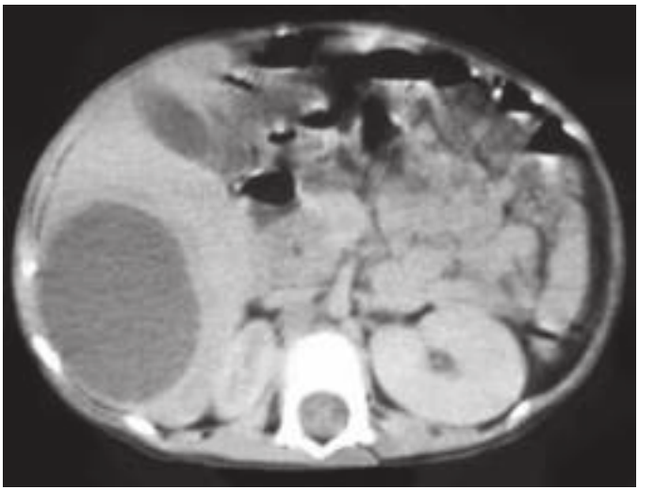

Fig. 15.2: **Liver abscess.**

anaerobic organisms with subsequent modification according to culture reports for a total duration of 4–6 weeks. Serial USG may be required to assess the response to therapy.

Percutaneous drainage is indicated where lesions are accessible under CT or ultrasound guidance. Catheters placed via these techniques are generally left in place until abscess collapse (*pig tail*). Open surgical drainage may be required if percutaneous drainage is not feasible or fails.

15.7 CHRONIC LIVER DISEASE

Chronic liver disease (CLD) denotes *persistent hepatic dysfunction for >6 months*, with or without clinical symptoms, often culminating into irreversible or end-stage hepatic disease.

Etiology: HBV is the commonest cause of CLD in Indian children, followed by cholestatic syndromes and autoimmune liver disease **(Table 15.10)**.

Pathologically, CLD may be classified as:

- *Chronic persistent hepatitis*, without jaundice and with mild/moderate elevation of liver enzymes. Hepatocellular inflammation in these cases is limited within portal triads.
- *Chronic lobular hepatitis*, more moderate disease with mixed intra-portal as well as centri-lobular inflammation. Mild jaundice is common.
- *Chronic active hepatitis*, with intra-portal and lobular inflammation as well as destruction of normal liver architecture. Definite signs of CLD and portal hypertension are present and most survivors progress to cirrhosis.
- *Cirrhosis* is the end-stage, characterized by—(a) shrunken liver, (b) extensive fibrosis, (c) destroyed liver architecture and (d) nodule formation.

TABLE 15.10: Causes of chronic liver disease

- **Infective**
  - *Hepatotropic virus infections:* HBV, HCV
  - Intrauterine (TORCH) infections
- **Metabolic liver disease**
  - *Common:* Wilson disease, Gaucher disease, GSD
  - *Rare:* Cystic fibrosis, Indian childhood cirrhosis
  - *Others:* Galactosemia, α1-antitrypsin deficiency
- **Drug/toxic liver injury**
  - Veno-occlusive disease
  - *Drugs:* Methotrexate, INH, etc.
- **Autoimmune liver disease**
- **Neonatal cholestasic syndromes (Table 12.41)**

GSD: Glycogen storage disorders

Depending on the nodular size, cirrhosis is also termed (a) *micronodular*, e.g. Indian childhood cirrhosis, biliary cirrhosis, etc.; (b) *macronodular*, e.g. Wilson disease, post necrotic/hepatitic cirrhosis, etc. or (c) *mixed*, e.g. metabolic liver diseases, etc.

Clinical spectrum of CLD ranges from—(a) asymptomatic biochemical abnormalities, to (b) signs of progressive liver disease, or (c) signs of acute decompensation over pre-existing liver disease. Liver may or may not be palpable, depending on primary pathology. Important clinical features of CLD are tabulated in **Table 15.11**.

TABLE 15.11: Clinical indicators of chronic liver disease

Signs of impaired hepatic metabolism
- Icterus (s/o impaired bilirubin metabolism)
- Edema (s/o impaired protein metabolism)
- S/o fat malabsorption
  - Growth failure, steatorrhea, phrynoderma
- S/o Fat-soluble vitamin deficiency
  - Xerophthalmia (Vitanin A)
  - Rickets (Vitamin D)
  - *Bleeding:* epistaxis, GIT bleeds (Vitamin K)
- S/o impaired steroid metabolism
  - Spider nevi, palmar erythema, gynecomastia

S/o Portal hypertension
- Splenomegaly
- Ascites (also due to hypoproteinemia)
- *Others:* Esophageal varices, caput medussae

S/o Cholestasis
- Clay-colored stools
- Pruritis

S/o Primary disease
- *Autoimmune:* Arthropathy, hemolytic anemia, rash
- *Wilson disease:* KF ring, CNS signs

S/o Impending liver failure
- Altered behavior and sleep pattern
- Fetor hepaticus
- Flapping tremors

S/o: Signs of.

Laboratory investigations aim to assess and monitor the extent of liver damage as well as to identify the etiology and include:

- *To assess liver functions*:
  - Liver function tests
  - Coagulation profile
  - Radionuclide liver scan
  - Ultrasonography
  - Esophagoscopy for varices
- *To identify etiology*:
  - Liver biopsy
  - Serology, e.g. viral markers, autoantibodies
  - Selective tests for specific metabolic defects

Management of CLD includes specific therapy for primary cause, as well as supportive therapy to prevent and treat complications. Most cases can be managed at home after initial evaluation, though intermittent hospitalizations are often necessary to treat complications. Important supportive measures include:

- ***Nutritional management:*** *Diet* in CLD should provide 120–150% of caloric requirements with ~50% as carbohydrates, 25–30% as fats and rest as good-quality proteins. Medium chain triglycerides are preferred as fats, which do not require bile for absorption. Protein restriction (~1 gm/kg/d) is necessary only in cases with impending liver failure, while salt-restriction is advised in presence of ascites.

  All cases should be supplemented with fat-soluble vitamins-vitamin A (5000–10000IU/day), vitamin D (2000–5000 IU/day), vitamin K (2–5 mg/week) and vitamin E (15–25 IU/kg/day).
- ***Management of ascites:*** Ascites in CLD is contributed by portal hypertension as well as hypoproteinemia and must be managed by:
  - *Dietary sodium restriction* to maximum of 5 gm/day. Fluid restriction is unnecessary, except in hyponatremia.
  - *Diuretic therapy*, preferably with potassium-sparing *spirolactone* (PO 1–3 mg/kg/d). Loop diuretics or thiazides are used in severe cases.
  - *Abdominal paracentesis* is required in large ascites with respiratory embarrassment. Amount of tapped fluid at one sitting should not exceed 10–15% of body weight, to prevent hypovolemia. Simultaneous administration of albumin or plasma expanders is advisable in large-volume paracentesis.
- ***Management of bleeding*****:** Intermittent bleedings is common in CLD due to esophageal varices or vitamin K deficiency and should be managed according to the cause and severity, with blood transfusions, vitamin K therapy and endoscopic therapy, whenever indicated. (Ch 15.9).
- ***Management of hepatic failure*****:** All cases should be periodically monitored for impending liver failure and managed accordingly (Ch 15.5).
- ***Specific management*** includes use of penicillamine in Wilson disease, Entecavir or Sofosbuvir/Velpatasvir in HBV or HCV respectively and steroids in autoimmune hepatitis, discussed later in this chapter.
- ***Liver transplant*** is last resort in cases with poor response to above measures and repeated hospitalizations. However, it is *contraindicated* in—(a) multisystemic metabolic disorders, (b) metastatic malignancies, and (c) during acute hepatic failure. Outcome of liver transplant depends on primary disease, though overall 5-year survival is >50–60%. *Complications*, e.g. graft-rejection, opportunistic infections and reappearance of disease are common.

Outcome of CLD depends on primary etiology and extent of liver damage. Most cases of chronic persistent or lobular hepatitis recover spontaneously. Chronic active hepatitis has poorer prognosis with eventual development of cirrhosis and occasionally, secondary carcinoma. Many patients may also develop hepatorenal syndrome.

Hepatopulmonary syndrome is a triad of: (a) chronic liver disease or portal hypertension, (b) wide alveolar-arteriolar gradient with/out hypoxemia, and (c) intrapulmonary vascular dilatations. It presents with progressive hypoxia, cyanosis and clubbing, with echocardiography suggestive of intrapulmonary shunting. Liver transplant is required in all cases.

Some important causes of CLD are discussed here in greater details:

Chronic hepatitis B infection (HBV), defined as *persistence of HBsAg positivity for > 6 months*, is the one of the commonest causes of CLD in Indian children, accounting for >40% cases. About 3–7% of Indian population is HbsAg positive (carrier), of which ~35–40% are likely to develop CLD.

Three different phases have been described in natural course of HBV infection:

- *Immune tolerance phase* with active viral replication (high HBV-DNA levels in millions) but minimum liver damage (normal ALT). While HBsAg and HBeAg are positive, anti-HBeAg antibodies are absent.
- *Immune clearance phase* after many years with clearance of infection (reduced HBV-DNA levels) but progressive liver injury with/without symptoms (elevated ALT). Serology continues to be same with positive HBsAg and HBeAg and negative Anti-HBeAg antibodies.
- *Inactive carrier phase* with resolution of liver injury (normal ALT) and infection (very low HBV-DNA levels) as well as reversal of HBe serology, i.e. HBeAg negativity with presence of anti-HBeAg antibodies. Most of these cases remain HBsAG positive despite being asymptomatic carriers, before turning HBsAg negative after 15–20 years.

Diagnosis of chronic HBV infection depends on: (a) clinical evaluation with Liver function tests, (b) serology including quantitative HBV-DNA, and (c) liver biopsy in cases with elevated ALT levels, for staging of disease. All these cases should also be tested for HCV and HIV due to common mode of infection.

Management: As per recent guidelines, these cases are divided into two groups-those with *chronic HBV infection* (normal ALT) and those with *chronic HBV hepatitis* (raised ALT), second group needing liver biopsy.

All cases with chronic HBV Hepatitis having persistent elevation of liver enzymes and/or evidence of active disease on liver biopsy need treatment under expert guidance with:

- Subcutaneous interferon (5–10 million units/m^2 thrice weekly) in children < 2 years or Pegylated interferon- 2a/b in older children of 2–18 years, for 6–10 months to inhibit viral protein synthesis.
- Oral antivirals, e.g. Entecavir (0.5–1 mg/day) or Lamivudine (3 mg/kg/day) in children aged -2 years and Tenofovir (300 mg OD) or Adefovir (10 mg OD) in adolescents >12 years, for 1–8 months.

Both groups of drugs may be used concurrently or sequentially in different regimens. Treatment should continue till normalization of liver function tests, undetectable HBV-DNA or HBeAg and resolution of histopathology. Success rate is ~ 40–60%.

Autoimmune hepatitis (AIH) is responsible for ~10% cases of CLD in children, characterized by:

- Chronic hepatocellular inflammation on biopsy,
- Presence of liver-specific autoantibodies, and
- Co-existing autoimmune disorders, e.g. arthropathy, rash, hemolytic anemia, thyroiditis, etc.
- Response to immunosuppressive therapy

Etiology: Although autoimmune in origin, exact triggers are unknown, probably related to genetic predisposition or preceding viral/drug exposure.

Pathologically, liver biopsy reveals distorted hepatic architecture of variable severity, including—(a) inflammatory infiltrates, (b) piecemeal and bridging hepatic necrosis, (c) bile duct epithelial injury, and (d) interface hepatitis.

Clinically, AIH predominantly presents in young females with three different presentations:

a. *Acute hepatitis* like presentation in 3–0%, rapidly progressing to AHF;
b. Insidious-onset liver disease with waxing and waning course in another 3–0%
c. *Chronic liver disease* with complications, e.g. ascites and portal hypertension in 1–0%

Extrahepatic manifestations, e.g. arthritis, vasculitis, nephritis, Coombs-positive anemia, and rash are not uncommon.

Diagnosis rests on liver biopsy and serological studies. According to the type of autoantibodies, AIH is divided into type I in 6–0% (ANA/SMA antibody positive), type II in 2–0% (LKM1 antibody positive) and type III (SLA antibody positive, in young females). Hypergammaglobulinemia is common with IgG levels often exceeding 16 g/L. Other causes, e.g. viral hepatitis or Wilson disease must be excluded.

Treatment includes long-term immunosuppression with steroids and azathioprine. While >80% cases achieve remission with treatment, relapses are common after discontinuation of therapy.

Prednisolone is started as PO 1–2 mg/kg/day until serum ALT values normalize, followed by gradual tapering to a maintenance dose of 0.1–0.3 mg/kg/d till normal liver histology. In cases with poor response or side-effects, Azathioprine (PO 1.5–2.0 mg/kg/d) may be added. Mycophenolate, Tacrolimus and Rituximab are other options.

Wilson disease is a common disorder of copper metabolism (1:10000–00000 births), clinically characterised by a triad of—(a) *chronic liver disease*, (b) *neurological signs,* and (c) *kayser-Fleischer* (KF) *ring* over cornea.

Etiopathogenesis: It is an autosomal recessive disorder involving chromosome 13, with *basic defect in mobilization of copper from hepatocytic lysosomes* due to mutations in gene ATP7B.

In fetal life, high *metallothionein* (copper-binding protein in tissues) with low *ceruloplasmin* (copper-binding protein in plasma) activity facilitates deposition of copper in tissues. Normally, this pattern reverses to adult pattern of low-metallothionein/high-ceruloplasmin levels by 2 years of age. Failure of this switch-over in Wilson disease leads to accumulation of copper in hepatocytes and consequent destruction. Escaped copper from hepatic cells also leads to systemic copper deposition and toxicity in other tissues, e.g. brain, cornea, kidneys and joints.

Clinically, age and mode of presentation in Wilson disease usually follows a familial pattern. Most cases present between 5–10 years of age with:

- *Hepatic involvement*, as the earliest feature, presenting with hepatomegaly, jaundice, sub-acute hepatic failure and portal hypertension.
- *Neurological manifestations* usually after the first decade with intention tremors, dysarthria, dystonia, rigidity, chorea and behavioral changes. Preceding liver involvement is common but not mandatory.
- *Ocular manifestation*, i.e. development of a rusty-brown *Kayser-Fleischer ring* over cornea is usually present at the time of liver disease **(Fig. 15.3)**.
- *Systemic complications* due to involvement of other tissues are seen in long survivors, as Fanconi syndrome, hemolytic anemia, chronic arthropathy and endocrinopathies.

Diagnosis: *Low serum ceruloplasmin level (<20 mg/dl) is the best screening test for Wilson disease,* supported by elevated

Fig. 15.3: **Kayser-Fleischer ring in Wilson disease.**

urinary copper levels (>100 µg/day). Serum copper may be low, normal or elevated.

Diagnosis is conventionally confirmed by:

- Penicillamine challenge test, i.e. >5–10 fold rise in urinary copper excretion (>1000 µg/day) after two doses of d-penicillamine (PO 500 mg/dose at 12-hr interval),
- Increased copper content in dry liver tissue (>250 µg/gram of liver tissue).

However, combination of—(a) low serum ceruloplasmin, (b) presence of KF ring, and (c) elevated 24-hr urine copper may be used to confirm the diagnosis of Wilson's disease.

Penicillamine challenge test is not routinely recommended n due to high false-positivity and liver copper estimation is not easily available with quality issues. Uneven copper distribution in liver limits its usefulness. High liver copper may also be present in cholestatic liver disorders.

Family screening with serum ceruloplasmin and urinary copper levels is necessary.

Management revolves around the cop*per chelation therapy* by PO Penicillamine (20 mg/kg/day q12hr) to increase urinary excretion. Uncommon but significant toxicities of penicillamine include SLE, aplastic anemia and nephrosis.

In cases with penicillamine intolerance or toxicity, alternative copper chelator *Trientine* (Triethylenetetramine-2-dihydrochloride) may be used.

Zinc may be added to decrease gut copper absorption (PO 25 mg/kg/day q8hr).

Outcome: Early chelation therapy is most important determinant for outcome, which leads to complete resolution of liver histology and disappearance of KF ring. Untreated cases die due to AHF or renal/neurological complications. Chelation therapy is indicated even in asymptomatic siblings.

Indian childhood cirrhosis (ICC), was a unique disease limited to Indian subcontinent, extremely rare at present.

Epidemiology: ICC was almost exclusively seen in children aged 6 months-3 years, more common in males, top-fed children and certain communities—North-Indian banias and south-Indian Brahmins.

Etiopathogenesis yet remains uncertain, proposed to be infective, immunological, toxic, metabolic or nutritional injury to hepatocytes. Most acceptable one is the role of increased copper deposition in liver either due to altered metabolism or increased dietary intake due to cooking/water storage in copper/brass vessels.

Clinically ICC commonly presented as gradually progressive disease with 3 stages:

a. ***Pre-icteric stage*** (3–6 months), with abdominal distension, failure to thrive, anorexia, and altered behavior. Moderate hepatomegaly with *typical firm consistency, sharp-leafy margins and finely nodular surface* was pathognomonic..
b. ***Icteric stage*** with gradual increase in liver size, jaundice and portal hypertension with splenomegaly and ascites.
c. ***Terminal stage*** of liver failure with bleeding diathesis and encephalopathy.

Diagnosis rested onliver biopsy showing: (a) complete destruction of liver architecture with nodule formation, (b) diffuse creeping fibrosis without regeneration, (c) increased copper content on orcein staining, and (d) presence of *Mallory's hyaline bodies*—clumps of eosinophilic hyaline material, in 15–20%.

Management: ICC was almost always fatal, though very few cases have recovered spontaneously. Apart from supportive measures attempts were made to treat ICC with immunomodulatory drugs, e.g. steroids, or copper chelators, e.g. d-penicillamine, with equivocal results.

Non-alcoholic fatty liver disease (NAFLD) or steatohepatitis (NASH) is a common but benign cause of chronic liver disease, usually associated with obesity and insulin resistance.

NAFLD is a pathological diagnosis with macrovesicular steatosis, without inflammation or with inflammation, later termed as NASH.

Clinically, most children are obese and asymptomatic or present with vague abdominal pain and moderate hepatomegaly. Acanthosis nigricans (velvety brown-black pigmentation over nape of neck, axilla and skin folds) is common in 3–0% cases, often associated with hyperinsulinemia due to insulin resistance.

Diagnosis: Although radioimaging procedures can detect fatty liver, biopsy may be necessary in some

cases to exclude serious pathologies. Non-invasive measurements of fibrosis by transient elastography or acoustic radiation forced impulse may be useful to avoid biopsy. Liver enzymes may be elevated, along with hypertriglyceridemia and hyperglycemia despite hyperinsulinemia.

Management aims to reverse the liver disease by life styles changes to control obesity, e.g. dietary modifications and exercise. Most cases respond well to weight reduction and vitamin D or E supplementation. Progression to cirrhosis is very rare.

Congenital hepatic fibrosis, an autosomal recessive disorder, is an important cause of portal hypertension. These cases usually present in late childhood with hepatosplenomegaly and esophageal varices with intermittent hematemesis. Liver biopsy is diagnostic with diffuse periportal and perilobular fibrosis in broad bands, containing distorted duct-like structures or microcyst formation. Renal disease, e.g. polycystic kidney is present in ~ 3/4th cases.

Management includes control of esophageal bleeding/varices and treatment of renal disease. Some cases may need shunting procedure.

Caroli disease, i.e. congenital saccular dilatations of intrahepatic cuboidal epithelium, may be an isolated defect or associated with congenital hepatic fibrosis and polycystic kidneys (***Caroli syndrome***). Both variants are autosomal recessive. Most cases present with recurrent acute cholangitis and gallstones, before development of portal hypertension.

15.8 PORTAL HYPERTENSION

Portal hypertension (PHT) is defined as '*elevation of portal venous pressure >12 mm Hg*, due to hepatic or extrahepatic obstruction in portal blood flow'.

Portal vein is formed by joining of splenic and superior mesenteric veins and carries most of the gastrointestinal blood flow to liver for further metabolism of absorbed nutrients.

Etiologically, PHT may be broadly classified as—*(a) prehepatic* or extra-hepatic, *(b) hepatic*, and *(c) post-hepatic* or post-sinusoidal *obstruction* **(Table 15.12)**. Extrahepatic PHT accounts for ~75% cases in Indian children. Umbilical sepsis or cannulation in neonatal period is the commonest cause of extrahepatic PHT.

Pathogenesis: Irrespective of etiology, primary hemodynamic abnormality in PHT is the obstruction in portal blood flow, leading to:

a. Development of collateral flow (porto-caval shunts), e.g. *esophageal varices*, *rectal hemorrhoids* or periumblical *caput medussae*.
b. Chronic hepatic ischemia, with compromised liver functions.

TABLE 15.12: Causes of portal hypertension

- **Pre-hepatic or extrahepatic**
  - Umblical sepsis/cannulation in newborns
  - Dehydration/septicemia in early infancy
  - Acute peritonitis in older children
  - *Hypercoagulable states:* Protein C or S deficiency
  - Portal vein malformations, e.g. AV fistula
- **Intra-hepatic (Chronic liver disease)**
  - Congenital hepatic fibrosis
  - Chronic viral/autoimmune hepatitis
  - Cirrhosis
  - Metabolic disorders, e.g. Wilson disease
  - Hepatic tumors
  - Cholestasis, e.g. total parenteral nutrition
- **Post-hepatic or post-sinusoidal**
  - Budd-Chiari syndrome
  - Veno-occlusive disease of liver
  - Constrictive pericarditis

c. Cavernous transformation of portal vein (acquired portal cavernoma).

Clinical features of PHT depend on the site of obstruction, severity of portal pressure and extent of collateral flow. Important features include:

- *Recurrent GIT bleeding* as hematemesis or melena is the common, originating from esophageal varices. Hemorrhoids are uncommon in children. Hematemesis may be preceded by mild respiratory infections and cough (increase in intra-abdominal pressure) or drug intake, e.g. salicylates.
- *Dilated periumbilical veins* (*caput medussae*) with blood flow *away from umbilicus*, i.e. reversal of normal direction. Engorged veins with upward flow in abdominal flanks indicate inferior vena cava obstruction in post-hepatic PHT.
- *Splenomegaly* with/without hypersplenism is invariably present, though the size may reduce temporarily after GIT hemorrhage.
- *Signs of chronic liver disease*, e.g. ascites, icterus, hypoproteinemic edema and spider nevi, etc. are common in hepatic/post hepatic PHT, but not in extrahepatic PHT.
- *Hepatic encephalopathy* may develop after severe GIT bleeds due to further compromise of hepatic blood flow, though uncommon in extrahepatic PHT.
- *Secondary complications*, e.g. anemia, shock are often present, immediately after severe bleeds.

Important clinical differences between various types of PHT are summarized in **Table 15.13**.

Diagnostic investigations in PHT include:

- *Ultrasonography* to confirm the site of obstruction, estimate portal vein size, and visualize esophageal varices. Doppler flow studies may demonstrate reversed blood flow in portal circulation.

TABLE 15.13: D/D portal hypertension

	Extra-hepatic	*Hepatic*	*Post-hepatic*
